FOREWORD

The original version of this book, published in 1990, was a unique contribution to the literature on manic-depressive illness. For a long time, certainly since Bleuler and Schneider developed broad criteria for schizophrenia, manic-depressive illness had been neglected both as a clinical diagnosis and as a topic for research. The influence of psychoanalysis and Meyer's psychobiology exacerbated this neglect. Meaningful attention to the illness began to increase with the discovery of lithium as a surprisingly effective treatment for mania (this book is very appropriately dedicated to John Cade and Mogens Schou). But it was Goodwin and Jamison's work, coming at a time when manic-depressive illness remained curiously marginalized in the scientific literature, that gave the subject the treatment it deserved. Remarkably, their text was lengthy enough to allow detailed accounts and comprehensive summaries of all the available literature while at the same time being accessible in style and presentation, with an authentic continuity in the voice of its two authors.

Kay Jamison and Fred Goodwin are, of course, giants in this field, and their contribution seemed even then a remarkable one: Jamison for her profound clinical and psychological understanding, and Goodwin for his immense pharmacological and biological knowledge. To attempt a repeat of their efforts in a new edition was an enormous challenge, especially since the rapid expansion of scientific and clinical information that has occurred in the last 20 years has made the single- or dual-author textbook an increasingly endangered species. The authors' solution for this new edition of *Manic-Depressive Illness* is an innovative one that works exceedingly well: by enlisting the help of close colleagues with various specialized interests and producing an interpretive synthesis of those views through the filter of their own unparalleled expertise, they have avoided creating a compilation of chapters written by individual authors and preserved the unity and structure of the original work.

The book is divided into five parts covering the diagnosis, clinical characteristics, psychology, pathophysiology, and treatment of manic-depressive illness. It is an exceptional record of the current state of the art, and we are confident

that it will satisfy the most discriminating readers, from those who simply want to acquaint themselves with a single aspect of the illness and its many manifestations to those who wish to use this text as the basis for a comprehensive understanding of the subject.

A number of key differences between this and the first edition of the book deserve to be highlighted. The discussion of the spectrum diagnoses has been greatly expanded and informed by an increase in empirical work on the topic: diagnoses such as bipolar-II were not as commonly accepted prior to the publication of the *Diagnostic and Statistical Manual*, 4th edition (DSM-IV) in 1994, and the previously underappreciated topic of mixed states, especially depressive mixed states, is now properly included. Phenomenological studies of manic-depressive illness in children, women, and the elderly are now examined. The chapter on course of illness incorporates some major new outcome studies that began in the 1990s and have since expanded. The treatment chapters are, inevitably, greatly expanded to review the literature on benchmark therapies such as electroconvulsive therapy and lithium, as well as to accommodate the new literature on atypical antipsychotics, novel anticonvulsants, antidepressants, and structured psychosocial interventions. These chapters are also preceded by a discussion of the research methods now needed to evaluate increasingly complex clinical trials. Studies of molecular genetics, second messenger and intracellular mechanisms, and functional imaging were just starting two decades ago, but are quite central now. Even the historical assessment of how the illness was understood in previous eras is being revised on the basis of new evidence discussed in this edition.

The title of the second edition remains *Manic-Depressive Illness*, with the addition of a subtitle, *Bipolar Disorders and Recurrent Depression*. As in the first edition, the main emphasis is on the inclusive Kraepelinian concept of manic-depressive illness, a perspective too easily lost within the post-DSM-III nosology of mood disorders. This second edition underlines how Kraepelin's "central insight—that all of the recurrent major mood disorders (in today's terms) belonged together under the rubric of *manic-depressive*

illness—still provides the best model for what we know to date, as well as for understanding emerging clinical, pharmacological, and genetic data.”

We have no doubt that this second edition of *Manic-Depressive Illness*, like the first, will have an immense impact on the field; it will be a great resource for research, and it will help improve diagnosis and treatment of those who suffer from the illness. While the volume of new work it describes is encouraging, however, manic-depressive illness remains a much lower public health priority than schizophrenia and depression, not to mention many physical conditions, as evidenced by the relative paucity of research funds devoted to its study. Hence this second edition

can help us all in an important additional task: to promote awareness and investment of both time and money in this major illness by the best and brightest around the world. As Kraepelin said, “What goal could be more sacred than that of caring for a brother in distress, especially when the affliction stems from his very humanity . . . and when it cannot be halted by reason, rank or riches?”¹

ACKNOWLEDGMENTS

Without the sustained commitment and clinical and scientific expertise of our collaborators, whose names appear opposite the title page, there would be no second edition of *Manic-Depressive Illness*. We are immensely indebted to them for their time and scholarship. The collaborators' individual contributions ranged from a slight to substantial updating of a first-edition chapter (retaining the original organization and most of the original material) to, in a few instances, the drafting of an entirely new chapter; most contributions fell somewhere in between. They followed general guidelines formulated by us, including our specifications about the conceptualization and usage of the terms *manic-depressive illness* and *bipolar disorder*, the critical need for rigorous and impartial review, and the shared goal of contributing to a book that would maintain the unified authorship voice of the first edition. There was extensive interaction between us and our collaborators throughout, with many drafts of each chapter going back and forth.

In each case the last draft provided to us by a collaborator was revised and updated, usually extensively, by one or both of us. When our judgment about a specific clinical or scientific point differed from that of a collaborator, which was not infrequently the case, we carefully considered the collaborator's point of view before making a final decision. In the end, the two authors take responsibility for the contents of the book.

The collaborators would like to acknowledge the contributions of Po Wang and John Brooks (Dr. Ketter); Susan Bachus, Lisa Catapano, Guang Chen, Jing Du, Holly A. Giesen, Fatemi Hosein, Libby Jolkovsky, Celia Knobelsdorf, Phillip Kronstein, Rodrigo Machado-Vieira, Andrew Newberg, Jennifer Payne, Jorge Quiroz, Giacomo Salvadore, Peter J. Schmidt, Jaskaran Singh, and Carlos A. Zarate, Jr. (Dr. Manji); Al Lewy, Joseph Soriano, John Stiller, Leonardo Tonelli, and Thomas Wehr (Dr. Postolache); Gregory Fuller (Dr. Potash); Rice Fuller (Dr. Sackeim); and Helena Verdeli (Dr. Weissman). Drs. Goodwin and Jamison would like to acknowledge additional colleagues who reviewed chapters or otherwise provided input: Jules Angst, Ross Baldessarini, Robert Belmaker, Charles Bowden, Joseph Calabrese, Kiki Chang, Guy Goodwin, Heinz Grunze, Dean Jamison,

Athanasiou Koukopoulos, Andreas Marneros, Roger Meyer, Gary Sachs, Mauricio Tohen, Eduardo Vieta, Jeremy Watzky, and Peter Whybrow.

Dr. Goodwin's two research assistants, Mark Goldstein and Jaclyn Saggese Fleming, worked full time on this book and were essential to its production, Mr. Goldstein during the critical first two years of the project and Mrs. Fleming during the final three. Not only were they responsible for many of the literature searches and the preparation of tables and figures, they also often went beyond that, preparing summaries of critical areas of research. During the final two years in particular, Mrs. Fleming was the indispensable hub of the whole operation, coordinating the work of both the authors, the input from all of our collaborators, the work of our chief medical editor, and the editorial and production staff at Oxford University Press. She did this with a rare combination of intelligence, care and thoroughness, organization, blinding speed, and good humor. The ability of Mr. Goldstein and Mrs. Fleming to perform at such a high level is consistent with their career trajectories—Mr. Goldstein is already in medical school and Mrs. Fleming is in a post-baccalaureate biology program.

Dr. Goodwin is further indebted to his executive assistant, Joanne Davis, for facilitating his work on this book by skillfully keeping other aspects of his professional life on track. Dr. Goodwin would also like to acknowledge his first mentor, William E. Bunney, Jr., M.D., and his long-term colleague Dennis Murphy, M.D., who together contributed so much to the emergence of manic-depressive illness as a major focus of research at the National Institute of Mental Health. He would also like to thank the George Washington University Medical Center's Department of Psychiatry and Behavioral Sciences and its chairman, Jeffrey Akman, M.D., for support. Finally, the unceasing encouragement and support of Rosemary Goodwin, M.S.W., has been, as always, a mainstay.

Dr. Jamison would like to acknowledge the invaluable contributions of Silas Jones, William Collins, and Ioline Henter. It has been a delight to work with them and it would have been impossible to complete this book without their help. She would also like to acknowledge the support of

her colleagues in the Department of Psychiatry at the Johns Hopkins School of Medicine. Adam Kaplin, M.D., Ph.D., has been particularly helpful and generous with his time. Most deeply she would like to extend her heartfelt appreciation to her psychiatrist, Daniel Auerbach, M.D., who not only taught her how to live with manic-depressive illness but also encouraged her to study and write about it. His profound clinical understanding of the medical and psychological aspects of bipolar disorder were life saving; they have also strongly influenced her research, clinical practice, and writing. She owes a deep debt as well to her late husband, Richard Wyatt, M.D. He too encouraged her to write about manic-depressive illness, from both a clinical and personal perspective, and provided the kind of love and support that made it possible. He was a wonderful husband, colleague, and friend.

It is impossible to overstate the contribution of our medical editor, Rona Briere. Her consummate editing abilities, coupled with an extraordinary level of professionalism and intellectual integrity, made working with her both an education and a pleasure. Alisa Decatur meticulously prepared the manuscript of each chapter, tracked and reconciled the text citations and reference lists, edited the references, and performed numerous additional tasks that were invaluable in finalizing the book. Deb Uffelman and Gerald Briere assisted with proofreading and preparation of the reference lists. We are also grateful to Marion Osmun, Nancy Wolitzer, and Sarah Harrington at Oxford University Press for their dedication, skill, and

impressive ability to implement and meet near-impossible deadlines.

During the time that this book was in preparation, Dr. Goodwin received research support from George Washington University Medical Center, the Foundation for Education and Research on Mental Illness, the Dalio Family Foundation, GlaxoSmithKline, Pfizer, Eli Lilly, and Solvay. He has received honoraria from GlaxoSmithKline, Pfizer, Solvay, and Eli Lilly and unrestricted educational grants to support the production of this book from Abbott, AstraZeneca, Bristol Meyers Squibb, Forest, GlaxoSmithKline, Janssen, Eli Lilly, Pfizer, and Sanofi. Dr. Goodwin has been a consultant and/or advisor for Eli Lilly, GlaxoSmithKline, Pfizer, Janssen, Novartis, and Solvay. He is not a shareholder in any pharmaceutical or biotechnology company. He is a partner in Best Practice Project Management, Inc.

Dr. Jamison, as a MacArthur fellow, received generous financial support from the John D. and Catherine T. MacArthur Foundation, as well as funding from the Dana Foundation. She has received occasional lecture honoraria from AstraZeneca, GlaxoSmithKline, and Eli Lilly. She has received no research support from any pharmaceutical or biotechnology company, nor is she a consultant to, or shareholder in, any pharmaceutical or biotechnology company. As with the first edition of this text, all of her royalties go directly to a not-for-profit foundation that supports public education about manic-depressive illness.

INTRODUCTION

Melancholia is the beginning and a part of mania The development of a mania is really a worsening of the disease (melancholia) rather than a change into another disease.

—*Aretaeus of Cappadocia, ca. 100 AD*¹

It has been 17 years since the publication of the first edition of this text; they have been the most explosively productive years in the history of medical science. In every field relevant to our understanding of manic-depressive illness—genetics, neurobiology, psychology and neuropsychology, neuroanatomy, diagnosis, and treatment—we have gained a staggering amount of knowledge. Scientists and clinicians have gone an impressive distance toward fulfilling the hopes articulated by Emil Kraepelin in the introduction to his 1899 textbook on psychiatry. Those who treat and study mental illness, he wrote, must first, from bedside observation, delineate the clinical forms of illness; they must define and predict its course, determine its causes, and discover how best to treat and then ultimately prevent insanity. Psychiatry, he argued, was a “young, still developing science,” and it must, “against sharp opposition, gradually achieve the position it deserves according to its scientific and practical importance. There is no doubt that it will achieve the position—for it has at its disposal the same weapons which have served the other branches of medicine so well: clinical observation, the microscope and experimentation.”²² Kraepelin was right, as usual. And he was remarkably astute in his observations and predictions about the immensely complex group of disorders collectively known as manic-depressive illness.

Manic-depressive illness magnifies common human experiences to larger-than-life proportions. Among its symptoms are exaggerations of normal sadness and joy, profoundly altered thinking, irritability and rage, psychosis and violence, and deeply disrupted patterns of energy and sleep. In its diverse forms, manic-depressive illness afflicts a large number of people—the exact number depending on how the illness is defined and how accurately it is ascertained. First described thousands of years ago, found in widely diverse cultures, manic-depressive illness always has fascinated medical observers, even as it has baffled and frightened

most others. To those afflicted, it can be so painful that suicide seems the only means of escape; indeed, manic-depressive illness is the most common cause of suicide.

We view manic-depressive illness as a medical condition, an illness to be diagnosed, treated, studied, and understood within a medical context. This position is the prevailing one now, as it has been throughout history. Less universal is our diagnostic conception of manic-depressive illness, which evolved as we were writing both editions of this book. Derived from the work of Kraepelin, the “great classifier,” our conception encompasses roughly the same group of disorders as the term *manic-depressive illness* in European usage. It differs, however, from contemporary concepts of bipolar disorder. Kraepelin built his observations on the work of a small group of nineteenth-century European psychiatrists who, in their passion for ever finer distinctions, had cataloged abnormal human behavior into hundreds of classes of disorder. More than any other single individual, Kraepelin brought order and sense to this categorical profusion. He constructed a nosology based on careful description, reducing the categories of psychoses to two: manic-depressive illness and dementia praecox, later renamed *schizophrenia*.

It is to Kraepelin, born in the same year as Freud, that we owe much of our conceptualization of manic-depressive illness. It is to him that we owe our emphasis on documenting the longitudinal course of the illness and the careful delineation of mixed states and the stages of mania, as well as the observations that cycle length shortens with succeeding episodes; that poor clinical outcome is associated with rapid cycles, mixed states, and coexisting substance abuse; that genetics is central to the pathophysiology of the disease; and that manic-depressive illness is a spectrum of conditions and related temperaments.

Kraepelin’s model consolidated most of the major affective disorders into one category because of their similarity

in core symptoms; presence of a family history of illness; and, especially, the pattern of recurrence over the course of the patient's lifetime, with periods of remission and exacerbation and a comparatively benign outcome without significant deterioration. Kraepelin viewed mania as one manifestation of the illness, not as the distinguishing sign of a separate bipolar disorder as it is regarded in today's American (and increasingly worldwide) diagnostic practice.

The European and American concepts of manic-depressive illness began to diverge almost immediately after Kraepelin's ideas became widespread in the early years of the twentieth century. Europeans, adhering to a traditional medical disease model, emphasized the longitudinal course of the illness in both research and clinical work. Ever pragmatic, Americans wanted to treat the illness with the techniques at hand, which at that time were derived from the "moral treatment" movement in mental hospitals and the emerging dynamic therapies based on psychoanalytic theory. Research and clinical efforts in the United States thus slighted clinical description and genetics and turned instead to the psychological and social contexts in which the symptoms of the illness occurred.

Exploration of the linkages between clinical typology and family history led to the formulation of the bipolar-unipolar distinction, by which manic-depressive patients were grouped according to the presence or absence of a prior history of mania or hypomania. First proposed by a German, Karl Leonhard, the distinction was elaborated by other Europeans, such as Jules Angst and Carlo Perris, and by the Washington University group in St. Louis, Missouri, the neo-Kraepelinians who gave impetus to the new concern for an etiology-free, description-based diagnostic system in the United States.

The bipolar-unipolar distinction represented a logical refinement of the already well-defined Kraepelinian model, with its emphasis on recurrence and endogeneity. As useful as the distinction is in both research and clinical contexts, it proved to be problematic when applied to the much broader American conception of affective disorders. The bipolar subgroup was clearly defined, but the other component of Kraepelinian manic-depressive illness—endogenous, recurrent unipolar depression—was obscured by its confusion with other affective disorders. In American usage, *unipolar* disorder came to mean any mood disorder that was not bipolar, regardless of its severity or course. Although the third edition of the *Diagnostic and Statistical Manual* (DSM-III) clarified the situation somewhat by requiring that criteria for major affective disorder be met before the bipolar-unipolar distinction is drawn, a diagnosis of unipolar disorder was still broader than the Kraepelinian concept since it did not require a prior course of illness. Even the DSM-III/IV category of

recurrent depression is overly broad, requiring only two episodes in a lifetime.

Our own struggle to confine and limit the focus of the first edition of this text followed a course similar to the larger historical one. We started with a framework of Kraepelinian manic-depressive illness, that is, recurrent major affective illness with and without mania. Later, we focused more exclusively on bipolar disorder as a way of imposing workable boundaries on the scope of our efforts. Once thoroughly immersed in the subject, however, we became increasingly convinced that isolating bipolar disorder from other major depressive disorders and unduly emphasizing polarity over cyclicity (as do DSM-III and DSM-IV) pre-judges the relationships between bipolar and unipolar illness and diminishes appreciation of the fundamental importance of recurrence. By the end, we had returned to a position close to where we began, convinced of the value of the original unified concept of manic-depressive illness, albeit with a special emphasis on the bipolar form. Scientific and clinical advances of the past two decades have only added to the strength of our belief that, as important as polarity is, cyclicity or recurrence is fundamental to understanding manic-depressive illness. This conviction is made clear in the second edition's new title: *Manic Depressive Illness: Bipolar Disorders and Recurrent Depression*. Genetic findings will have the ultimate etiologic and diagnostic say, of course, but in the interim we think a broader rather than narrower concept of the illness is warranted by the data; we also think it is heuristically most valuable.

DIMENSIONS OF THE ILLNESS

It bears repeating that the presence or absence of mania in addition to depression is but one critical aspect of manic-depressive illness. The other is cyclicity, which may ultimately prove to be as useful as polarity in differentiating forms of affective illness. The classic European focus on longitudinal studies has provided an ample database for redirecting the emphasis of pathophysiology to mechanisms of cyclicity—that is, the biology of recurrence. To conduct such research, an investigator must analyze each patient's biological functioning over time and relate it to the natural course of illness. The priority that American clinicians are beginning to assign to recurrence is a tribute to the persuasiveness of our European colleagues' meticulous longitudinal clinical observations. Kraepelin's descriptions have been enduring: again and again during our study of the contemporary literature, we returned to his original writings to rediscover modern ideas. To a remarkable degree, his work anticipated, explicitly and implicitly, contemporary theoretical developments. One example is the spectrum concept—the continuity of manic-depressive symptoms with normal fluctuations in mood, energy

patterns, and behavior—a concept whose database has greatly expanded since the publication of the first edition.

The longitudinal view provided by Kraepelin and many others both before and since persuaded us to survey the literature on recurrent unipolar illness along with that on bipolar illness, our primary focus. If we had confined ourselves to the bipolar literature, we would have excluded many potentially relevant data and insights. This recognition of the essential unity of major recurrent affective illness is evident throughout the book. When discussing lithium prophylaxis in Chapter 20, for example, we point out that similarities between recurrent unipolar and bipolar illness constitute firm ground for speculating about common neurobiological substrates.

The issue of cyclicity opens up many new areas of inquiry. Manic and depressive episodes can be predicted to revert to normal at some finite time, either spontaneously or in response to effective treatment. The opportunity to compare biological measures during the illness with the same measures in the recovered state is essential in psychobiological research, since it permits longitudinal studies that can circumvent the problem of variability among individuals. The recurrent pattern of the illness—that of recovery to normal or change to an opposite state—makes it an unsurpassed paradigm for separating state and trait variables in mental illness. The regularity of recurrence in some patients permits the clinical investigator to anticipate the onset of an episode and thus to schedule data collection at critical points. The frequent rapidity of the switch from one state to another, especially the switch into mania, allows for intensive efforts to understand the relationships between stress and biological changes in the onset of illness by looking at the temporal sequence of events—one approach to the ultimate question of causality.

The bipolar form of the illness also is an interesting study in the coexistence of opposites or, more precisely, deviations from normal in opposite directions. Even lay observers may recognize that bipolar disorder is at times accompanied by periods of euphoric mood, productivity, and high energy, but at other times by despair and profound lassitude. Clinicians see a more subtle manifestation of this Janus-like illness in lithium's effects in preventing its apparently opposite expressions. Lithium's dual action, perhaps diminishing some of the silver lining along with the cloud, challenges the clinician's psychotherapeutic skills in managing the issue of treatment acceptance, especially medication adherence.

THE SCIENCE OF THE ILLNESS

Over the past six decades, research has yielded effective treatments that have radically altered clinical work in manic-

depressive illness. Principally, it was the discovery of lithium that galvanized the treatment community, instilling new hope among clinicians, their patients, and the public. Also important, the emergence of lithium, the antidepressants, the antipsychotics, and the anticonvulsants gave birth to whole new fields of scientific investigation. Studies of the illness have dominated biological psychiatry, which itself has begun to lead the profession. Manic-depressive illness has been an increasingly important focus of work in other disciplines as well. Insights gained from the study of an illness that is biological in origin yet psychological in expression have underscored the urgency and inevitability of paradigms of mental illness that give balanced attention to biology, psychology, and the environment. Methodologies developed expressly for studies of manic-depressive illness have been incorporated as standard tools of clinical investigation in other areas of biomedical and behavioral research in psychopathology. Because symptoms of the illness shade over into normal human experience, it provides a model for the study of normal states as well.

Nearly 60 years have passed since the initial clinical observation of lithium's effectiveness in treating manic-depressive illness and 50 years since early clinical trials—most important, those completed by Mogens Schou, Poul Christian Baastrup, G. P. Hartigan, and Alec Coppen—were conducted so that lithium could be approved for general clinical use throughout the world. More recently, research on manic-depressive illness has played a central role in efforts to apply new and emerging techniques, such as molecular genetics, to the study of psychiatric conditions. The application of these techniques depends on the use of sensitive and reliable epidemiological and diagnostic case-finding methodologies to identify family pedigrees with a high incidence of the illness. Preliminary results suggest that several genotypes underlie different forms of manic-depressive illness. It is also possible that, as with the multiple genetic forms of diabetes, several genotypes are expressed in clinical phenomena commonly associated with the illness.

Research on manic-depressive illness also has contributed new, empirically based theories about the pathophysiology of psychiatric disorders, including the influence of the physical environment—light and temperature in particular—on their course and expression. Of equal interest are efforts to describe mechanisms by which the psychosocial environment interacts with the individual's biology to produce symptoms. One of the most promising lines of inquiry grew out of longitudinal observations: external stress appeared to activate or precipitate some initial episodes of illness, but eventually the illness seemed to take on a life of its own, since later episodes began without obvious precipitating stress.

OVERVIEW OF THIS TEXT

In a text of this size and scope, a certain amount of redundancy is inevitable. Issues pertaining to the dimensional aspects of manic-depressive illness, such as severity, polarity, and cyclicity, are introduced in the first two chapters and then discussed further throughout the book. Where an issue could logically be discussed in more than one chapter, our decisions on placement occasionally were somewhat arbitrary.

Clinical Description and Diagnosis

The text is divided into five parts, the first of which focuses on clinical phenomenology and diagnosis. Chapter 1 traces the evolution of the concept of the illness, which has remained remarkably consistent since the time of Hippocrates, and describes the spectrum of the illness in detail. We highlight the fact that diagnostic and subgroup boundaries represent somewhat arbitrary distinctions, with individual patients often falling in a gray area. Also emphasized is the spectrum of manic states, which, unlike the well-described depressive spectrum, is often overlooked. We stress that while the spectrum concept has validity and utility, there are risks in subclassifying the bipolar forms of the illness to such an extent that they are confusing, on occasion to the detriment of both clinical and research purposes.

We begin the chapter on clinical description (Chapter 2) with classic descriptions of the illness by early clinical observers who worked in the era before effective medications altered the natural expression of the illness; these are followed by patients' descriptions of their experiences of the illness. We also review data-based studies of mania, mixed states, and bipolar depression, with a particular emphasis on new research findings pertaining to mixed states and bipolar depression.

Chapter 3 guides the clinician through the problems of diagnosis. Most important is the differential diagnosis of bipolar disorder and unipolar depression, schizophrenia, organic brain disorders, substance abuse, and borderline personality disorders. The shortcomings of our current diagnostic systems, including their emphasis on polarity rather than cyclicity, the absence of a category for highly recurrent depression, the underrecognition of bipolar-II disorder, and the inadequacy of the diagnostic criteria for mixed states, are discussed in detail.

Clinical Studies

The second part covers various clinical aspects of manic-depressive illness. Appropriately, we begin in Chapter 4 with a discussion of course and outcome, fundamental characteristics of the illness that provide the basis for differentiating it from schizophrenia. In addition to its obvi-

ous importance for clinicians who are assessing prognosis and planning treatment, natural course is important to scientists since it offers many useful clues as to pathological processes. We consider historical observations on course and outcome together with data gathered from the large-scale studies conducted since the first edition of this text.

Chapter 5, on epidemiology, argues that manic-depressive illness, especially its bipolar form, is more common than is usually thought. Among the most important recent observations are the early age at onset documented in careful community surveys; determinations of the rates of bipolar-II and bipolar spectrum disorders; and the results of several important international studies, including those of death and disability, that document the high toll exacted by manic-depressive illness worldwide.

The next three chapters highlight special clinical aspects of manic-depressive illness. Chapter 6 addresses aspects of the illness in children and adolescents. Because there are essentially no data on highly recurrent depression in these populations, the chapter focuses exclusively on bipolar disorder, which all too often goes unrecognized in youth. Although relatively rare in prepubertal children, classic bipolar disorder often begins in adolescence; indeed, well over one-third of all cases begin before the age of 20. Were the kindling hypothesis substantiated, early recognition and immediate, vigorous treatment would be expected to reduce subsequent pathology. Early treatment would reduce the psychological scarring caused by untreated illness, as well as the high mortality rate from suicide, which is disproportionately likely to occur early in the course of bipolar disorder. All too typical is the individual, initially treated in his or her mid- to late twenties, who has already lived with the disorder for more than a decade, a period critical for life's major beginnings in relationships, education, and career. The research findings on childhood bipolar disorder published since the first edition of this text have been prodigious, but continue to be marked by confusion and controversy. Even so, many more young children with severe mood lability and behavioral dyscontrol are now being identified and treated with mood stabilizers, antipsychotics, and antidepressants.

A focus on the young highlights the frequent coexistence of drug and alcohol abuse among young manic-depressive patients. Growing recognition of the frequent coexistence of the illness with substance abuse prompted us to devote an entire chapter (Chapter 7) to describing these problems and another (Chapter 24) to reviewing their treatment. In these two chapters, we also discuss other important comorbid conditions, such as anxiety disorders, eating disorders, cardiovascular disease, thyroid dysfunction, overweight and obesity, and migraine, as well as their treatment. The presence of a depressive or anxiety disorder can double the

chances of subsequent substance abuse. Conversely, illicit drugs and alcohol can adversely affect the course and treatment of manic-depressive illness by altering the same brain mechanisms that regulate mood, including the potential for kindling.

As with substance abuse and other comorbid conditions, the importance of suicide in manic-depressive illness is reflected in our devoting two chapters to the subject—one describing rates, putative causes, and clinical correlates (Chapter 8), and another detailing preventive measures (Chapter 25). The high mortality associated with this illness cannot be overemphasized. Fortunately, considerable progress has been made in understanding the causes of suicide in manic-depressive patients, in addition to the accumulating evidence that lithium exerts a strong protective influence.

The reader may note that there is no chapter on gender differences in manic-depressive illness, reflecting the relative scarcity of literature on this subject. However, reports of male–female differences are noted throughout the book; here we summarize those for which there is general agreement: the first episode is more likely to be mania in males and depression in females, while women have more mixed episodes (consistent with a predominance of depression) and are overrepresented among rapid cyclers; consistent with the general population, men are more likely to have comorbid substance abuse and histories of pathological gambling and conduct disorder, while women are more likely to have comorbid eating disorders as well as changes in appetite and weight during depressive episodes; and, in contrast to the general population, the completed suicide rate for bipolar women is higher than that for bipolar men. It may be that the risk of suicide associated with manic-depressive illness is so powerful that it overrides the usual male–female patterns. Bipolar women generally are more likely than their male counterparts to seek treatment, but there is as yet no consensus regarding gender differences in response to mood stabilizers.³

Psychological Studies

Manic-depressive illness has been a rich source of theory and data for investigators interested in psychological mechanisms. The third part of the book considers these developments. Manic-depressive illness has contributed to the general study of psychology by serving as a paradigm for explorations of state and trait differences. It also has been a model for the general psychological assessment of cognition and for the more specific differentiation of cognition in manic and depressive states from that in schizophrenia. We begin with a survey of what is known about neuropsychological deficits in mood disorders, including recent research documenting significant impairments in intellec-

tual functioning, attention, learning and memory, and executive functioning (Chapter 9).

The psychological manifestations of manic-depressive illness, observable in personality and behavior as well as cognitive patterns, can result in profound discord in family life and other social relationships; this is especially true for those with the bipolar form of the illness. In Chapter 10 we review studies of personality functioning in manic and depressed states and how it compares with that in normal states in patients themselves and in the general population. We also discuss personality disorders that commonly co-exist with manic-depressive illness, as well as the effects of medication on personality. The chapter then addresses interpersonal aspects of the illness, with emphasis on the bipolar subgroup.

Chapter 11 is devoted to the wide array of methods that now exists for assessing manic, mixed, and depressive states; these assessment measures add the perspective of formal psychological evaluation to the discussion of differential diagnosis in Chapter 3.

Widespread interest in creativity, the subject of Chapter 12, has lent visibility to this aspect of the study of manic-depressive illness. The age-old link between “madness” and creativity has been studied with increasingly sophisticated methods in recent years. Research has demonstrated that it is not schizophrenia but manic-depressive illness, especially its bipolar forms, that is more often associated with creative accomplishment. Among the most interesting developments in this field is the hypothesis that the genetic predisposition for manic-depressive illness also confers a creative edge on affected individuals and their close relatives. Explorations of the characteristics that help make some individuals more creative than others should have implications for the general population. Among the positive features of the bipolar form of the illness being examined in relation to creativity are the heightened energy level and speed of cognition of hypomania, linked to a global, inclusive associative process, and certain temperamental factors; positive (and painful) experiences derived from having affective illness are salient as well. In addition to raising important psychological, social, and ethical issues, these and related positive features of the bipolar form of the illness can play a key role in reducing the burden of stigma borne by patients. Understanding these features is, of course, necessary in dealing with one of the most sensitive and difficult issues in treatment—medication adherence.

Pathophysiology

The size of the fourth part of the book, the largest, testifies to the wealth of biological knowledge that has accrued through research on manic-depressive illness. The illness has come to represent an extraordinarily rich

source of information about the interrelationships between behavioral and biological phenomena; certainly it has stimulated fascinating and productive theories about brain-behavior relationships.

We begin with a survey of the salient literature on genetics (Chapter 13). In this chapter we review genetic epidemiology, results of studies using the linkage method, alternative phenotypic definition, association methods, gene expression and pathogenesis, pharmacogenetics, and genetic counseling. We then look at the future of the field, including new technologies and what we can expect to learn from each.

Chapter 14, on neurobiology, provides the conceptual base necessary for an appreciation of the biochemical and pharmacological studies whose review follows. Much of modern neurobiology and neuropharmacology has been driven by efforts to understand the effects of mood-altering drugs. Indeed, attempts to understand why certain drugs affect mood have inspired major hypotheses about the neurobiology of behavior. The chapter also describes animal models designed to simulate affective illness and reviews the formidable literature on the major neurotransmitter, neuroendocrine, and neuropeptide systems involved in manic-depressive illness, along with extensive new findings related to postsynaptic signal transduction networks and gene expression.

With the emergence of highly sophisticated brain-imaging technologies, it has become important to review the anatomical correlates of mania and depression critically, if only to help guide the application of imaging approaches; we do so in Chapter 15. Functional neuroimaging work has advanced rapidly in recent years. We review research findings on cerebral activity in normal, depressed, and manic states, as well as summarize what is known about baseline cerebral activity markers of treatment response.

Chapter 16 covers sleep and biological rhythms, reflecting our judgment that these two fields, which developed independently of one another, have found a natural point of convergence in the pathophysiology of manic-depressive illness. It is increasingly clear that sleep physiology is important to circadian physiology and that sleep disturbances seen in affective illness reflect disturbances in circadian rhythms. This area of study has, in our estimation, yielded some of the most interesting developments in understanding manic-depressive illness. The identification of seasonal affective disorder, for example, represents a systematic, quantitative rediscovery of ancient observations of seasonality in mood disorders and suicide. The speed with which the initial observation of seasonal mood disorder was incorporated into the DSM nosology testifies to the responsiveness of our current diagnostic system. Research

on biological rhythms has spawned the development of three novel physiological but nonpharmacological treatments for mood disorders—sleep deprivation, phase advance, and high-intensity light—that are described in Chapter 19 on the treatment of acute depression, especially in bipolar patients. At a more general level, the contemporary focus on biological rhythms has given rise to environmental psychiatry, and thus the discussion of the subject in Chapter 16 emphasizes the subtle environmental influences on manic-depressive illness and offers relevant clinical suggestions.

Treatment

The final part of the book covers all aspects of the treatment of manic-depressive illness. It is traditional in its organization, separating acute from prophylactic treatment and medical from psychological treatment. Despite this division, we wish to emphasize the profound importance of integrating medical and psychological approaches. Although the structure of this part of the book is traditional, the organization of each chapter is not. Each begins with practical recommendations for clinical management and then reviews the treatment literature, highlighting areas inadequately explored in existing reviews, including the efficacy of lithium in treating depression as well as mania and the quality of the prophylactic response. We discuss treatment controversies such as antidepressant-induced mania, mixed states, and rapid cycling; the use of adjunctive treatments for breakthrough episodes during prophylactic treatment with mood stabilizers; the important but often overlooked distinction between prevention of relapse and prevention of recurrence (new episodes); the relative efficacy and side-effect profiles of the mood stabilizers and the antipsychotics; and the use of alternative or adjunctive approaches for patients who do not respond to initial treatment. It has been of great, often life-saving clinical importance to now have anticonvulsant and antipsychotic medications that provide an alternative for those patients who do not respond to or will not take lithium. We make clear our belief that lithium remains the gold standard of treatment, however, despite an increasing tendency to use less-proven medications.

The two chapters on adherence and psychotherapy (Chapters 21 and 22, respectively) should be read together. Our purpose here is not to provide a general psychotherapy primer but to focus on issues of special importance to the psychotherapy of manic-depressive illness, especially the bipolar form. These issues include fears of recurrence, the psychological scars left by the illness, and concerns about genetic vulnerability. The central issue in the psychological management of bipolar patients is medication adherence. Recent studies suggest that outcomes of medical treatment

are substantially enhanced by adjunctive psychotherapy, no doubt reflecting the contribution of improved adherence. In our discussion of adherence, we return to the core issue of the paradox of drugs that are often very effective, yet can have an impact on some aspects of the illness that may be valued by the patient. Given clinicians' all-too-common tendency to be unaware of subtle adherence problems, we believe this issue warrants a separate chapter.

Chapter 23 is devoted to the special issues that arise in treating children and adolescents with bipolar illness. Chapter 24 deals with the treatment of comorbid conditions such as anxiety disorders, substance abuse, and medical conditions that frequently accompany manic-depressive illness.

The fact that manic-depressive illness is often lethal bears repeated mention. We have underscored this fact by summarizing what is known about rates and clinical correlates of suicide in Chapter 8; in Chapter 25, we emphasize clinical methods we believe to be most useful in reducing the risk of suicide among acutely ill patients. We emphasize again the fundamental premise that the best approach to the prevention of suicide is the effective and aggressive treatment of the underlying illness.

THE DEVELOPMENT OF THIS BOOK

The overwhelming size of the literature on manic-depressive illness makes it all but impossible for clinicians and researchers to keep pace with the latest findings and to see the broader clinical, human, and scientific picture. The National Library of Medicine's Medline file on bipolar disorder alone has grown from 16 citations in 1950; to approximately 600 citations in 1990, the year the first edition of this book was published; to more than 1,100 citations in 2006. We were aware of the problem before we began writing the first edition of this book. As we struggled through the scientific literature that had grown exponentially since 1990, we once again were concerned that the very magnitude of the new, scattered evidence threatens the ability to form a coherent overall view of the illness. In recent decades, research on manic-depressive illness has contributed to an extraordinary expansion of the knowledge base in increasingly specialized fields. The productivity of the research enterprise has generated diverse points of focus, which are often appreciated only by individuals in a given subfield. An unfortunate outgrowth of such specialization is that the wealth of new information typically has been made available only in the form of individual research reports or reviews of selected areas; at best, these occasionally are published in edited volumes.

Working during this period of extraordinary productivity and ferment in the study of manic-depressive illness, we saw the need for a comprehensive book that would at-

tempt to impose order on a rich but vast and disparate literature. We were convinced that this goal could be accomplished only by seeing the subject through from beginning to end—in other words, by writing a book rather than editing a collection. We were able to accomplish this by jointly authoring the first edition. As indicated in our acknowledgments and in the list of collaborators for this edition, however, we found it imperative to seek the help of colleagues; we could not have completed this book without them. Our intent was to go beyond a review of the literature—to assess the nodal points in knowledge of the illness, to integrate them in a way that would enhance the quality of clinical care available, and to suggest opportunities for future research. In the early twenty-first century, manic-depressive illness continues to present new challenges and questions that extend from the realm of basic neurobiological science to those of clinical practice and social ethics. The skill the field brings to identifying these questions will determine the strategies formulated to answer them, and in turn will bear directly on future advances in treatment and prevention.

Throughout the writing of this edition of the book, as during the first, we have been impressed time and again by the excellent science, imaginative clinical research, and profoundly important treatment advances generated by our colleagues. We are delighted to acknowledge our debt to them, both for their science and for the lives they have saved. As before, our debt to our students and patients is immeasurable.

PART I

CLINICAL DESCRIPTION AND DIAGNOSIS

This page intentionally left blank

Conceptualizing Manic-Depressive Illness: The Bipolar–Unipolar Distinction and the Development of the Manic-Depressive Spectrum

Manic-depressive insanity . . . includes on the one hand the whole domain of the so-called periodic and circular insanity, on the other hand simple mania, the greater part of the morbid states termed melancholia and also a not inconsiderable number of cases of amentia [confusional insanity].

—Emil Kraepelin¹ (1921, p. 1)

It was the work of Angst and Perris that helped spread my theory that unipolar and bipolar diseases . . . have different clinical pictures. The bipolar form displays a considerably more colorful appearance; it varies not only between the two poles, but in each phase offers different pictures. The unipolar forms . . . return, in a periodic course, with the same symptomatology.

—Karl Leonhard (1979, pp. 3–4)

Medical conceptions of mania and depression are as old as medicine itself. From ancient times to the present, an extraordinary consistency characterizes descriptions of these conditions. Few maladies have been represented with such unvarying language. Yet while the essential features are recognizable in the medical literature through the centuries, the boundaries that define mania and depression and the relationship between them have changed during that time. In this chapter, we begin by reviewing the historical roots of our current concepts. We then discuss the two different but overlapping conceptualizations of manic-depressive illness: the bipolar–unipolar distinction and the manic-depressive spectrum.

HISTORICAL ROOTS

Pre-Nineteenth-Century Ideas

The medical writers of ancient Greece conceived of mental disorders in terms that sound remarkably modern.² They believed that melancholia was a psychological manifestation of an underlying biological disturbance, specifically, a perturbation in brain function. In documents dating back to the fifth and fourth centuries BC, Hippocrates and his school³ described melancholia as a condition “associated with ‘aversion to food, despondency, sleeplessness, irritability, restlessness,’ and they stated that fear or depression that is prolonged means melancholia” (Jackson, 1986, p. 30). Early conceptions of melancholia and mania were, however, broader than those of today. The two terms, together with phrenitis, which corresponds roughly to an acute organic delirium, made up all mental illness throughout

most of the ancient period. As Jackson (1986, p. 249) pointed out, “disorders similar to our mania and our melancholia constituted significant portions of the larger groupings of mental disorders that were subsumed under those rubrics in ancient times.”

As they did with other illnesses, the Hippocratic writers argued forcefully that mental disorders were not due to supernatural or magical forces, beliefs that characterized most primitive societies and that have resurfaced from time to time throughout history. In Greece, “Hippocrates did not encounter excessive resistance in the magical sphere because these diseases had long been interpreted as phenomena deriving from an underlying humoral disturbance” (Roccatagliata, 1986, p. 170). This essentially biological explanation for the cause of melancholia, which survived until the Renaissance, was part of the prevailing understanding of all health as an equilibrium of the four humors—blood, yellow bile, black bile, and phlegm—and all illness as a disturbance of this equilibrium. First fully developed in the Hippocratic work *Nature of Man* (ca. 400 BC), the humoral theory linked the humors with the seasons and with relative moistness. An excess of black bile was seen as the cause of melancholia, a term that literally means “black bile.” Mania, by contrast, was usually attributed to an excess of yellow bile.

Aristotle, who differed with the Hippocratic writers by seeing the heart rather than the brain as the dysfunctional organ in melancholy, introduced the notion of a “predisposition” to melancholy. The “marker” of that predisposition was a relative excess of black bile, which he thought was common in small amounts in all people. As Whitwell⁴ (1936, p. 59) pointed out, Aristotle thought those with the

excess had melancholic temperaments that were associated with being gifted:

Aristotle appears to have been the first to draw attention to the problem of the frequent occurrence of melancholia, or at least a degree of mental depression in the case of philosophers, statesmen, artists and poets, and he gives as examples Plato, Socrates and Empedocles. This is a question which is constantly recurring in later literature, the explanation of which is attempted by Marsilius Ficinus.⁵

Deliberations on the relationship between melancholia and mania date back at least to the first century BC, as noted by Soranus of Ephesus: "The followers of Themison, as well as many others, considered melancholy a form of the disease of mania" (Jackson, 1986, p. 250). Soranus himself (fl. 100 AD) believed that melancholia and mania were two distinct diseases, but with similar prodromal symptoms and requiring similar treatments (Jackson, 1986, p. 250):

For Soranus, mania involved an impairment of reason with delusions; fluctuating states of anger and merriment, although sometimes of sadness and futility and sometimes "an overpowering fear of things which are quite harmless"; "continual wakefulness, the veins are distended, cheeks flushed, and body hard and abnormally strong"; and a tendency for there to be "attacks alternating with periods of remission." Melancholia involved being "downcast and prone to anger and . . . practically never cheerful and relaxed"; "signs . . . as follows: mental anguish and distress, dejection, silence, animosity toward members of the household, sometimes a desire to live and at other times a longing for death, suspicion . . . that a plot is being hatched against him, weeping without reason, meaningless muttering, and again, occasional joviality"; and various somatic symptoms, many of them gastrointestinal.

Aretaeus of Cappadocia, who lived in the second century AD, appears to have been the first (whose work has survived to modern times) to bring together the syndromes described in Greek medicine and propose that mania was an end stage of melancholia, a view that was to prevail for centuries to come. Roccatagliata (1986, p. 229), who referred to Aretaeus as "the clinician of mania," noted that he "isolated . . . a form of mental disease presenting phases of depression alternating with phases of mania," and reported Aretaeus's characterization of the illness:

"Some patients after being melancholic have fits of mania . . . so that mania is like a variety of being

melancholy." He described a kind of cyclothymia which presented only intermittent stages of mania: "It arises in subjects whose personality is characterised by gayness, activity, superficiality and childishness." The mania was expressed in "furor, excitement and cheerfulness." Other types of mania, he said, had delirious manifestations of an expansive type, so that the patient "has deliriums, he studies astronomy, philosophy . . . he feels great and inspired." So he identified a bipolar cyclothymia, a monopolar one consisting only of manic phases, and a paranoid psychosis which he considered akin to schizophrenic mania.

Although Aretaeus included syndromes that today might be classified as psychoses beyond mania, his clear descriptions of the variety of manic conditions influenced medicine for many centuries, and have a modern ring to them (Roccatagliata, 1986, pp. 230–231):

According to Aretaeus, the classical form of mania was the type that was associated with melancholia: the patient who previously was gay, euphoric, and hyperactive suddenly "has a tendency to melancholy; he becomes, at the end of the attack, languid, sad, taciturn, he complains that he is worried about his future, he feels ashamed." When the depressive phase is over, such patients go back to being gay, they laugh, they joke, they sing, "they show off in public with crowned heads as if they were returning victorious from the games; sometimes they laugh and dance all day and all night." In serious forms of mania, called furor, the patient "sometimes kills and slaughters the servants"; in less severe forms, he often exalts himself: "without being cultivated he says he is a philosopher . . . and the incompetent [say they are] good artisans . . . others yet are suspicious and they feel that they are being persecuted, for which reasons they are irascible."

Aretaeus believed that mania was a brain dysfunction that "deprived its imaginative functions" (Roccatagliata, 1986, p. 229). Melancholy, similarly, had an endogenous etiology; melancholic delirium arose (Roccatagliata, 1986, p. 231):

"without motive, like the loss of reason, insomnia, and despair." The vital tone was subject to typical circadian variations, which in melancholy were inverted with respect to the normal person, so that the patients "wake up suddenly and are seized by a great tiredness."

The next important medical writer, Galen of Pergamon (131–201 AD), firmly established melancholia as a chronic and recurrent condition. His few comments on mania included the observation that it can be either a primary

disease of the brain or secondary to other diseases. Galen's "contribution" was, in the opinion of most medical historians, his brilliant, all-encompassing elaboration of the humoral theory, a system so compelling that it dominated—and stifled—medical thought for more than a millennium.

Medical observations in succeeding centuries continued to reflect these conceptions of depression and mania laid down in classical Greece and Rome. As Jackson (1986) observed, most authors wrote of the two conditions as separate illnesses, but usually in adjoining chapters and ascribing them to humoral causes that suggested a close connection between them. Yet where mania and depression are considered in the historical medical literature, a link is almost always made, as can be seen in the time line in Box 1-1.

As we have seen, from classical Greece until the Middle Ages, mental and physical afflictions were primarily the concern of medical doctors. As illness gradually became the responsibility of the priests, the above early insights were submerged. The period that followed was, in retrospect, a dark age, when mental illness was generally attributed to either magic or sin or possession by the devil.

By the late Middle Ages, empirical science had attracted interest and the beginnings of acceptance, engendered by the ascendancy of Baconian philosophy. At that point, however, in the clinical realm now encompassed by psychiatry, scientific interpretations were limited to anatomical, physiological, and pathological studies of the brain.

Empirical clinical observations without religious overtones did not reappear until the beginning of the seventeenth century. A key figure in this descriptive renaissance was Felix Platter, who in 1602 published his systematic observations and classifications of mental disorders. Although his descriptions of mania and melancholia were extensive and methodical, there was little to suggest the longitudinal or recurrent nature of the illness, or the distinctions between manic-depressive illness⁶ and what is now known as schizophrenia.

A unique eighteenth-century discussion of manic-depressive illness can be found in a 1759 monograph by Andres Piquer ("the Spanish Hippocrates"), physician to King Ferdinand VI of Spain ("Discurso sobre la Enfermedad del Rey nuestro Señor Fernando VI"), recently republished with an introduction by Eduard Vieta and Demetrio Barcia. Piquer diagnosed the king with "melancholic-manic affect" (p. 17), clearly anticipating later French and German authors in viewing this condition as a single illness: "Melancholy and mania, although treated in many medical books separately, are one and the same illness, and only differ according to the various grades of activity and diversity of affective states that occur in both." (pp. 57–58; translated

segments by Nassir Ghaemi) Piquer went on to quote Hippocrates and Arateus in support of his view.

As noted previously, the subsequent literature of the seventeenth and eighteenth centuries is replete with clinical observations of manic and depressive symptomatology. As pointed out by Pichot (1995), the disciples of Esquirol played a critical role as they paved the way for recognition of the mental disease that ultimately came to be known as manic-depressive insanity through the work of Kraepelin (1899). For instance, Jules Baillarger⁷ wrote in 1854:

There exists a special type of insanity characterized by two regular periods, the one of depression and the other of excitement. . . . This type of insanity presents itself in the form of isolated attacks; or, it recurs in an intermittent manner; or, the attacks might follow one another without interruption.

This theme is echoed in subsequent French psychiatric writing:

By circular insanity, or *folie à double forme*, we understand a special form of mental derangement, the attacks of which are characterised by a regular sequence of two periods—one of depression, and another of excitement, or inversely. (Ritti, 1892)⁸

There are literally thousands of such observations, for the most part disconnected from one another. Many are accompanied by hastily erected classification systems and etiological speculations, which sometimes anticipate contemporary theory to a striking extent. As Jelliffe (1931) wrote, the "epidemic of classification" was further spread by the powerful influence of Linnaeus's work on the classification of plants. Even more new empirical observations were added when the advent of autopsies opened the door for neuropathologic observations and their attendant speculations. This evidence was gathering in a conceptual climate still dominated by the traditional separation of the mind ("soul") from the body. The era was not yet ready for a new synthesis or unifying insights, despite its increasing need of them.

Nineteenth-Century Ideas

The explicit conception of manic-depressive illness as a single disease entity dates from the mid-nineteenth century. As noted above, the French "alienists," Falret and Baillarger, independently and almost simultaneously formulated the idea that mania⁹ and depression could represent different manifestations of a single illness. Students of Esquirol and, therefore, intellectual descendants of Pinel, they had been strongly influenced by Pinel's sharp disdain for the "classification epidemic," as well as by contemporary arguments for a unitary concept of general paresis.

BOX 1-1. Linking of Mania and Depression throughout History^a

- ca. 400 BC An excess of black bile was seen as the cause of melancholia, a term that literally means “black bile.” Mania, by contrast was usually attributed to yellow bile. (Hippocrates)
- ca. 150 AD “Some patients after being melancholic have fits of mania . . . so that mania is like a variety of being melancholy.” (Aretaeus of Cappadocia^b)
- ca. 575 “Those affected with such a condition are not suffering from melancholia only, for they tend to become maniacal periodically and in a cycle. Mania is nothing else but melancholia in a more intense form.” (Alexander of Tralles^c)
- ca. 1000 “Undoubtedly the material which is the effective producer of mania is of the same nature as that which produces melancholia.” (Avicenna^d)
- ca. 1300 “Mania and melancholia are different forms of the same thing.” (Joh. Gaddesden^e)
- ca. 1500 “[Melancholia] manifestly differs from what is properly called mania; there is no doubt, however, that at some time or other, authorities agree that it replaces melancholia.” (Joh. Manardus^f)
- ca. 1549 “Perturbation of the spirit of the brain when mixed with and kindled by other matter can produce melancholia, or if more ardent, mania.” (Felix Platter^g)
- ca. 1672 “[Manics and melancholics] are so much akin, that these Distempers often change, and pass from one into the other; for the Melancholick disposition growing worse, brings on Fury; and Fury or Madness [mania] growing less hot, oftentimes ends in a Melancholick disposition. These two, like smoke and flame, mutually receive and give place to one another.” (Thomas Willis^h)
- ca. 1735 “If Melancholy increases so far, that from the great Motion of the Liquid of the Brain, the Patient be thrown into a wild Fury, it is call’d Madness [mania]. Which differs only in Degree from the sorrowful kind of Melancholy, is its Offspring, produced from the same Causes, and cured almost by the same Remedies.” (Herman Boerhaaveⁱ)
- ca. 1759 “Melancholy and mania, although treated in many medical books separately, are one and the same illness, and only differ according to the various grades of activity and diversity of affective states that occur in both.”—Andres, Piquer (quoted in “El trastorno bipolar en el siglo XVIII,” by Eduard Vieta and Demetrio Barcia, 2000, Burdeos, Spain: Mra ediciones, pp. 57–58, segment translated by Nassir Ghaemi).
- ca. 1806 “[Mania is] often no other than a higher degree of melancholia. . . . [I]t does not appear to me any wise difficult to suppose, that the same state of the brain may in a moderate degree give melancholia; and in a higher, that mania which melancholia so often passes into.” (William Cullen^j)
- ca. 1845 “Several distinguished masters, Alexander de Tralles, and Boerhaave himself, were of the opinion, that melancholy . . . was only the first degree of mania. This is in some cases true. There are in fact, some persons who, before becoming maniacs, are sad, morose, uneasy, diffident and suspicious.” (Jean-Etienne-Dominique Esquirol^k)

^aAlthough the idea for this time line was ours, locating the quotations would have been next to impossible without the excellent historical sources cited for each. We are especially indebted to Whitwell (1936), Jackson (1986), and Roccatagliata (1986). The quotations, particularly those from the Middle Ages, do not always represent prevailing thought, but they do illustrate the thread of this theme throughout history. Also, when the conditions we would characterize as manic-depressive illness were interpreted as medical rather than philosophical or religious problems, a relationship between mania and depression was almost always suggested, explicitly or implicitly.

^bCited by Whitwell (1936, pp. 163–164). From *De acut, et diut, morborum, causis, signis, et curatione* (Paris), 1554. Transl. R. Moffatt.

ⁱQuoted by Jackson (1986, p. 256) from Boerhaave, H.: *Boerhaave’s Aphorisms: Concerning the Knowledge and Cure of Diseases, Which Is That of a Vital and Sensitive Man. The First Is Physiological Shewing the Nature, Parts, Powers, and Affections of the Same. The Other Is Pathological, Which Unfolds the Diseases Which Affect It and Its Primary Seat; to Wit, the Brain and Nervous Stock, and Treats of Their Cures: with Copper Cuts* (London: W and J Innys), 1735, pp. 323–324.

^jQuoted by Jackson (1986, p. 259) from Cullen, W.: *First Lines of the Practice of Physic*. 2 vols., in 1. ed. J. Rotheram (New York: E. Duyckinck), 1806, p. 497.

^kQuoted by Jackson (1986, p. 262) from Esquirol, E.: *Mental Maladies: A Treatise on Insanity*. Transl. E. K. Hunt (Philadelphia: Lea and Blanchard), 1845, pp. 381–382.

In 1854, Falret described a circular disorder (*la folie circulaire*), which for the first time expressly defined an illness in which “this succession of mania and melancholia manifests itself with continuity and in a manner almost regular” (perhaps a foreshadowing of the modern concept of rapid cycling). In the same year, Baillarger (1854) described “double insanity” (*la folie à double forme*), emphasizing that the manic and depressive episodes were not two different attacks but rather two different stages of the same attack. Thus, cyclicity with or without clear-cut remission was already being described in these pioneering French contributions. Although clearly anticipating Kraepelin’s later synthesis, these descriptions nonetheless focused on chronic illness with poor prognosis; the relationship of these “forms” to other varieties of mania or melancholia was not delineated. Other valuable contributions were made by Griesinger (1867), who provided rich clinical descriptions of melancholia and mania, although he described primarily chronic states with poor prognosis. As Aretaeus had centuries before, Griesinger conceived of mania as an end stage of a gradually worsening melancholia and of both as different stages of a single, unitary disease (Jackson, 1986).

Although mild cases of mania had been described by the ancients, as well as by Falret, Esquirol, and other observers, Mendel (1881) was the first to define *hypomania* as “that form of mania which typically shows itself only in the mild stages abortively, so to speak.” Kahlbaum (1882) described circular disorders (*cyclothymia*), which were characterized by episodes of both depression and excitement but did not end in dementia, as chronic mania or melancholia could. Despite these contributions, most clinical observers continued to regard mania and melancholia as separate entities, chronic in nature, and following a deteriorating course. Nonetheless, some German authors during this period, such as Hecker (see the translation by Koukopoulos, 2003), reserved cyclothymia for the milder, nondeteriorating, forms observed in private clinical practice. Hecker’s work is actually quite consistent with what today we have come to recognize as bipolar-II disorder:

Virtually all of the [patients with cyclothymia] presented with a depressive state. The state of excitation—and I should like to emphasize this—had escaped the attention, in the majority of milder cases, of the patient’s doctor, his family and friends, and the patient himself. The patients only became aware of it when I described the characteristics of this state to them. Even more often, however, it was the patients themselves who, having up until that moment considered them as their ‘healthiest’ periods, were forced to recognize that they were ill in these periods also.

The Kraepelinian Synthesis

It was left to Kraepelin to segregate the two major psychotic illnesses—manic-depressive insanity and dementia praecox—from one another and clearly draw the perimeter around manic-depressive illness. The early editions of his textbook of psychiatry contained the seeds of his later synthesis, particularly his special emphasis on careful diagnosis based on both longitudinal history and the pattern of current symptoms. Nevertheless, these early editions still reflected a struggle with the then-traditional categories of melancholia and circular psychosis. In the sixth edition, published in 1899, the term *manic-depressive* encompassed the circular psychoses and simple manias. Kraepelin expressed doubt that melancholia and the circular psychoses (a category that includes today’s bipolar and schizoaffective disorders) were really separate illnesses, but he was still reluctant to take a definite stand.

By 1913, in the eighth edition of Kraepelin’s text, virtually all of the major clinical forms of melancholia had been subsumed under “manic-depressive illness.” Under his unitary concept, much of what had once been considered involutional melancholia was reclassified as mixed states,¹⁰ based on a follow-up study by his pupil, Dreyfus.¹¹ Kraepelin placed special emphasis on the features of the illness that differentiated it most clearly from dementia praecox (schizophrenia): the periodic or episodic course, the more benign prognosis, and a family history of manic-depressive illness.

Within a relatively short time, Kraepelin’s views were widely accepted, thus bringing some unity to European psychiatry. His was the first fully developed disease model in psychiatry to be backed by extensive and carefully organized observations and descriptions. This model did not exclude psychological or social factors, and in fact, Kraepelin was one of the first to point out that psychological stresses could precipitate individual episodes. By including “slight colourings of mood,” which “pass over without sharp boundary into the domain of personal predisposition,” he also provided the basis for the development of spectrum concepts, described later in this chapter.

Wide acceptance of Kraepelin’s broad divisions led to further exploration of the boundaries between manic-depressive illness and dementia praecox, the delineation of similarities across the two, and the possibility that sub-groups could be identified within each. Kraepelin’s extraordinary synthesis is important not because it drew the ultimately “correct” picture of nature, but because it built a solid and empirically anchored base for future work. This was his major accomplishment. Indeed, as we will see later, his central insight—that all of the recurrent major

mood disorders (using current nomenclature) belonged together under the rubric of *manic-depressive illness*—still provides the best model for what we know to date, as well as for understanding emerging clinical, pharmacological, and genetic data.

Post-Kraepelinian Developments

After Kraepelin, the evolution of the concept of manic-depressive illness proceeded differently in Europe and the United States (Pichot, 1988). Europeans continued to place primary emphasis on the traditional medical disease model of mental illness, whereas psychiatrists in the United States were profoundly influenced by the new perspectives of psychoanalysis and other theories emphasizing psychological and social factors. During the first half of the twentieth century, the views of Meyer (1866–1950) gradually assumed a dominant position in American psychiatry, a position maintained for several decades. Meyer believed that psychopathology emerged from interactions between an individual's biological and psychological characteristics and his social environment.¹²

The disease model, by contrast, is based on the premise that clinical phenomena in a given patient are understandable (and therefore potentially predictable) in terms of a given disease with a specific natural history and pathophysiology. European psychiatry in the nineteenth and early twentieth centuries had successfully employed this traditional medical disease model in the definition and treatment of general paresis secondary to syphilis of the central nervous system and organic syndromes associated with vitamin deficiencies (especially pellagra).¹³ Failure to identify mechanisms of pathophysiology in the major so-called functional psychoses, including manic-depressive illness, stimulated doubts about the continued usefulness of the model, particularly since the prevailing biological hypotheses emphasized infectious agents and neuropathological lesions. Consistent with this pessimism was the failure of the biologically based treatments of the time. In this climate, it is not surprising that American psychiatrists, manifesting the national penchant for pragmatism, were drawn to treatment approaches that emphasized psychological and social factors. When the Meyerian focus, considerably influenced by psychoanalysis, turned to manic-depressive illness, the individual and his environment were the natural focus, and clinical descriptions of symptoms and the longitudinal course of the illness were given less emphasis.¹⁴

Until the latter part of the twentieth century, the American nosological systems for affective disorders reflected these competing sets of etiological assumptions. Depression was divided into several dichotomies: reactive–endogenous, neurotic–psychotic, and, more recently,

primary¹⁵–secondary. Forgotten in these conceptions is the fact that a single parameter cannot differentiate aspects of illness that are at least partially independent of one another: severity, “neurotic features,” thought disorder, precipitating events, physiological symptoms, and genetic vulnerability. Dichotomous systems thus founded on their a priori assumptions about etiology. Even the primary–secondary distinction, although free of assumptions about severity, quality of symptoms, and precipitating events, is based on another supposition: it assumes that depression or mania associated with other illnesses is relatively free of genetic influence, an assumption that has not been supported by the data (Andreasen et al., 1988).¹⁶

In Europe, the post-Kraepelinian evolution of the concept of manic-depressive illness took a different turn. The European psychosocial and psychoanalytical traditions continued to develop in relative isolation from the mainstream of psychiatry, which largely retained its medical or disease orientation; psychoanalytic thinking per se did not have as important an influence on the European concept of manic-depressive illness as it did on the American concept. Although Kraepelin's fundamental distinction between manic-depressive illness and dementia praecox endured (Mayer-Gross et al., 1955), nosological disputes soon arose.

In his classic contributions to descriptive psychiatry, Bleuler (1924) departed from Kraepelin by conceptualizing the relationship between manic-depressive (affective) illness and dementia praecox (schizophrenia) as a continuum without a sharp line of demarcation.¹⁷ Bleuler believed that a patient's location on the spectrum depended on the number of schizophrenic features he demonstrated. In that sense, Bleuler considered the affective symptoms to be nonspecific. These issues are explored more fully in Chapter 3.

Bleuler also broadened Kraepelin's concept of manic-depressive illness by designating several subcategories and using the term *affective illness*. The influence of his modifications of Kraepelin's taxonomy could be seen in the *International Classification of Diseases* (ICD) (8th and 9th editions) and the closely related early versions of the *Diagnostic and Statistical Manual*, the first and second editions (DSM-I and -II). Bleuler's subcategories of affective illness anticipated the principal contemporary subdivision of the classic manic-depressive diagnostic group—the bipolar–unipolar distinction.

THE BIPOLAR–UNIPOLAR DISTINCTION

From its inception, Kraepelin's unitary concept of manic-depressive illness was criticized for being too inclusive, but it was not until 1957 that Leonhard proposed a classification

system that went beyond clinical description alone. Leonhard observed that, within the broad category of manic-depressive illness (i.e., recurrent affective illness), some patients had histories of both depression and mania, whereas others had depressions only. He then noted that patients with a history of mania (whom he termed *bipolar*) had a higher incidence of mania in their families as compared with those with recurrent depressions only (whom he termed *unipolar*). In 1966, Angst and Perris independently provided the first systematic family history data to support Leonhard's distinction, validating it by an independent criterion—family history. As discussed in Chapter 13, some of the subsequent family history studies are consistent with a model in which bipolar and the more highly recurrent forms of unipolar depression are variants of the same fundamental disorder (Kraepelin's manic-depressive illness), with bipolar illness representing the more severe end of the spectrum.

The bipolar–unipolar distinction was formally incorporated into the American diagnostic system, DSM, the third edition (DSM-III), in 1980; was subsequently carried forward into DSM, the fourth edition (DSM-IV); and became explicit in the international classification system in ICD-10. Unfortunately the structure of DSM-IV (see Fig. 3-1 in Chapter 3), which breaks out bipolar disorder as a separate illness distinct from all other mood disorders (i.e., from the depressive disorders) obscures the fact that originally, the bipolar–unipolar distinction was conceived of as a way to distinguish two forms of a *recurrent* illness. In other words, the DSM structure gives precedence to polarity over cyclicity, obscuring the reality that one rather common variant of unipolar illness is as recurrent or cyclic as bipolar illness. Further, DSM-IV really has no language for the unipolar patient with frequent recurrences, since its “recurrent” category is so broad as to include patients with only two depressions in a lifetime (see Chapter 3 for a more extensive discussion of this point).

Before the mid-1970s, the scientific literature on manic-depressive illness typically did not include information on the number of patients with or without a history of mania. During the past three decades, however, the bipolar–unipolar distinction has been examined in numerous studies encompassing family history, natural course, clinical symptoms, personality factors, biological measures, and response to various pharmacological treatments. The question of bipolar–unipolar differences in clinical features of depression is reviewed in this chapter; these as well as other reported bipolar–unipolar differences (e.g., biological, pharmacological, psychological) are summarized in Table 1-1 and further detailed in the relevant chapters (including this one—see also Table 1-3 on clinical differences later in the chapter). Our purpose in outlining these

reported differences here is to introduce a framework helpful in understanding them.

An Overview of Differentiating Features

The criteria that distinguish bipolar from unipolar illness have changed over the years, at least among American investigators. As noted above, in the original descriptions of Leonhard and the subsequent studies of Angst and colleagues (1998), Perris and colleagues (1971), and Winokur and colleagues (1981), both *bipolar*¹⁸ and *unipolar* were used to describe patients with a phasic or cyclic course of recurrent episodes, characterized by autonomous “endogenous” features and clear functional impairment. It is worth repeating that in DSM-III and -IV, *unipolar* has come to mean all depressed patients without a history of hypomania or mania (i.e., to mean simply nonbipolar)—a heterogeneous population that includes both highly recurrent and nonrecurrent depressions, not to mention patients who might have been classified as “neurotic,” “reactive,” “characterological,” or “atypical” in other diagnostic systems. As Roth (1983, pp. 47–48) observed about DSM-III:

The significant point in this context is that Leonhard intended that bipolar–unipolar dichotomy for endogenous states alone. . . . When the endogenous syndrome is discarded, unipolar disorders become a large and compensious bag to be commingled with a wide variety of disorders of affect, including neuroses of different kinds.

The critical issue of recurrence is further obscured by DSM-IV, which does not include an item concerning prior history or course, despite evidence suggesting a clear distinction between family history and course in different illness subtypes (Winokur, 1979).¹⁹ We believe that the next revision of the DSM and ICD systems should include a category (and operational definition) for the more recurrent forms of unipolar depression, which might be designated as “highly recurrent,” or “cyclic.” A related contributor to unipolar heterogeneity is the subgroup of unipolar patients with certain bipolar-like characteristics, as discussed below.

Bipolar groups are also heterogeneous. Most studies, particularly those first to use the distinction, did not specify criteria for bipolar beyond indicating a “history of mania.” In many studies, bipolar included only those patients with a history of frank mania requiring hospitalization; in others, the bipolar group included patients with milder symptoms (hypomania). Then, Goodwin and colleagues at the National Institute of Mental Health (NIMH) suggested that bipolar patients could be classified more meaningfully as either bipolar-I or bipolar-II (Dunner et al., 1976b). They based this recommendation on their studies of hospitalized depressed patients who met criteria for primary

TABLE 1–1. Overview of Reported Differences between Bipolar and Unipolar Depression

Phenomenology of Depression	Bipolar (I and/or II)	Unipolar
Depressive Symptoms	See Table 1–3	See Table 1–3
Natural Course		
Age at onset	Younger Narrower range	Older Broader range
Number of episodes	More	Fewer
Length of depressive episode ^a	Shorter	Longer
Cycle length	Shorter	Longer
Precipitants of episodes	More important at illness onset than for later episodes	Relation to illness onset not clear
Interepisode mood shifts	More	Fewer
Marital Status	Single status not a risk factor for episodes	Single status a risk factor
Epidemiology		
Lifetime risk	1.2–1.5%	5–10%
Proportion of major affective illness	20–50%	50–80%
Gender ratio	F=M	F>M
Substance abuse	More frequent	Less frequent
Suicide	Unclear	Unclear
Personality		
Depression/introversion	Less	More
Impulse control	Less	More
Stimulus seeking	More	Less
Personality profile	More normal	Less normal
Hyperthymic temperament	More	Less
Cyclothymia	More	Less
Family History/Genetics		
Monozygotic twin concordance rates	Higher	Lower
Mania among first-degree relatives	More	Less
Biological/Physiological		
Monoaminergic function (metabolites, receptors, neuroendocrine response, electrolytes, etc.)	Some studies report UP–BP differences (see Chapter 15)	
Pain sensitivity	Less	More
Hemispheric function dysfunction	More nondominant	?
Brain imaging parameters	? (see Chapter 15)	?

(continued)

TABLE 1–1. Overview of Reported Differences between Bipolar and Unipolar Depression (*continued*)

Phenomenology of Depression	Bipolar (I and/or II)	Unipolar
Sleep/Rhythms		
Sleep duration	Longer	Shorter
Phase advance	Less frequent (?)	More frequent (?)
Seasonal patterns	Fall/winter depression Spring/summer mania	Spring depression (?)
Pharmacological Response		
Response to antidepressants	Less (?)	More (?)
Speed of response to antidepressants	More rapid (?)	Less rapid (?)
Tolerance to antidepressants	More frequent	Less frequent
Antidepressant response to mood stabilizers	More frequent	Less frequent
Manic/hypomanic response to antidepressants	More frequent	Less frequent
Prophylactic response to lithium	Equivalent when bipolar and unipolar cycle length are comparable	
Prophylactic response to antidepressants	Poor	Good

*Studies demonstrating longer duration of episodes with unipolar versus bipolar depression are generally not corrected for number of episodes. See text.

Note: See individual chapters for details. Some of the bipolar–unipolar comparisons included both bipolar-I and -II, while others focused on either one or the other, an obvious source of heterogeneity. Not all of the reported differences have been replicated uniformly, which is not surprising given the heterogeneity of both the bipolar and “unipolar” groups (for example, early-onset, highly recurrent unipolar depression will be closer to bipolar depression in clinical characteristics). The sequence of the table follows that of the chapters in this volume.

F=female; M=male; UP-BP=unipolar–bipolar.

major affective disorders; that is, they had no prior history of another psychiatric diagnosis. Bipolar-I patients were defined as those with a history of mania severe enough to have resulted in treatment, usually hospitalization. Such full-blown mania was often accompanied by psychotic features. Bipolar-II patients, by contrast, had, in addition to major depression requiring hospitalization, a history of hypomania—that is, specific symptoms of sufficient magnitude to be designated as abnormal by the patient or the family and to result in interference with normal role functioning, but not severe enough to result in hospitalization.

This original distinction between bipolar-I and -II is different from that made in subsequent studies that also employed the bipolar-II terminology.²⁰ Whereas the work of Dunner and colleagues (1976b) and the NIMH Collaborative Program on the Psychobiology of Depression-Clinical Studies, as well as that of Angst and colleagues (2005) in

their long-term follow-up study, emerged from observations of hospitalized depressed patients without other psychiatric diagnoses, many of the more recent studies were conducted in patients in whom neither the depressed nor the hypomanic phase was severe enough to require hospitalization and in whom concomitant diagnoses (principally borderline personality disorder and substance abuse disorder) were not uncommon (Coryell et al., 1985, 1995; Endicott et al., 1985). Such definitional broadening is not universally accepted (Ghaemi et al., 2002). Thus, Baldessarini (2000) pointed out that mood fluctuations can be found in many if not most psychiatric disorders and expressed concern that the continued broadening of the bipolar diagnosis risks weakening the core concept of bipolar disorder. Similar concerns were expressed by van Praag (1993), and we agree.

Angst (1978), having earlier recognized the problem of the range of meanings that could confuse application of

the bipolar-II category, proposed a nomenclature that would account for milder forms of both depression and mania. He divided bipolar patients into *Md* and *mD*, with *M* and *D* indicating episodes of mania and depression requiring hospitalization, and *m* and *d* episodes clearly different from normal but not of sufficient severity to necessitate hospitalization. Although Angst's *mD* group is analogous to the original definition of bipolar-II of Dunner and colleagues (1976b), other systems have no subcategory analogous to his *Md* group. This is unfortunate, since Angst reported interesting differences among these subgroups. For instance, the ratio of females to males is substantially higher in the predominantly depressed subgroups (unipolar and *Dm*), whereas males are a higher proportion of the predominantly manic subgroups (*MD* and *Md*); these data are consistent with the higher female-to-male ratio in bipolar-II compared with bipolar-I disorder (Weissman et al., 1996; Cassano et al., 1999). More recently, Angst completed a long-term follow-up study of his original 1959–1963 cohort. He concluded that the *Md* group, compared with their *MD* counterparts, have a more favorable course and are less likely to require long-term maintenance medication, while their first-degree relatives have a lower affective morbidity risk (Angst et al., 2004).

The extent of overlap between Angst's *dm* category and the bipolar-II outpatients in subsequent studies (by Akiskal, Benazzi, and others) cannot be assessed because Angst's system defines *d* episodes by an absence of hospitalization for depression, whereas a bipolar-II diagnosis is based on meeting DSM-IV criteria for major depression. Angst's *dm* grouping is inherently broader than bipolar-II and includes patients who would be classified as cyclothymic in DSM-III and -IV (see Chapter 3). Whatever the level of depressive severity,²¹ however, bipolar-II patients represent a very important group. Moreover, as discussed below, both family history and pharmacological response data indicate that, while in some respects bipolar-II should be considered an intermediate form between bipolar-I and unipolar,²² some of the data are consistent with its being a distinct subgroup.

As noted in the first edition of this text, one problem complicating research on bipolar-II disorder has been the poor reliability of the diagnosis, which results principally from the difficulty of establishing a history of hypomania (Andreasen et al., 1981; Dunner and Tay, 1993). Depressed patients are especially poor at recalling prior episodes of hypomania. Fortunately, family members generally do better. Moreover, the sensitivity to hypomania can be increased by multiple interviews over time (Rice et al., 1986). And current data indicate excellent reliability when clinicians trained in recognizing bipolar-II make the diagnosis (Dunner and Tay, 1993; Simpson et al., 2002). Other issues

involved in making a DSM diagnosis of hypomania include the not-always-warranted primacy accorded to elated mood over dysphoric mood and the durational requirement of 4 or more consecutive days, both of which have been widely criticized by clinical researchers (see the discussion in Chapter 3).

Most significant, contemporary data necessitate revision of the more traditional view of bipolar as substantially less common than unipolar illness. In Egeland and Hotstetter's (1983) study, using sensitive methods of ascertainment and considering cyclothymia, bipolar-II, and bipolar-I together, the incidence of bipolar disorder was approximately equal to that of unipolar illness—that is, it accounted for 50 percent of major affective illness.²³ Angst and colleagues (1978) also found that the ratio of bipolar to unipolar illness was about 1:1 in patients followed for up to 16 years, a ratio very close to that noted in the subsequent follow-up of that cohort, in which only 46 percent of the patients were still unipolar (Angst et al., 2002, 2004). Other recent studies using this broader definition of bipolar have found a similarly high bipolar/unipolar ratio.²⁴

Unfortunately, many studies of recurrent affective illness employ relatively insensitive methods of ascertainment and correspondingly rigid criteria for an episode. Although such inflexible criteria are useful for certain research purposes, they exclude many patients from consideration. Egeland and Hotstetter (1983) referred to the bipolar illness typically cited in the literature (i.e., bipolar-I) as the “tip of the iceberg” of bipolarity. Current data indicate that manic-depressive spectrum conditions (see below), many of them below the threshold of mania, may be found in 5–8 percent of the population (Angst, 1978) (see Chapter 5). However, the validity of the diagnoses in most of these surveys (obtained by trained lay interviewers) has been questioned, primarily because estimates based on diagnoses by experienced clinicians tend to be substantially lower (see Chapters 4 and 5).

A broad range of bipolar–unipolar differences have been reported (see Table 1-1). They include four separate spheres of data—genetic, clinical, biological, and pharmacological. Considerable caution is warranted in interpreting these differences, however, given the heterogeneity in both groups. While most of these studies have focused on bipolar-I patients (reducing heterogeneity on that side),²⁵ the unipolar groups have been highly heterogeneous with respect to the critical variable of recurrence or cycle length; clearly the unipolar groups represented in Table 1-1 have generally not been selected for frequent recurrences (Cassano et al., 1992; Winokur et al., 1993, 1994, 1995; Judd et al., 2003a). Indeed, to our knowledge, there have been no studies comparing bipolar and unipolar illness in which

the groups have actually been matched for episode frequency. This is a serious limitation in light of the increasing evidence that more highly recurrent unipolar patients appear to be quite similar to bipolar patients in some important respects (e.g., early age at onset, family history of mania, "atypical" features, and prophylactic response to lithium).

Implicit in the foregoing discussion of bipolar–unipolar distinctions is the need for a more explicit focus on the relationship between cyclicity and polarity. To what extent do differences in cyclicity contribute to or obscure reported bipolar–unipolar differences? In other words, how are we to know whether a given bipolar–unipolar difference is a function of the presence or absence of a history of mania/hypomania, or occurs because the bipolar group is more cyclic or recurrent than the unipolar group? These important questions are discussed later in the chapter. The relationship between polarity per se and other dimensions of affective illness—family history, age at onset, severity, psychotic features, response to treatment, and biological markers—generally has been studied one dimension at a time. A more comprehensive understanding of these interrelationships awaits studies that employ simultaneous weighing of multiple dimensions.

Unipolar Mania

The classic studies of Leonhard (1957), Perris (1966), Angst (1966), and Winokur and colleagues (1969) noted the relatively rare occurrence of manic patients with no apparent history of depression. In Leonhard's series, "pure mania" represented 9 percent of the bipolar group, whereas in the other studies it made up less than 5 percent. Although Leonhard initially considered patients with pure mania a separate group, subsequent studies indicated that they could not be distinguished from bipolar patients by either family history, course, treatment, or clinical features of mania. Thus, pure mania has generally been considered a variant of bipolar illness. Present knowledge suggests the likelihood that patients so identified either have had unreported depressions or have not been followed long enough to rule out future depressions. For some unipolar manic patients, depressive episodes are subsyndromal: they fail to be diagnosed because they lack a prominent or reported mood component; that is, the depressions manifest themselves primarily as episodes of increased sleep, decreased energy, and slowed thinking.

Abrams and colleagues²⁶ (Abrams and Taylor, 1974; Abrams et al., 1979) prompted a reevaluation of this question by reporting a 28 percent and an 18 percent incidence of unipolar mania among two relatively large independent samples of manic patients ($N=127$ for the two samples). Among the problems with these two studies, however, is

the method used to ascertain a history of depression.²⁷ Like previous authors, Abrams and Taylor found that their "unipolar manics" did not differ fundamentally from the bipolar patients in demographic characteristics, family history variables, symptoms, or response to "doctor's choice" treatment.

Nurnberger and colleagues (1979) surveyed 241 bipolar-I patients in a lithium clinic and found that 16 percent had not been medically treated for depression, although most of them did show depressive features on a systematic interview. These authors, like other investigators, concluded from their review of phenomenological and family history data that unipolar mania is a variant of bipolar illness, not a separate entity. The NIMH Collaborative Program on the Psychobiology of Depression-Clinical Studies followed 27 patients (from a pool of 163 bipolar-I patients) initially admitted with a diagnosis of unipolar mania (Solomon et al., 2003) and found that 7 of them suffered no episodes of major depression during the 15- to 20-year follow-up; that is, unipolar mania represented 4 percent of the total bipolar sample. Yazici and colleagues (2002), by contrast, found that unipolar mania accounted for 16 percent of patients in their lithium clinic in Turkey, the higher rate perhaps reflecting cultural differences; that study also revealed a significantly higher rate of psychotic features associated with unipolar mania. Shulman and Tohen (1994) found the rate of unipolar mania to be 12 percent in a group of 50 elderly manic patients.

Perugi and colleagues (1998a) reported that hyperthymic temperament was the baseline in many unipolar manic patients, whose course appeared to be more chronic than that of the typical bipolar patient. Unlike the work of Angst and colleagues (2004), who reported a relatively favorable course among their pure M and Md patients, the findings of the two aforementioned studies suggest that unipolar mania represents a prognostically unfavorable variant of bipolar-I disorder. Yet this discrepancy may reflect differences in the populations designated as unipolar manics. For example, a late-onset bipolar disorder with predominantly manic course has been described, and is associated with evidence of organic contributions and negative family history for bipolarity (Shulman and Post, 1980; Moorhead and Young, 2003). The condition of these patients is best considered a phenocopy of mania, and should probably be excluded from the manic-depressive spectrum.

Future studies attempting to evaluate the validity of the concept of unipolar mania will have to employ careful diagnostic criteria, sensitive methods of ascertainment (especially family informants), and extensive follow-up periods. As the evidence now stands, we would agree with most authorities in the field that the existence of true

unipolar mania as a separate entity is questionable. In our discussions here, it is included in the bipolar group.

False Unipolar Patients

As reviewed in the first edition of this volume, patients classified as unipolar who subsequently experience a manic or hypomanic episode—so-called *false unipolars*—confound studies of bipolar–unipolar differences (unipolar patients with some bipolar characteristics—sometimes called *pseudounipolar*—represent a different issue and are discussed below). Obviously, substantial numbers of false unipolar patients in a sample could distort or conceal bipolar–unipolar differences.

Table 1–2 presents data from three longitudinal studies (Perris, 1968; Angst et al., 1978; Grof, unpublished). The number of false unipolar patients is expressed as a percentage of the total unipolar group and as a function of numbers of depressive episodes without a mania. One might have expected the percentage of false unipolar patients to decrease as the group was “purified” by requiring more episodes of depression, that is, allowing more and more opportunity for latent bipolarity to express itself. In fact, however, the denominator (i.e., the number of true unipolar patients) also decreases as patients with more episodes are selected, since the unipolar patients who have only one, two, or three episodes are dropped. Thus, the actual percentage of false unipolar patients in the apparent unipolar population is relatively stable beyond the second episode, so that the convention of requiring more than two episodes of depression before diagnosing unipolar illness is ineffective in reducing the percentage of false unipolar patients. However, this convention does reduce the heterogeneity among unipolar groups

with respect to recurrence, increasing the chances that bipolar–unipolar comparisons will really be about polarity, as noted above. Perris’s (1966) bipolar–unipolar studies come closest to this in that his unipolar patients had all experienced at least three depressions. But the median number of episodes experienced by his unipolar patients was still substantially below that of his bipolar group.

A number of important studies of the unipolar-to-bipolar conversion conducted since 1990 are not included in Table 1–2 because they do not provide this type of analysis. They generally found rates of conversion from an initial unipolar to a subsequent bipolar diagnosis that range up to 50 percent;²⁸ the highest rate was found in the study of the Angst group, which had the longest follow-up period. Generally, the younger the age at onset of depression, the higher was the rate of subsequent conversion to bipolar (see, for example, Rao et al., 1995; Geller et al., 2001). These issues are detailed in Chapter 4.

We have already noted that some unipolar patients have bipolar-like courses—namely early age at onset and frequent recurrences. Akiskal and Mallya (1987) pursued this observation by examining unipolar patients for depressive symptoms that might be considered analogous to mania/hypomania. Koukopoulos and Koukopoulos (1999) described these agitated depressions as “depressive mixed states,” a concept that overlaps considerably with “agitated depression” (see Chapter 2). Depressive mixed states were studied more systematically in the Ravenna–San Diego Collaborative Study.²⁹ In that research, only three “manic-hypomanic” symptoms were required, the most frequent being psychomotor agitation (which was not goal directed), distractibility, and racing–crowded (predominantly

negative) thoughts, all symptoms traditionally associated with agitated depression.

The examination of depressive “mixed states” has accelerated since the first edition of this text was produced. For example, Benazzi (2001) found that 49 percent of his bipolar-II patients had three or more concurrent manic-like symptoms, versus only 3 percent of his unipolar patients. Likewise, Sato and colleagues (2003) found significantly more manic-like symptoms in their bipolar depressed patients—especially irritability, racing thoughts, and distractibility—than in their unipolar patients. In their study of 441 bipolar patients, Bauer and colleagues (2005) found that 70 percent had “clinically significant” manic-like symptoms while in a depressive episode. Maj and colleagues (2003) compared bipolar-I patients who became agitated when depressed with those who did not and found that one in four of the former had other manic-like symptoms, such as racing thoughts and pressured speech. In a more recent study of major depressive disorder, Maj and colleagues (2006) compared agitated patients with the same number of nonagitated patients, and found more bipolar relatives among the former. Serretti and Olgiati (2005) analyzed the patterns of “manic” symptoms in 372 patients diagnosed with major depressive disorder and identified agitated activity as the most frequent (18 percent), followed by irritable mood (7 percent), distractibility (3 percent), reduced need for sleep (2 percent), and reckless activity (2 percent). Note that in these studies, the most frequent “manic” symptom identified was psychomotor agitation, which recalls our speculation in the first edition of this text that agitation in unipolar depression may be analogous to mania in bipolar illness. However, we noted that manic hyperactivity and depressive agitation generally connote different phenomena, the former being more variable and goal directed, and the latter more repetitive, stereotyped, and purposeless.

The contention that these conditions should be called “mixed states” (and therefore bipolar) rather than “agitated depression” can complicate the interpretation of bipolar–unipolar differences because it broadens the concept of bipolarity to include patients *without* a history of mania or hypomania. While the finding of an elevated risk for bipolarity in first-degree relatives of agitated unipolar patients reinforces the conclusion that activation/agitation in a subgroup of unipolar patients may be a marker of a bipolar diathesis, it falls short of being an adequate basis for designating such unipolar patients as bipolar *per se* (Goodwin and Ghaemi, 2000). The contemporary delineation of depressive mixed states harkens back to Kraepelin (1899), who cited the existence of certain manic-like signs and symptoms during recurrent depression in some patients as he developed his argument for the essential unity of the recurrent affective disorders as manic-depressive

illness. Clearly this is a critical issue and one that is central to the discussion of mood disorders. The centrality of mixed affective states, along with the belief that recurrence/cyclicity is as or more defining a feature than polarity *per se*, underscores our use of the more inclusive diagnostic term manic-depressive illness. Future research on depressive mixed states and their relationship to bipolar disorder will in time clarify which characteristics of depression and mania are most important to differentiating among and understanding the affective illnesses.

The Primacy of Mania

Koukopoulos (2006) has made a novel suggestion about the relationship between mania and depression that may explain the occurrence and frequency of mixed states, as well as the connection between manic and depressive episodes in the course of this illness. According to his hypothesis, mania is primary, with depression being the consequence of a preceding mania. Thus according to this perspective, the recurrent unipolar subgroup of manic-depressive illness does not really exist since all depressive presentations are preceded by a manic presentation. Obviously, this hypothesis would require a much broader notion of mania than occurs in DSM-IV, one corresponding to concepts used 100 years ago and into ancient times. In this model, mania represents any kind of “excitement” or agitation. Thus in mania’s most severe forms, we have type I bipolar disorder, while in its less severe forms, hypomania or hyperthymic personality precedes depressive episodes. Even with respect to nonrecurrent major depression, other manifestations of excitation (e.g., stress-induced anxiety conditions) could be seen as precursors of a later major depressive episode. As with any bold hypothesis, numerous objections can be made to the thesis of Koukopoulos; however, it is testable, and considering it in examining the spectrum of mood conditions may be heuristically useful.

Clinical Differences between Bipolar and Unipolar Depression

In his early observations, Leonhard noted that his bipolar patients (proportion of bipolar-I versus -II not specified) showed more symptomatic variability from episode to episode than did his recurrent unipolar patients, whose depressive symptoms he characterized as “stereotyped” (Leonhard, 1957). This differential brings to mind more recent comparisons in which bipolar-II depressed patients have been noted to have less stability and uniformity of symptoms across episodes than unipolar patients (Hantouche and Akiskal, 2005). Many studies over several decades, the results of which are summarized in Table 1-3, have found unipolar and bipolar-I differences over a wide

range of clinical features. We have already noted the heterogeneity in both the bipolar and unipolar groups (especially the latter), which makes any generalizations difficult to say the least. In addition to the unknown variability in extent of recurrence (cycle lengths), most of these studies did not control for differences in severity of depression or age at onset.³⁰

It is worth noting that the comparisons in Table 1–3 are predominantly between unipolar and bipolar-I patients (although several of the studies refer only to “bipolar” without specifying subtype). Indeed, it has been suggested that bipolar–unipolar differences become clearer when the bipolar-II group is excluded. The most widely replicated studies point to a picture of the bipolar-I depressed patient as having more mood lability, psychotic features, psychomotor retardation, and comorbid substance abuse. In contrast, the typical unipolar patient in these studies had more anxiety, agitation, insomnia, physical complaints, anorexia, and weight loss. As noted in the table, there are a number of other features for which there is only one study or conflicting studies; certainly some of the apparent disagreement may be related simply to inadequate description of the bipolar or unipolar samples.

There is a much smaller body of data on unipolar–bipolar-II comparisons, and most of these data focus on depressive “mixed states” (more frequent in bipolar-II, as discussed above and in Chapter 2) and on so-called atypical features. Atypical depression was originally described in unipolar patients on the basis of a group of symptoms including hypersomnia, increased weight and appetite, leaden paralysis, interpersonal rejection sensitivity, and preferential response to monoamine oxidase inhibitors (MAOIs) (reviewed by Raskin and Crook, 1976). Given the suggestion of earlier studies that MAOIs are preferentially effective in bipolar depression (Himmelhoch et al., 1991), an interest in the relationship between atypical features and bipolar illness has developed. Following up on studies of atypical features reviewed in the first edition, a number of more recent

studies have reported more atypical symptoms in bipolar-II than in unipolar depressed patients.³¹ On the other hand, not all investigators have found such differences.^{32,33} Some of these latter studies, however, did not systematically assess bipolar-II as recommended by Dunner and Tay (1993) and Ghaemi and colleagues (2002), among others. As noted above, heterogeneity among samples of unipolar patients is another potential source of divergent findings. For example, Benazzi (2003) found that some bipolar–unipolar differences depended on the age at onset in the unipolar sample: only those unipolar patients with later age at onset were significantly different from the bipolar-II group with respect to bipolar family history, atypical features, number of episodes, and depressive mixed states.

Another approach to examining the relationship between atypical depression and bipolar disorder was pursued by Akiskal and Benazzi (2005). They examined 602 consecutively evaluated outpatients with DSM-IV major depression (58 percent were bipolar-II,³⁴ 42 percent unipolar), 43 percent of whom met DSM-IV criteria for atypical features, in agreement with the data of Perugi and colleagues (1998a) and Angst and colleagues (2002). They found a robust association between atypical features (especially leaden paralysis and hypersomnia) and a bipolar family history.³⁵ In a recent analysis of this same cohort, Akiskal and Benazzi (2006) found that hypomania scores (using The Hypomania Interview Guide) were distributed normally, not bimodally and there was a “dose response” relationship between these scores and the extent of bipolar family history, both findings suggesting that highly recurrent unipolar and bipolar II are on the same spectrum rather than representing separate categories. On this basis, Akiskal and Benazzi suggested that atypical depression may represent a bridge between unipolar and bipolar-II disorder.

Heun and Maier (1993) interviewed 80 bipolar and 108 unipolar patients and 80 controls, along with their first-degree relatives, and found that while the morbid risk for

bipolar-I was equivalent in relatives of the bipolar-I and -II groups (and was higher for both than for the unipolar group), the morbid risk for bipolar-II distinguished the relatives of this group (6.1 percent) from those of the bipolar-I group (1.8 percent). Like the findings of earlier studies (Dunner et al., 1976b; Gershon et al., 1982), these data suggest that bipolar-II may be genetically heterogeneous, some evidence being consistent with categorical integrity (Simpson et al., 1993) and some with a bipolar-I–bipolar-II spectrum. (These genetic issues are discussed more thoroughly in Chapter 13.)

Clinical Differences between Bipolar-I and -II Depressions

In the first edition, we reported on a series of NIMH clinical, genetic, pharmacological, and biological studies of bipolar–unipolar differences in which bipolar-I and -II patients were analyzed separately (Dunner et al., 1976a; Dunner, 1980). On some measures (for example, a family history of mania), the bipolar-I and -II groups were similar to one another and dissimilar to the unipolar patients. On other measures (for example, age at onset), the bipolar-II group appeared to be intermediate between the bipolar-I and unipolar groups. Finally, on some measures (for example, “atypical” features of depression), the bipolar-II patients were more similar to the unipolar than to the bipolar-I patients. One problem limiting interpretation of this interesting series of studies is the fact that the initial diagnosis of depressive illness was made prior to the availability of formal diagnostic criteria; thus, even though all of the patients had depressions severe enough to require hospitalization, the unipolar groups were undoubtedly heterogeneous.

Endicott and colleagues (1985) advanced the field by applying the formal Research Diagnostic Criteria (RDC) to 122 bipolar-I, 66 bipolar-II, and 104 recurrent unipolar depressed patients (two or more episodes of major depressive disorder). In the earlier study of Dunner and colleagues (1976) of patients hospitalized for depression, the age at onset of the bipolar-II group was intermediate (consistent with a spectrum based on severity of mania), whereas in the study of Endicott and colleagues (1985), the age at onset of the two bipolar groups was similar and different (younger) from that of the unipolar group. On the other hand, bipolar-II and unipolar patients were similar (and different from bipolar-I patients) in that both had higher proportions of time spent depressed, a finding that was confirmed and extended by the longitudinal NIMH Collaborative Program on the Psychobiology of Depression-Clinical Studies (Judd et al., 2003c) (see Chapter 4). Bipolar-II females had higher rates of alcoholism than unipolar or bipolar-I females, consistent with the earlier findings of Dunner and colleagues (1979), and they

were more likely to suffer from premenstrual dysphoria. Most important, Coryell and colleagues (1984) and Endicott and colleagues (1985) found that bipolar-I and -II patients tended to breed true. That is, bipolar-I patients tended to have bipolar-I relatives and bipolar-II patients to have bipolar-II relatives, a finding that is in agreement with the data of Fieve and colleagues (1984)³⁶ and Simpson and colleagues (1993) and partly with those of Gershon and colleagues (1982).

Table 1–4 updates those findings with studies published since the first edition. One important question is how these reported bipolar-I–bipolar-II differences may affect our understanding of the relationship between unipolar and bipolar depression and the concept of the manic-depressive spectrum. Focusing on the most replicated findings, a picture emerges of the bipolar-II patient as more likely to be female, with less severe but more frequent and more chronic depressions, shorter interepisode intervals, and more comorbid anxiety and alcohol abuse (the latter among females). By contrast, the bipolar-I patient has more severe and prolonged depressions with more psychosis and hospitalizations. With regard to age at onset, agitation, irritability, and frequency of rapid cycling, there is no consensus on bipolar-I–bipolar-II differences.

Examining Tables 1–3 and 1–4 together, one notes that bipolar-II is closer to unipolar in some respects (e.g., percent female and time spent depressed), but closer to bipolar-I in others (e.g., number of episodes and substance abuse).

As noted earlier, the DSM-IV construct of bipolar-II requires a threshold of 4 or more days. However, findings of more recent studies suggest that 2 days may be a more appropriate threshold (judged on the basis of external validating strategies, such as age at onset, depressive recurrence, and familial bipolarity). These are mainly cross-sectional studies from different clinics in the United States (Akiskal and Mallya, 1987; Manning et al., 1997) and Italy (Cassano et al., 1992; Benazzi, 2001). Epidemiologic data reveal that most hypomanias are of 1–3 days’ duration (Wicki and Angst, 1991). It is interesting to note that if one takes a dimensional view of hypomania in manic-depressive illness (symptoms rather than syndrome), bipolar–recurrent unipolar differences are attenuated (Cassano et al., 2004);³⁷ these clinical observations require independent validation by external markers, such as family history and prospective course.

Few long-term studies have been conducted with lower thresholds for hypomania. The two exceptions are derived from the prospective NIMH Collaborative Program on the Psychobiology of Depression-Clinical Studies, which showed, first, longitudinal stability of bipolar-II over time (Coryell et al., 1995) and, second, no significant differences in clinical and course parameters when either 2- or 7-day

TABLE 1–4. Clinical Differences between Bipolar-I and Bipolar-II

Symptom	Clinical Comparisons	Studies
Anxiety	BP-II > BP-I	Dunner et al., 1976b; Hantouche et al., 1998; Judd et al., 2003c
Time spent in depression (major and minor)	BP-II > BP-I	Endicott et al., 1985; Vieta et al., 1997; Judd et al., 2003
Interepisode intervals	BP-II < BP-I	Judd et al., 2003b
Number of episodes	BP-II > BP-I	Vieta et al., 1997; Judd et al., 2003c; Akiskal and Benazzi, 2005
Rapid cycling	BP-II > BP-I	Coryell et al., 1992; Maj et al., 1999; Baldessarini et al., 2000
Psychotic features	BP-II = BP-I	Vieta et al., 1997; Coryell et al., 2003
Suicide/suicide attempt	BP-I > BP-II	Vieta et al., 1997; Mitchell et al., 2001
Premenstrual dysphoria	BP-II > BP-I	Dunner et al., 1976; Goldring and Fieve, 1984; Arato et al., 1988; Rihmer and Pestalija, 1999
Hospitalizations	BP-I > BP-II	Coryell et al., 1989; Vieta et al., 1997
Agitation; irritability	BP-I > BP-II	Endicott et al., 1985
Alcohol abuse (females)	BP-II > BP-I	Vieta et al., 1997
Percent female	BP-II > BP-I	Dunner et al., 1976b; Hantouche et al., 1998; Serretti and Olgiati, 2005
Severity of depressive episodes	BP-I > BP-II	Coryell et al., 1985; Weissman et al., 1996; Cassano et al., 1999
Length of depressive episode	BP-I > BP-II	Vieta et al., 1997; Benazzi, 1999
Percent medicated	BP-I > BP-II	Coryell et al., 1985

BP=bipolar.

thresholds were applied to RDC-defined bipolar-II patients (Judd et al., 2003b). Akiskal and Pinto (1999) suggested that those with the shortest duration of hypomania are more unstable and have a highly recurrent course, typically arising from a cyclothymic temperamental base, which they designate bipolar-II ½.³⁸ It remains to be seen whether such continued splitting of diagnostic groups is productive or is simply confusing to the field. This is an empirical question, one that will be resolved ultimately by genetic studies. It is noteworthy that Angst and Gamma (2002), in defining subthreshold bipolarity, set no thresholds for the duration of hypomania as long as the hypomania is recurrent.

EMERGENCE OF THE MANIC-DEPRESSIVE SPECTRUM

The concept of a spectrum is used in two different ways in the description of affective disorders, both clearly delineated by Kraepelin. On the one hand, spectrum

conceptualizes a continuum between bipolar and unipolar illness—historically, this is the manic-depressive spectrum. On the other hand, a spectrum is a way to conceptualize the relationship between full-blown affective illness, either bipolar or unipolar, and milder states or characteristics that might be construed as temperament. When we refer to the manic-depressive spectrum here, we are using it in this latter way.

Kraepelin (1921, p. 1) was the first to formally posit a continuum between the psychotic and less severe of affective disorders, merging imperceptibly with normality (although this concept was implicit among many of the ancient physicians):

Manic-depressive insanity . . . [includes] certain slight and slightest colourings of mood, some of them periodic, some of them continuously morbid, which on the one hand are to be regarded as the rudiment of more severe disorders, on the other hand pass without sharp boundary into the domain of personal predisposition. In the course of the years I have become more and more convinced that

all the above-mentioned states only represent manifestations of a single morbid process.

As we noted in the first edition, the classic descriptions cited in Chapter 2, systematic observations reported in the literature, and our own research and clinical experience and that of our colleagues all convince us that the cardinal features of manic-depressive illness are dimensional, that is, distributed along a spectrum. Indeed, to give emphasis to the spectrum concept in the first edition, we devoted a separate chapter to it. Our 1990 conclusion was echoed by an international panel of experts that summarized the increasingly rich and sophisticated database supporting such a spectrum (Akiskal et al., 2000). More recently, Ghaemi and colleagues (2004) proposed a definition of bipolar spectrum disorder (or as we would prefer for clarity, the manic-depressive spectrum), which is outlined in Box 1–2.

We further explore the spectrum model here because it introduces concepts that shaped the formal diagnostic systems reviewed in Chapter 3, and it clarifies our own conceptions of manic-depressive illness, implicit in discussions throughout this volume.

Although diagnosis is central to all of medicine, the assumptions underlying its various meanings are seldom examined. The most common medical classification model—the categorical approach—posits discrete diagnostic entities or discrete subtypes within a larger diagnostic group. Dimensional approaches, the most common competing model, characterize the individual patient according to where he or she falls on a number of separate dimensions. In this model, each individual represents the point of intersection of multiple parameters. Both models have gained support from studies using discriminant function analysis and other statistical techniques. Clearly, the categorical approaches tend to prevail, not because they are supported more compellingly by the empirical evidence, but because they are much easier to grasp conceptually and to deal with statistically. Indeed, multidimensional approaches, however eloquently descriptive of an individual patient, will remain essentially unhelpful if they cannot test generalizations—that is, be applied to prediction.

Contrary to the common assumption, the categorical approach does not preclude the concept of a continuum (Grayson, 1987; Kraemer et al., 2004). A diagnostic category need not have absolutely discrete and discontinuous boundaries. Let us suppose for the moment that individuals with depressive disorders are distributed more or less evenly along a continuum with self-limiting grief reactions on one end and severe, disabling major depressive illness on the other (Kendell, 1968; Goodwin, 1977). Even if discontinuity (i.e., clustering at discrete points along the spectrum) is not

BOX 1-2. A Proposed Definition of Bipolar Spectrum Disorder

- A. At least one major depressive episode
- B. No spontaneous hypomanic or manic episodes
- C. Either one of the following, plus at least two items from criterion D, or both of the following plus one item from criterion D:
 - 1. A family history of bipolar disorder in a first-degree relative
 - 2. Antidepressant-induced mania or hypomania
- D. If no items from criterion C are present, six of the following nine criteria are needed:
 - 1. Hyperthymic personality (at baseline, nondepressed state)
 - 2. Recurrent major depressive episode (>3)
 - 3. Brief major depressive episodes (on average, <3 months)
 - 4. Atypical depressive features (increased sleep or appetite)
 - 5. Psychotic major depressive episode
 - 6. Early age at onset of major depressive episode (before age 25)
 - 7. Postpartum depression
 - 8. Antidepressant tolerance ("wear-off," acute but not prophylactic response)
 - 9. Lack of response to >3 antidepressant treatment trials

Source: Ghaemi et al., 2004.

demonstrable, a useful category can still be defined by establishing a minimum (or maximum) threshold of symptoms for inclusion in the category; consider, for example, hypertension and hypothyroidism. And the pattern of illness characteristics—symptoms, course, family history, and treatment response, for example—reflects a convergence of several dimensional variables. Such a model should be acceptable to those who are comfortable with large, internally variable categories—the “lumpers”—as well as to those who want to create a new category for every variant—the “splitters.” This conception is simply for the sake of narrative convenience, not to reflect a conviction that any particular group has discrete, discontinuous boundaries. On the contrary, and as we emphasized in the first edition of this book, we are impressed with the subtlety of the shadings.³⁹ How these issues bear on diagnosis is discussed in Chapter 3.

Exploration of spectrum models is important for several reasons. The reliable characterization and validation of subsyndromal states similar to bipolar illness would enhance research on genetic markers and modes of genetic transmission, as discussed in Chapter 13, as well as provide an approach for identifying individuals at risk for the development of full-blown bipolar illness (Alda, 2004). Additionally, a spectrum model would permit the evaluation of treatments for attenuated variants, including the question of whether early intervention could lessen the chance

of progression to bipolar illness. Existing prospective and retrospective data indicate that approximately one-third of individuals with subthreshold conditions phenomenologically related to bipolar illness (i.e., cyclothymia) will go on to develop the full bipolar syndrome (Akiskal et al., 1979a, 1995; Depue et al., 1981, 1989; Cassano et al., 2002, 2004). The possibility that this progression may be hastened by treatment with antidepressant drugs (see Chapter 19) lends further urgency to identifying subsyndromal precursors of bipolar disorder. Indeed, the term *bipolar spectrum*, which conveys the continuum of cyclothymia with bipolar-II and with hypomanias associated with antidepressants, is a logical extension of concepts laid out long ago by Kraepelin and his predecessors.

The concepts of secondary depression and secondary mania have received considerable attention because they are important to differential diagnosis (see Chapter 3) and because they may shed light on the pathophysiology of mood states (see Chapter 14). Reexamined in light of spectrum models, secondary mania and depression, like their primary counterparts, also appear to be expressions of an underlying diathesis, but a weaker one, which therefore requires a greater perturbation to be expressed clinically. This possibility is most credible in the case of pharmacologically induced hypomanias.

Bearing on the concept of a manic-depressive spectrum (i.e., the relationship between unipolar and bipolar illness), recent data from the French national EPIDEP (Epidemiology of Depression) study (Akiskal et al., 2003a) suggest a familial vulnerability for hypomania associated with antidepressant pharmacotherapy, which is similar to that for spontaneous bipolar-II disorder (see Table 1-1), but one that is probably less severe than that associated with spontaneous hypomanic episodes. For this reason, Akiskal and colleagues (2003a) have suggested the term *bipolar-III* for this group of patients. A prospective study by Kovacs and colleagues (1994) showed that many dysthymic children followed up beyond puberty do switch to hypomania and/or mania even without pharmacological treatment. These data suggest a threshold of vulnerability among subjects with early-onset dysthymia that may not routinely require external triggers, such as antidepressants.

Along the same lines, Akiskal and colleagues (1979b) reported that familial affective "loading" (defined as more than three affected members in a pedigree) predicted those "neurotic depressives" who progressed to hypomania and/or mania during prospective follow-up. In another study, Akiskal and colleagues (1978) followed 100 outpatients with mild depressive states—variously referred to as "neurotic," "reactive," or "situational"—for 3 to 4 years. They found that 40 percent developed a major affective disorder, and nearly half of these were bipolar.

The terminology applied to the "soft bipolar spectrum" includes overlapping conditions in the less-than-manic range. The soft spectrum includes Dunner and colleagues' (1980) "bipolar, not otherwise specified," as well as conditions described by Akiskal and Akiskal (1988) as depressions arising from cyclothymic and hyperthymic temperament. In addition, it includes hypomanic reactions occurring during antidepressant and other somotherapies for depression.

An elevated risk for familial bipolarity (Cassano et al., 1992; Akiskal, 2001) represents the main external validation of the bipolar nature of these "soft" phenotypes. Akiskal and colleagues (2003a) and Hantouche and colleagues (2003a) have suggested that within the broadly conceived cyclothymic temperamental domain there are "dark" and "sunny" types. Although family history for bipolar disorder is equally high in both groups, in clinical practice bipolar-II associated with the darker core cyclothymic temperament is more likely to be diagnosed as a personality disorder. There is little justification for this practice, because as in the case of full-blown bipolar patients, those with spectrum diagnoses in the broad cyclothymic–bipolar-II realm are equally likely to engage in dramatic and socially inappropriate behaviors (Akiskal, 1994; Deltito et al., 2001). In the end, it may not be easy to distinguish among clinical, subclinical, subthreshold, and personality expressions of bipolarity (Akiskal et al., 1979a; Sass et al., 1993; Akiskal, 2001). Again, it is important to stress that although the spectrum concept is essential, there must be concern that the spectrum of bipolarity can become so far extended that it becomes theoretically and clinically meaningless (if not actually damaging, as would be the case with a diagnostic overinclusiveness resulting in the inappropriate diagnosis and treatment of individuals with intense normal variants of temperament).

The Akiskal and Pinto (1999) formulation acknowledging more subtle intermediary forms, a formulation indebted to the observations of many earlier clinicians and investigators, captures the dilemmas of the clinician and the researcher working within a spectrum model of bipolar illness from the most severe (mood-incongruent mania) to the least severe (hyperthymic temperament). Similar dilemmas are encountered when exploring the manic-depressive spectrum between bipolar disorder and unipolar depression.

Using both clinical and nonclinical populations of college students, Depue and colleagues developed a systematic approach to the evaluation of subsyndromal affective states, focusing particularly on bipolar forms. The touchstone of this series of studies was the development of the General Behavioral Inventory (GBI), a self-report measure of traits that can assess the pattern of cyclothymia over time (Depue et al., 1981; Depue and Klein, 1988). Each of its

73 items, drawn from clinical descriptions of hypomania and depression and focused on lability, incorporates the dimensions of intensity, duration, and frequency. (The GBI is described in more detail in Chapter 11.) GBI scores for depression are distributed across normal, cyclothymic, and bipolar-II populations; each group merges imperceptibly into the other, consistent with the concept of a spectrum.⁴⁰ These studies imply that the concept of a depressive spectrum applies equally to bipolar and unipolar depression, challenging the conventional wisdom that neurotic depression should be subsumed entirely in the unipolar spectrum.

Unfortunately, the cyclothymic scale introduced by Depue and colleagues did not command sufficient interest in the literature, conceivably because its system for assessing mood lability, intensity, and cyclicity was quite elaborate. A new instrument was subsequently developed to measure the broader temperamental domain of bipolarity (Akiskal et al., 1998b): the temperament scale of Memphis, Pisa, Paris, and San Diego (TEMPS), which, while lacking the psychometric sophistication and strong validating research base of the GBI, appears to be somewhat less unwieldy from a psychometric standpoint and represents the dominant tendency for each of the cyclothymic, hyperthymic, irritable, and depressive types.⁴¹

As noted earlier, and as elaborated in Chapter 2 on clinical description, Kraepelin described a “manic temperament,” which he originally termed “constitutional excitement.” The antithesis of the “depressive temperament,” the manic temperament, at its most severe, was defined as a handicapping condition marked by desultory, incoherent, and aimless thought; hasty and shallow judgment; restlessness; and exalted, careless, and confident mood. Kraepelin viewed the manic temperament as a “link in the long chain of manic-depressive dispositions,” which in its least severe form could still be considered normal.

Akiskal and colleagues (1979a) characterized—and psychometrically validated (Akiskal et al., 1998b)—the most discriminatory features of what they termed the “hyperthymic temperament,” representing the softest expression of Kraepelin’s manic type. Like cyclothymia, hyperthymia represents a trait and possibly a lifelong disposition, with a familial excess of bipolar disorder as compared with depressive states without bipolar temperaments (Cassano et al., 1992; Akiskal, 2001; Akiskal et al., 2005). Unlike the studies of Kagan and colleagues (see Chapter 10), however, these studies of temperament have not been carried out across the lifetime or in a prospective context, which limits our understanding of the relationship among measured “hyperthymia,” subsyndromal illness, and actual illness.

In his discussion of the manic spectrum based on cross-sectional observations, Klerman (1981) described a

continuum from normal happiness or joy through cyclothymic personality, nonpsychotic hypomania, and psychotic mania. It is clear, however, that this string of states does not reflect a spectrum of ever-increasing happiness and joy, since these pleasant emotions are replaced by qualitatively very different moods and sensations as one crosses the line from hypomania into mania. Klerman’s recommendation that the term “elations” be used to encompass the spectrum of mania emphasizes mood over other important features, such as energy level, activity, behavior, and cognition. As noted earlier, the terminology can be confusing. In Klerman’s spectrum, cyclothymic personality falls between normal happiness and hypomania. In DSM-IV, a diagnosis of cyclothymia requires hypomanic episodes. In this diagnostic system, cyclothymia is differentiated from bipolar-II major affective disorder on the basis of its less severe depressions, which do not meet criteria for major depressive disorder. Using elation as the criterion for the manic spectrum also is reminiscent of older formulations in which depression and mania were at opposite ends of a continuum, with normal in the middle. Such a continuum is quite limited as a model, primarily because it cannot account for mixed states, which, as discussed in Chapter 2, are quite common. Some believe it preferable to consider the depressive and manic spectra as independent and capable of interacting in a variety of combinations and permutations.⁴² It is interesting that in both the Endicott (1989) and the Angst and Gamma (2002) schema, the manic-depressive spectrum is dominated by depressive recurrences, with very mild and short hypomanias. This conception is in line with our view that recurrence and cyclicity are more fundamental than polarity, which in turn accords with Kraepelin’s nosologic position. We remain concerned, however, that relatively little research has been conducted on the continuum of manic states (Jamison, 2004), a concern we expressed in the first edition of this text.

As reviewed in Chapter 2, severe psychotic features, including mood incongruence, are extensively documented for bipolar patients in both the classical and the recent literature. The boundary between severe mania and schizobipolar disorder is not clear (see Chapter 3). Suffice it to say that new data appear to be consistent with the view that schizobipolar patients lie on a continuum with severe mania, whether one examines family history (Van Eerdewegh et al., 1987; Toni et al., 2001) or course (Cutting, 1990).

If we integrate the depressive and manic spectra, we can construct an overall spectrum of bipolar illness. At one end is cyclothymic personality; then cyclothymic disorder (bipolar, other in Dunner’s terms or md in Angst’s terms⁴³); followed by bipolar-II disorder (mD or bipolar disorder, not otherwise specified, in DSM-IV); then Md (often misdiagnosed as unipolar mania); and finally MD (i.e.,

bipolar-I), which is the core critical bipolar disorder.⁴⁴ Figure 1-1 illustrates this spectrum by displaying the mood variation characteristic of each subgroup. Note that in this spectrum, we implicitly consider mania to be more severe than depression, since the Md form is closer than mD (bipolar-II) to the severe end of the spectrum. Current international data indicate that much of the bipolar spectrum is in the midrealm (type II) and beyond.⁴⁵

As presented here, the spectra are only descriptive. They do not necessarily imply a progression, nor do they require that all these states share some unitary relationship. Individuals fitting the description of cyclothymic personality, for example, may have a family history or response to treatment unrelated to bipolar-I disorder. The data reviewed in this chapter suggest, however, that a large percentage of individuals with soft or subsyndromal states apparently analogous to bipolar disorder do indeed belong in the bipolar spectrum by virtue of their positive family history and their tendency to progress to full clinical disorder. While those on the soft end of the spectrum may not be bipolar in the formal sense of having a history of diagnosable mania or hypomania, many of them no doubt have a bipolar diathesis.

Once we move beyond the temperaments into cyclothymic disorder (described more fully in Chapter 2), the evidence argues compellingly for the inclusion of cyclothymic disorder in the bipolar spectrum. Cycles of mood and energy can continue indefinitely, constituting a mild form of bipolar illness, or they can progress to a more severe expression of the disorder, sometimes after years.

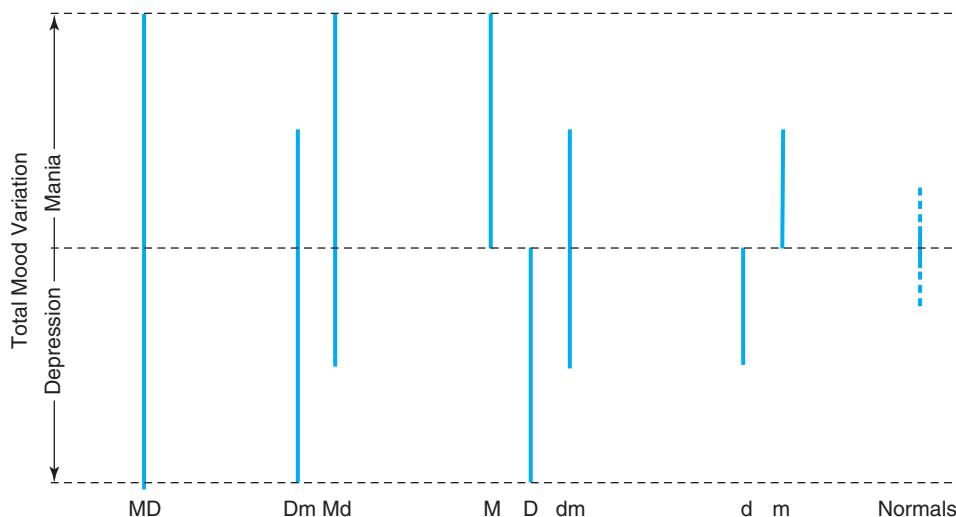

As noted in Chapter 2, Kraepelin assumed that cyclothymia is part of the bipolar spectrum, and modern investigators⁴⁶ have argued persuasively for its inclusion on

the basis of (1) family history data linking cyclothymia with the more severe forms of bipolar illness, (2) overlap and similarity of symptom patterns between cyclothymia and bipolar disorder, (3) comparability of rates for pharmacologically induced hypomania, and (4) the subsequent development of full syndromal illness in many patients initially diagnosed as cyclothymic. In some instances, cyclothymia can be regarded as a milder expression of bipolar illness and in others as a precursor to the full syndrome.

Some bipolar-II patients show considerable erratic “character” pathology (often referred to as “cluster B” or borderline—see Chapters 2 and 10), interepisode lability, and related problems of substance abuse. Conventional wisdom (e.g., DSM-IV) would suggest that an intrinsic association of these features with bipolar disorder is less convincing, on the assumption that such features are simply a consequence of the fact that bipolar-II patients often lead chaotic lives, have poor or unpredictable social support systems, and fail to adhere to medications.⁴⁷ Nonetheless, new findings from the French EPIDEP study, as described in Chapter 2, suggest that from a familial standpoint, these patients may be as bipolar as those with bipolar-II. Perugi and colleagues (1999, 2003) have proposed a common link among these cyclothymic traits, borderline personality, and atypical depression.

Criticism notwithstanding, the concept of a manic-depressive spectrum appears to be shaping a new paradigm, much of it extending into the domain of traditional depressive disorders. Indeed, whether one examines bipolar pedigrees (Gershon et al., 1982; Tsuang et al., 1985), offspring of bipolars (Akiskal et al., 1985), epidemiologic samples (Angst et al., 2003), or the microstructure of the course of bipolar-I and -II disorders (Judd et al., 2002, 2003b), bipolar illness is

Figure 1-1. Range of total mood variation by subgroup.

dominated by depressive symptomatology.⁴⁸ In this respect, bipolar-I and -II appear to be quite similar (Judd et al., 2003a). This is where a great deal of the disability associated with the illness appears to reside—in the subdepressive symptomatology between episodes (Altshuler et al., 2002). Given that the depressive dominance is found in epidemiologic samples and in pedigree and family studies, one cannot criticize the foregoing clinical studies on the basis of tertiary referral bias, by which the more depression-prone bipolar patients are retained in follow-up studies. As detailed in Chapter 2, the depressive phase of bipolar disorder and depressive presentations in clinical practice represent a highly important aspect of bipolarity.

The spectrum concept is not just a recent peculiarity of the clinical and research focus on soft bipolarity. As reviewed here and in Chapter 2, these concepts are ancient. Indeed, it has been suggested that all major mental disorders can perhaps best be characterized in spectrum models (Maser and Akiskal, 2002). As noted earlier, Baldessarini (2000) criticized the concept of a broad bipolar spectrum on methodological grounds, arguing that it risks diluting the concept of bipolar disorder, thereby reducing the rigor of contemporary research. We agree. It is true that most authors cited by Baldessarini as having made major contributions to the field (from Aretaeus on) endorsed a broad conceptualization of manic-depressive illness; as we noted earlier, however, “manic-depressive spectrum” denotes something different from “bipolar spectrum.”

While the more recently proposed soft forms of bipolarity make some clinical and intuitive sense to us, they still require considerably more research from a wider range of independent research groups focused on external validators, especially family history, treatment response, and long-term outcome. For the clinician dealing with individuals, deciding whether one is encountering one end of a normal range of behavior, a personality disorder, or manic-depressive illness requiring treatment remains a challenge.

CONCLUSIONS

The existence of the “softer” phenotypes on the fringes of classic or “hard” bipolar phenotypes that encroach into the territory of unipolar depression indicates the need for at least a partial return to the unitary Kraepelinian concept of manic-depressive illness. While some view the bipolar spectrum as the modern heir of this classic broader position, subsuming all conditions under the rubric of “bipolar” is a less than totally satisfactory way to emphasize the close relationship between bipolar illness and highly recurrent unipolar depression (many patients with the latter condition, after all, remain nonbipolar in the usual sense).

If our diagnostic systems were to return to the Kraepelinian position of taking recurrence as the first principle for organizing the affective disorders (as we propose in Chapter 3), one would not have to posit that all early-onset recurrent depressions are part of the bipolar spectrum. On the other hand, contemporary studies⁴⁹ of “depressive mixed states” appear to provide some empirical support for Kraepelin’s descriptions of “excited depression” and “depression with flight of ideas,” apparently representing those highly recurrent unipolar patients who, despite not having a history of manic or hypomanic episodes, may have enough manic-like features when depressed, as well as sufficient bipolarity in their family histories, to be considered part of the bipolar spectrum in the sense of having some bipolar diathesis. For conceptualizing the relationship between bipolar disorder *per se* and recurrent depressive disorders, however, we still prefer the Kraepelinian concept of manic-depressive illness because it is unitary; all recurrent affective illness is encompassed, although Kraepelin anticipated the later bipolar–unipolar subdivision. Indeed, while much future research needs to be conducted to fully validate the concept of a manic-depressive spectrum, the pendulum appears to have shifted distinctly in favor of the Kraepelinian position, which includes much of the domain of frequently recurrent depression under the broad manic-depressive rubric.

Finally, we should reiterate why the exploration of spectrum models of manic-depressive illness is so important. First, for the bipolar subgroup, validation of subsyndromal states will enhance research on genetic markers and modes of genetic transmission. Second, it will allow the identification of individuals potentially at risk for the development of full bipolar illness, opening up the possibility of trials of early interventions that could reduce the likelihood of progression. Lastly, the model of a manic-depressive spectrum increases clinicians’ awareness of the close relationship between bipolar illness and some forms of unipolar depression (an understanding that has been undermined by the structure of DSM-IV). It is only this awareness that can help the clinician avoid the all-too-common misdiagnosis of bipolar patients as unipolar, a mistake that can lead to the almost always ill-advised treatment decision, discussed in Chapter 19, of administering an antidepressant in the absence of a mood stabilizer.

NOTES

1. The authors acknowledge a deep intellectual debt to the great German psychiatrist Emil Kraepelin. Kraepelin, the son of an actor, was born in 1856 in Neustrelitz, near the Baltic Sea. His older brother Karl, a biology teacher, influenced Emil’s decision to become a doctor and an academician. Interested in

psychiatry while still at the Würzburg Medical School, Kraepelin, upon graduation in 1878, studied with the neuroanatomists Bernard von Gudden and P. E. Flechsig. He then turned to experimental psychophysiological research, under the tutelage of Wilhelm Wundt. He held psychiatric hospital appointments in Munich, Leibus, and Dresden. In 1886, he became professor of psychiatry in Dorpat, then moved to the same position in Heidelberg in 1890 and to Munich in 1904 [or 1903?]. In 1922, he retired from teaching and became head of the Research Institute of Psychiatry in Munich.

According to Alexander and Selesnick (1966), Kraepelin's training, personality, and dedication were well suited to the task of classifying and generalizing the myriad clinical observations made during the nineteenth century: "He learned early to respect authority, order, and organization.... "Imperial German psychiatry" was said to have gained its prominence under the "chancellorship" of Kraepelin, one of Bismarck's admirers" (pp. 162–163). As Bismarck unified Germany, Kraepelin brought order to the balkanized psychiatry of the turn of the century. The first edition of his textbook, which he continued to revise throughout his life, was published in 1883. In succeeding editions, he refined and expanded the textbook from the brief outline of the first edition to the 2,425 pages of the ninth edition, published in 1927, a year after his death. The textbook was notable for its division of major psychiatric illness into two categories and for its emphasis on prognosis. The third and fourth parts of the eighth edition, covering manic-depressive "insanity" and paranoia, were published separately in 1921, and it is that monograph that is cited throughout this book.

Zilboorg (1941), from his psychoanalytical perspective, summarized the personal observations of Kraepelin from those who knew him personally:

[They] tell of his rather pleasant, responsive personality, of his tactful ability in bringing people together to work as an organized group, and of his great gifts as a teacher; yet it is curious that his scientific personality was so very detached, almost distant from the inner life of the patient. To Kraepelin a mentally sick person seems to have been a collection of symptoms. He was a true son of the great, energetic, and creative age that was interested greatly in humanity but comparatively little in man. Perhaps this trait in Kraepelin as a psychiatrist, which today would be considered a defect, was the very characteristic which helped rather than hindered him in the creation of his great system and school. He was able to collect and to study thousands of case histories, covering not only the story of each illness, but the history of each patient's life before the illness and a follow-up history of his life after he left the hospital. Dealing with such large masses of data, Kraepelin was able to sort out everything these many individuals had in common, leaving out of consideration the purely individual data. He thus arrived at an excellent general picture, at a unique perspective of a mental illness as a whole. But he seems to have been almost unaware that in his careful study he lost the individual. (p. 452)

Berrios and Hauser (1988) took issue with this assessment, noting the "great depth and beauty" of Kraepelin's late

conceptual writing. They quoted from a 1920 work: "If these observations approximate the truth we will have to look for the key to the understanding of the clinical picture primarily in characteristics of the individual patient . . . his expectations play a decisive role."

2. For the material in this section we are indebted to the historians in our field, especially to Jackson (1986) and Roccagliata (1986) for their extensive scholarship. Whitwell (1936), in his modestly titled *Historical Notes on Psychiatry*, provided translations of ancient manuscripts and insights into the apparent manic-depressive symptoms of literary and historical figures, such as Orestes, Saul, and Herod the Great. Although not as sharply focused on affective illness, other sources have proved valuable in understanding the historical context in general medicine and psychiatry; they include Ackermann (1959, 1982), Zilboorg (1941), Alexander and Selesnick (1966), and Wightman (1971).
3. Medical historians believe that the works attributed to Hippocrates probably represent the work of his school. According to Ackermann (1982, p. 55), for example:

From fifty to seventy books were later attributed to Hippocrates, and in the third century B.C. they were collected in Alexandria into the *Corpus Hippocraticum*. It is not known which of these books, if any, were actually written by the great physician. As a matter of fact, none of them contains the ideas attributed to him in the writings of Plato and Menon.

4. Quoted by Whitwell (1936, p. 212) from Pratensis Jason: *De cerebri morbis* (Basil), 1549.
5. According to Jackson (1986, p. 100), Marsilius Ficinus (Marsilio Ficino) was a fifteenth-century philosopher, physician, and priest who revitalized Aristotle's views "with far-reaching effects on his own and later times."
6. Despite the presence of schizophrenic-like symptoms during the manic episodes, the diagnosis of manic-depressive illness was confirmed on follow-up. Demographic data suggested that the patients in this study were like manic-depressive patients in other studies in relapse frequency, duration of illness, and other features.
7. Quoted by Jackson (1986, p. 263) from Baillarger, 1854, p. 352.
8. Quoted by Jackson (1986, p. 268) from Ritti, A.: "Circular insanity." In *A Dictionary of Psychological Medicine Giving the Definition, Etymology and Synonyms of Terms Used in Medical Psychology, with the Symptoms, Treatment and Pathology of Insanity and the Law of Lunacy in Great Britain and Ireland*, edited by D. Hack Tuke, 2 vols. (Philadelphia: P. Blakiston), 1892, p. 214.
9. Some psychoanalytic writers implied that different phases of manic-depressive illness were linked through some underlying mechanism. Prominent here is the conception of mania as a defense against depression (see Chapter 11). This analytical formulation, reminiscent of the earliest observations that mania grew out of melancholia, could be said to have anticipated the current continuum model.
10. Some investigators (e.g., Koukopoulos et al., 1983; Akiskal and Akiskal, 1988; Cassano et al., 1988) focused on the opposite temperaments—depressive and hyperthymic—and proposed that a fundamental characteristic of bipolarity is the shift from one temperamental state into the opposite

- extreme in the form of an episode. Thus, depressive temperaments are vulnerable to a swing into hypomania or mania, whereas those with hyperthymic temperaments are likely to swing into depressions. According to Akiskal and colleagues (1998b), such propensities may serve as the basis for mixed states (see Chapter 2).
11. The very existence of depressive mixed states (isolated intradepressive "manic" symptoms) argued for a continuum, which is consistent with the contemporary work of Benazzi and Akiskal (2001) and Sato and colleagues (2003).
 12. Although not incompatible with Kraepelin's descriptions of manic-depressive illness, Meyer's approach implied a different conceptual framework. The Meyerians, although allowing for the operation of biological and genetic factors, understood them as part of an individual's vulnerability to specific psychological and social influences. This perspective was symbolized by the rubric "manic-depressive reaction" in the first official diagnostic manual of the American Psychiatric Association, published in 1952.
 13. This would apply most clearly to German and British psychiatry, perhaps less so to French psychiatry (Leff, 1977).
 14. This emphasis on presenting episode rather than course was somewhat ironic, because Meyer's own writings emphasized a longitudinal perspective.
 15. *Primary* is defined as depression in the absence of any preexisting or antecedent psychiatric or medical disorder.
 16. At any rate, from a clinical and epidemiologic standpoint, current data indicate that the foregoing depressive dichotomies are best regarded as part of a depressive spectrum (Judd and Akiskal, 2000).
 17. To Bleuler, a patient was predominantly schizophrenic or predominantly manic-depressive. Patients were distributed all along this spectrum, and an individual patient could be at different points on the spectrum at different times.
 18. Compared with unipolar patients, bipolar depressed patients were reported to have lower ratings of anxiety, anger, and physical complaints (Beigel and Murphy, 1971b); more psychomotor retardation (Beigel and Murphy, 1971b; Himmelhoch et al., 1972; Kotin and Goodwin, 1972; Dunner et al., 1976a; Katz et al., 1982); lower levels of measured physical activity (Kupfer et al., 1974); and more total sleep time (Hartmann, 1968; Kupfer et al., 1972; Duncan et al., 1979).
 19. Winokur divided his primary unipolar patients (none of whom had a family history of mania) into familial pure depressive disease (FPDD), sporadic pure depressive disease (SPDD), and depression spectrum disease (DSD). (*Primary* was defined as depression in the absence of any preexisting or antecedent psychiatric or medical disorder.) The two pure types had no other preceding psychiatric diagnoses and no alcoholism among first-degree relatives. The distinction between them was that FPDD patients had a first-degree relative with primary depression, whereas SPDD patients did not. DSD patients were those with alcoholism or antisocial personality among first-degree (male) relatives; they were predominantly female patients with early onset. Winokur (1980) suggested that genetically, the FPDD subtype was closely related to bipolar illness.
 20. Akiskal, 1981, 1983a, 1998; Benazzi, 1997, 2001, 2003; Akiskal and Pinto, 1999; Angst and Marneros, 2001; Benazzi and Akiskal, 2001, 2003; Marneros, 2001; Hantouche et al., 2003b.
 21. Some of the differences among individual manic-depressive patients reflect differences in the illness per se, whereas others reflect the interaction of the illness with individual characteristics, some of which certainly involve genetic differences unrelated to manic-depressive illness. The reactive-endogenous and neurotic-psychotic dichotomies (or spectra) should not be taken simply as a reflection of differential severity, that is, from mild to severe in consequences for the patient. As observed by Lewis (1936, p. 998):
- It may be said, simply, that severe emotional upsets ordinarily tend to subside, but that mild emotional states, when often provoked or long maintained, tend to persist, as it were, autonomously. Hence the paradox that a gross blatant psychosis may do less damage in the long run than some meager neurotic incubus: a dramatic attack of mania or melancholia, with delusions, wasting, hallucinations, wild excitement and other alarms, may have far less effect on the course of a man's life than some deceptively mild affective illness which goes on so long that it becomes inveterate. The former comes as a catastrophe, and when it has passed the patient takes up his life again, active, cheerful, normal in every way, while with the latter he may never get rid of his burden.
22. Akiskal et al., 1977, 1979a; Depue et al., 1981; Egeland and Hotstetter, 1983; Akiskal and Pinto, 1999; Angst and Marneros, 2001; Marneros, 2001; Ghaemi et al., 2002.
 23. It is possible that the high bipolar/unipolar ratio in Egeland's Amish data reflects special genetic factors limited to that population. As noted below, however, Angst's (1978) group also found a 1:1 ratio of bipolar to unipolar illness when the sample was followed for many years and hypomania was ascertained.
 24. Ghaemi et al., 1999; Goldberg et al., 2001; Dilsaver and Akiskal, 2005; Hantouche and Akiskal, 2005; Rybakowski et al., 2005; Sharma et al., 2005; Smith et al., 2005.
 25. Some bipolar-unipolar differences become more clear when bipolar-II is deleted from the comparison.
 26. In their second study, however, Abrams and Taylor (1979) found a higher morbid risk for unipolar depression in unipolar manic patients compared with bipolar patients.
 27. The method relied on reports of the manic patients themselves at or near admission, presumably while they were still ill. Davenport and colleagues (1979) at NIMH showed (as common sense would suggest) that manic patients report substantially fewer past depressive episodes than their families remember.
 28. Akiskal et al., 1995, 2005; Coryell et al., 1995; Goldberg et al., 2001; Angst et al., 2005.
 29. Benazzi and Akiskal, 2001; Maj et al., 2003; Akiskal and Benazzi, 2004; Biondi et al., 2005; Sato et al., 2005; Serretti and Olgiati, 2005.
 30. Even in the study by Katz and colleagues (1982), which employed prior screening by the Research Diagnostic Criteria (RDC) (see Chapter 3), greater heterogeneity in the unipolar group is plausible since the research criteria allowed for sleep and appetite changes in either direction. In fact, Kupfer and colleagues (1975), examining unipolar depressed patients with a variety of clinical and personality measures, described a subgroup with symptoms similar to those of

- bipolar depression. Like bipolar patients, these unipolar depressed patients were more retarded, had lower levels of anxiety, and ate and slept more. They, like the bipolar patients, had been hospitalized more often in the past than the unipolar patients, although the incidence of past depressive episodes, suicide attempts, and substance abuse was similar for all the patients. Kupfer suggested that this subgroup of unipolar patients may share some common biological and pharmacological response characteristics with bipolar patients. Overlapping with this grouping are the unipolar patients described by Winokur and Clayton (1967) as having familial pure depressive disease and by Mendels (1976) as "pseudounipolar." In a similar vein, Benazzi (2003) described a group of early-onset unipolar patients who, unlike later-onset patients, were very similar to his bipolar-II group.
31. Ebert et al., 1993; Perugi et al., 1998a; Serretti et al., 1998; Akiskal et al., 2000; Agosti and Stewart, 2001; Mitchell et al., 2001; Angst et al., 2002; Benazzi, 2003; Ghaemi et al., 2004; Akiskal and Benazzi, 2005; Hantouche and Akiskal, 2005.
 32. Horwath et al., 1992; Robertson et al., 1996; Levitan 1997; Posternak and Zimmerman, 2002; Sullivan et al., 2002.
 33. The negative studies generally involved small and/or unbalanced samples.
 34. The DSM IV criteria were modified to require only 2 days for hypomania.
 35. Other features that have been reported to differentiate unipolar from bipolar-II patients are irritability and agitation, symptoms that overlap with the concept of depressive "mixed states."
 36. Unpublished data cited by Dunner (1987).
 37. In the Cassano et al. study (2004), recurrent unipolar patients endorsed a substantial number of manic/hypomanic symptoms over their lifetimes.
 38. Hantouche and colleagues (2003b) and Akiskal and colleagues (2003b) have argued for the existence of such a bipolar-II variant on the basis of clinical, psychometric, and temperamental characteristics; further, the bipolar nature of the more unstable bipolar-II ½ patients is suggested by the observation that the rates of familial bipolarity in bipolar-II and bipolar-II ½ groups are highly similar.
 39. Even within categories, variation always occurs. Cantor and Genero (1986, p. 236) pointed out that the "natural" categories into which human beings organize their perceptual experiences do not have "obvious necessary and sufficient criterial properties, so that boundaries between closely related categories are ill-defined." People find it extraordinarily difficult or impossible to specify criteria for common object categories, such as furniture, birds, fruit, or clothing. Instead, they identify correlated features that imply a continuum of category membership, ranging from a prototype (an apple is a very typical fruit, for example) to a more atypical member (a tomato is a fruit often thought to be a vegetable). Assigning such atypical members to one category or another can be difficult, and the overlap of characteristic features from one category to another also "runs counter to the intuitive notion of well-defined, orthogonal categories with clearly demarcated boundaries."
 40. With appropriate cut-off scores, the GBI can be used for case identification in either nonclinical or clinical populations. It may be particularly useful in family studies. For example, evaluated against clinically determined DSM-III diagnoses, the GBI was found to have a sensitivity of 90 percent and a specificity of 98 percent when used with adolescent offspring of bipolar-I parents and parents with nonaffective major psychiatric diagnoses (Klein et al., 1986b). Originally structured to identify only bipolar affective states, the GBI has been broadened to apply to the separation of bipolar from unipolar subjects with considerable success (Depue et al., 1989).
 41. TEMPS exists in an interview format (TEMPS-I) (Akiskal et al., 1998a; Placidi et al., 1998) and a self-rated autoquestionnaire version (TEMPS-A) (Akiskal and Akiskal, 2005). The cutoffs, determined by extreme distributions based on z-scores (corresponding to +2 standard deviations), represent individuals at putative risk for clinical bipolar disorder. Akiskal (1995) actually proposes that temperaments can both provoke and react to life events, thereby leading to complex life situations, emotional arousal, and, eventually, affective episodes. This viewpoint is supported by data on juvenile subjects indicating that cyclothymic reactivity is associated with stress, anxiety, and behavioral disturbances (Signoretta et al., 2005). Only new research will reveal the extent to which the promise of TEMPS-A will be justified. Such research is in progress.
 42. Joffe et al., 1999; Angst and Marneros, 2001; Angst et al., 2003.
 43. The DSM-III-R category bipolar disorder—not otherwise specified, was originally meant to apply to bipolar-II patients; however, many such patients meet DSM-III-R criteria for bipolar major affective disorder, given that the criteria for major depression are broad enough to encompass a wide range of severity. On the other hand, cyclothymia in DSM-III-R reflects a milder state, referred to by Dunner as "cyclothymic personality," that is also milder than the cyclothymia described by Akiskal.
 44. More recently, using nonclinical community samples, Angst (1991) identified recurrent brief depression (RBD) or recurrent brief hypomania (RBM), each with a minimum of 12 episodes a year. He suggested that these are part of the bipolar spectrum.
 45. Akiskal and Mallya, 1987; Cassano et al., 1992; Simpson et al., 1993; Benazzi, 1997; Manning et al., 1997; Hantouche et al., 1998; Angst and Gamma, 2002; Mainia et al., 2002.
 46. Akiskal et al., 1977, 1978, 1979a, 1983: Depue et al., 1978; Waters, 1979; Akiskal, 1981, 1983a,b.
 47. As detailed in Chapter 21, nonadherence is a major problem for both bipolar-I and bipolar-II patients, although the factors that contribute to it may be different in each group.
 48. This predominance of depression in bipolar disorder might be reconciled with the proposal of Koukopoulos and others that mania represents the underlying state in bipolar disorder by noting that many depressions in the bipolar spectrum involve activation and other manic-like symptoms.
 49. The widespread use of effective pharmacological treatments, along with earlier recognition, probably accounts for the fact that contemporary studies of manic-depressive illness are more dependent on outpatient samples, whereas earlier studies were predominantly of inpatients.

[N]otwithstanding manifold external differences certain *common fundamental features* yet recur in all the morbid states mentioned. Along with changing symptoms, which may appear temporarily or may be completely absent, we meet in all forms of manic-depressive insanity a quite definite, narrow group of disorders, though certainly of very varied character and composition. Without any one of them being absolutely characteristic of the malady, still in association they impress a uniform stamp on all the multiform clinical states.

—Emil Kraepelin (1921, p. 2)

To understand manic-depressive illness—to diagnose it accurately and to treat it effectively—requires close familiarity with what Kraepelin calls “the common fundamental features” of the disease. This chapter gives a general clinical description of hypomania and mania, bipolar depression and recurrent unipolar depression, and mixed states, as well as the cyclothymic and other temperamental traits that often underlie these states. Clinical description is approached from three perspectives: that of uniquely experienced classic clinical observers, such as Kraepelin; that of manic-depressive patients themselves (especially the bipolar subgroup); and that of contemporary investigators who have conducted data-based clinical studies. By combining these perspectives (at the unavoidable cost of some redundancy), we hope to capitalize on the descriptive and heuristic strengths of each while avoiding the limitations of any one alone.

We have chosen to cite extensively the classic clinical literature, most of which predates the modern treatment era. We have done this for several reasons. First, descriptions found in these sources are powerful and have not been surpassed; Kraepelin, particularly, remains without peer. Second, the lack of effective treatments and the provision of residential care for patients over many years, often lifetimes, allowed prepharmacotherapy clinicians to observe the natural course of the illness in all its severity. Third, modern diagnostic systems, although vital in advancing treatment and research, have resulted in less emphasis on clinical description and proportionately more emphasis on quantifications susceptible to statistical analysis, employing symptom checklists, rating scales, and diagnostic algorithms. Regrettably, few psychiatric residents, graduate students, scientists, and clinicians now read Kraepelin and Bleuler. Fewer still have read Aretaeus,

Griesinger, Weygandt, Falret, Jaspers, Baillarger, Campbell, or Henderson and Gillespie. We believe the clinical writings of these classic authors provide both historical perspective and a singular understanding of the nature of manic-depressive illness.

The accounts of manic-depressive (predominantly bipolar) patients presented in this chapter provide the personal dimension missing from clinicians' and researchers' reports, however astute their observations. These descriptions, which vary widely, reflect both the nature of the illness and the nature of the people suffering from it. In the scientific literature, relatively scant attention is paid to firsthand accounts of manic-depressive illness; rather, the emphasis is on the use of objective observer ratings as a basis for studying and describing major affective disorders, including their psychotic variants. One reason for this virtual exclusion of experiential information is that firsthand accounts are subjective and necessarily biased. Thus, patients may remember with clarity some aspects of their disorder and forget or ignore others; they may verbalize what is easiest to describe and say little about aspects less readily articulated. They may relate only those experiences most novel to them, thus giving disproportionate weight to out-of-the-ordinary events, or they may describe what they think the observer wishes to hear. In addition, moods can radically alter memory and perception, resulting in state-dependent distortions. Finally, those individuals most capable of discussing their experiences in an articulate manner may belong, by virtue of this fact, to a more introspective and less representative group.

These are legitimate concerns for anyone desiring systematic, clear-cut, and reducible data. Clinicians have long been aware, however, that experiential accounts are vital to an understanding of individuals and their illnesses.

Likewise, the heuristic value of hypotheses generated from patients' descriptions of their feelings, thoughts, and behaviors is well established. Good clinical management of manic-depressive illness, both pharmacological and psychotherapeutic, depends upon recognizing the concerns of patients and the consequences (both negative and positive) the illness has for them. Descriptive information gathered from patients also has been important in clinical research, such as that describing the switch process (Bunney et al., 1972a,b,c), unraveling the paradoxical effects of lithium as both antidepressant and antimanic agent (Goodwin et al., 1969), and elucidating the occasional positive qualities of manic states (Jamison, 1993, 2004; Jamison et al., 1980), as well as the clinically related difficulties some patients have in adhering to a treatment regimen (see Chapter 21).

There are strong limitations on the effective use of language to describe unusual events, such as extreme moods, gross cognitive and perceptual distortions, and both subtle and profound changes in sensory experience. Despite the shortcomings of language and the highly personalized vocabulary often used by patients in describing their manic-depressive illness, certain words, phrases, and metaphors are chosen time and again, forming a common matrix of experiences. Often these images center on nature, weather, the day-night cycle, and the seasons; often, too, they convey unpredictability, periodicity, violence, tempestuousness, or a bleak dearth of feelings. Religious themes and mystical experiences pervade the language, conveying an extraordinary degree and type of experience—beyond control, comprehension, or adequate description.

At a narrower conceptual level, certain individual words and phrases are heard repeatedly by clinicians treating patients with manic-depressive illness. Depression is associated with common language fragments. The patient is "slowed down," "in a fog," or "exhausted" and describes life as having "lost its color," "dull, flat, and dreary." Everything is "hopeless," "heavy," "too much of an effort," "drab, colorless, pointless." Life is a "burden"; there is no point to living; all is meaningless. Hypomania and mania elicit descriptions of a more vivacious and energetic kind. Life is "effortless," "charged with intensity," and filled with special meaning. The patient is "upbeat," "racing," "full of energy," "speeded up," "wired," "hyper," "high as a kite," "moving in the fast lane," "ecstatic," "flying." Other people are described as "too slow" and unable to "keep up."

Clinical descriptions derived from data-based studies compensate, in part, for the selective attention of both clinicians and patients. They provide a more objective view of the frequency and character of symptoms in manic-depressive illness. In selecting such studies for review in this chapter, we have to some extent emphasized manic states, partly because differential diagnosis can be prob-

lematic in mania (see Chapter 3), and partly because more systematic studies of symptoms and their syndromic profiles have been carried out on mania than on bipolar depression, recurrent unipolar depression, mixed states, or cyclothymia. Moreover, we agree with Koukopoulos (2005) and those before him (Pinel, 1801; Heinroth, 1818; Griesinger, 1845) that mania is the fundamental clinical state in bipolar disorder.

In the first edition of this volume, we noted the relative scarcity of data-based studies of bipolar depression and mixed states as a cause for both surprise and concern. This was in contrast to an exceedingly large general literature on depression, one that seldom differentiated bipolar depression from the many nonbipolar forms. Fortunately, there has been a proliferation of studies of both bipolar depression and mixed states in recent years, and their inclusion here is an important addition to the first edition. Older data-based clinical studies, although using standardized diagnostic criteria and making the necessary distinctions between bipolar and unipolar depression, tended not to focus on clinical patterns of bipolar depression but on such issues as psychotic versus nonpsychotic status. Typically, bipolar patients were excluded from these samples. There is next to no research on the nature of depressions in unipolar patients with highly recurrent illness, which were included in Kraepelin's concept of manic-depressive illness, and how they may differ from that of depressions in patients with the less recurrent unipolar forms.

The same caveats about methodology that apply to earlier research findings on manic-depressive illness in general, particularly the bipolar form, apply as well to the older studies discussed in this chapter. First, diagnostic criteria, especially for mixed states, varied greatly across studies. Second, investigators often failed to specify the stage, severity, or duration of the affective state. Third, measurement techniques lacked sophistication; there was a tendency, for example, to measure only the presence or absence of a symptom rather than its intensity, constancy, and duration. Other methodological problems were widespread. The pioneering clinical study of mania, bipolar depression, and mixed states conducted by Winokur and colleagues (1969), for example, although an invaluable contribution to the literature, involved the analysis of data based on multiple episodes (e.g., 100 episodes of mania in 61 patients). To the extent that a given individual showed a similar symptom pattern from one affective episode to another, a contaminating element was introduced. Early clinical studies, while often methodologically flawed, were nonetheless important for the questions they raised and the patients they studied, individuals whose illnesses were generally uncomplicated by changes in clinical presentation due to treatment, especially antidepressant use. We

have included the findings of many of these pre-1990 studies because of their historical as well as clinical and scientific interest.

With greater attention to clinical research on bipolar disorder since 1990, the limitations of the older literature have to some extent been addressed. For instance, the twin French collaborative studies of the clinical epidemiology of mania (EPIMAN) and bipolar depression (EPIDEP) have focused on carefully measured clinical nuances of manic, mixed, and bipolar-II disorders, as well as their temperamental foundations (e.g., Hantouche et al., 1998). *Bipolarity beyond Classic Mania*, an extensive examination of soft bipolar variants (Akiskal, 1999), and a European monograph entitled *Bipolar Disorder One Hundred Years after Manic Depressive Illness* (Marneros and Angst, 2000) were published to pay tribute to—and extend—Kraepelin's clinical vision and methodology. Another trans-Atlantic monograph, *Bipolar Disorders*, focuses on mixed, atypical, and rapid-cycling bipolar disorder (Marneros and Goodwin, 2003). Finally, an entire issue of the *Journal of Affective Disorders* devoted to “soft” and “hard” phenotypes within the bipolar spectrum was published in 2003. The data-based contributions of this monograph came from the United States, France, Italy, Switzerland, and Germany, countries where clinical research is currently being conducted on the phenomenology of the broadly conceived manic-depressive spectrum.

In this chapter we address only those aspects of symptom presentation relevant to clinical description. These include the observable patterns of mood, energy, sleep, thought, and behavior typically used in clinical diagnosis. (Detailed discussion of related topics is found in Chapters 1, 3, 9, 10, and 15.) Before proceeding, we emphasize that while many generalizations can be drawn from clinical descriptions of manic-depressive illness, individuals are bound to differ widely with regard to an illness that is at once genetically based, environmentally influenced, and psychologically expressed. Kraepelin (1921), although committed to the idea and practice of classification, also was sensitive to the infinite capacity for individual expression in the illness. Referring to the subclassifications proposed by earlier writers, he concluded (p. 139): “I am convinced that that kind of effort . . . must of necessity wreck on the irregularity of the disease.” The clinical differences seen across individuals can be striking (as are, more often, the similarities), but it remains unclear to what extent one episode resembles another in a given individual. Anecdotal accounts, along with several studies discussed later, support some constancy of clinical presentation, including the presence or absence of melancholic and psychotic features, in the same patient across time.¹

Finally, although much of the clinical description presented here emphasizes differences among clinical states, we stress from the outset that the coexistence of affective states is fundamental to bipolar disorder and that oscillation into, out of, and within the various forms and states of manic-depressive illness is, in its own right, a hallmark of the disease. As we shall see, “pure” affective states are rare: mania is often complicated by depressive symptoms, and conversely, depression, especially the bipolar form, usually is accompanied by at least one or more symptoms of mania. Bauer and colleagues (2005), for example, found in their study of 441 bipolar patients that clinically significant depressive symptoms occurred in 94 percent of those with mania or hypomania, while 70 percent of patients in a depressive episode had clinically significant manic symptomatology. Thus, far from being a “bipolar” disorder, with the assumption of clinically opposite states, the illness is characterized by co-occurrence of manic and depressive symptoms more often than not. Bauer and colleagues (2005) also found that depressive and manic symptoms were positively, not inversely, correlated, suggesting that “a dimensional conceptualization of mood state in this disorder is more valid than the categorical conceptualization presumed by both the DSM [*Diagnostic and Statistical Manual*] and ICD [*International Classification of Diseases*]” (p. 88).

Patterns of manic and depressive symptoms clearly have a cyclic quality, but their overlapping, transitional, and fluctuating aspects are enormously important in describing and understanding the illness overall. Thus, Kraepelin (1921, p. 54) wrote:

The delimitation of the individual clinical forms of the malady is in many respects wholly artificial and arbitrary. Observation not only reveals the occurrence of gradual transitions between all the various states, but it also shows that within the shortest space of time the same morbid case may pass through most manifold transformations.

Campbell (1953, pp. 112–113) emphasized this fundamentally dynamic nature of bipolar illness by comparing the illness to a film:

The fluidity, change, and movement of the emotions, as they occur in the ever-changing cyclothymic process, may be compared to the pictures of a cinema, as contrasted with a “still” photograph. Indeed, the psychiatrist, observing a manic-depressive patient for the first time, or as he undergoes one of the many undulations in mood, from melancholia to euphoria or from hypomania to a depression, is reminded of the experience of entering a movie during the middle of the story. No matter where one takes up the plot, the story tends to swing around again to the

point where it started. The examiner may observe the manic-depressive patient first in a manic reaction, later in a depression, but eventually, if followed long enough, in another manic reaction. Like the movie, which is a continuous but constantly changing process, the cyclothymic process is also continuous even though for the moment the observer is attracted by the immediate cross-section view. This conception of change, or constant undulation of the emotions, is much more accurate than a static appraisal.

In the following sections, we address in turn manic, depressive, and mixed states and cyclothymia. For each we present clinical description in three general areas of functioning: mood, cognition and perception, and activity and behavior.

MANIC STATES

Classic Clinical Descriptions

Manic states are typically characterized by heightened mood, more and faster speech, quicker thought, brisker physical and mental activity levels, greater energy (with a corresponding decreased need for sleep), irritability, perceptual acuity, paranoia, heightened sexuality, and impulsivity. The degree, type, and chronicity of these cognitive, perceptual, and behavioral changes determine the major subclassification of mania, namely hypomania or mania. In hypomania, the above changes are generally moderate and may or may not result in serious problems for the individual experiencing them. In more intense episodes, however, they profoundly disrupt the lives of patients, their families, and society.

Mood

Mood in hypomania is usually ebullient, self-confident, and exalted, but with an irritable underpinning. Most early clinical descriptions emphasized the elevated, volatile, and fluctuating nature of hypomanic mood. Campbell (1953, pp. 151, 153) described its euphoric aspect:

Associated with the euphoria there is a genuine feeling of well-being, mentally and physically, a feeling of happiness and exhilaration which transports the individual into a new world of unlimited ideas and possibilities. . . . When a 19-year-old [hypo]manic was advised that he was indeed ill, he replied, "if I'm ill, this is the most wonderful illness I ever had."

Kraepelin (1921, p. 56) likewise described the euphoric aspect of hypomanic mood, but also emphasized the integral quick changes, irritability, and extreme volatility:

Mood is predominantly exalted and cheerful, influenced by the feeling of heightened capacity for work. The patient is in imperturbable good temper, sure of success, "courageous," feels happy and merry, not rarely overflowingly so. . . . On the other hand there often exists a great emotional irritability. The patient is dissatisfied, intolerant, fault-finding. . . . he becomes pretentious, positive, regardless, impertinent and even rough, when he comes up against opposition to his wishes and inclinations; trifling external occasions may bring about extremely violent outbursts of rage.

Mood in acute mania is not well described by the classic writers, perhaps because extreme changes in cognition and behavior are more clearly observable than subjective mood states. Two thousand years ago, however, Aretaeus of Cappadocia noted that those who are manic are gay, active, and expansive. They are naturally joyous; they laugh and they joke: "they show off in public with crowned heads as if they were returning victorious from the games; sometimes they laugh and dance all day and all night" (quoted in Roccatagliata, 1986, pp. 230–231). Kraepelin (1921, p. 63), writing centuries later, agreed, but stressed the instability of the manic mood:

Mood is unrestrained, merry, exultant, occasionally visionary or pompous, but always subject to frequent variation, easily changing to irritability and irascibility or even to lamentation and weeping.

Jaspers (1997, p. 596; first published in 1913) emphasized the essential liveliness of mood and behavior in *pure mania*, making the distinction, as Kraepelin had, between pure and mixed manic states:

The feeling of delight in life is accompanied by an increase in instinctual activities: increased sexuality, increased desire to move about; pressure of talk and pressure of activity which will mount from mere vividness of gesture to states of agitated excitement. The psychic activity characterized by flight of ideas lends an initial liveliness to everything undertaken but it lacks staying-power and is changeable. All intruding stimuli and any new possibility will distract the patient's attention. The massive associations at his disposal come spontaneously and uncalled for. They make him witty and sparkling; they also make it impossible for him to maintain any determining tendency and render him at the same time superficial and confused.

Cognition and Perception

Cognition and perception, especially the former, are strongly altered in hypomania. Falret (1854, cited in Sedler, 1983) wrote that "profusion of ideas [in manic states] is prodigious," and most early clinicians emphasized that, to

a point, associational fluency is furthered by mild hypomania. Bleuler (1924, pp. 466, 468), for example, commented that thought remains relatively intact in the less severe forms of mania:

The thinking of the manic is flighty. He jumps by by-paths from one subject to another, and cannot adhere to anything. With this the ideas run along very easily and involuntarily, even so freely that it may be felt as unpleasant by the patient. . . . Because of the more rapid flow of ideas, and especially because of the falling off of inhibitions, artistic activities are facilitated even though something worth while is produced only in very mild cases and when the patient is otherwise talented in this direction. The heightened sensibilities naturally have the effect of furthering this.

Tuke (1892, p. 765), in his *Dictionary of Psychological Medicine*, described the quickened senses so many manic patients appear to have:

Increased acuity in the perception of sense impressions certainly exists. Attention is lively and sharp though entirely unstable. The acute maniac appears to see and hear better than a sane person because every impression tells upon him. . . . Everything attracts his notice.

The filling of the mind with an enormous number of sense impressions, the blurring as it were of the mental canvas by the superposition of a crowd of details . . . account in a great degree for the confusion of memory which is one of the ordinary phenomena of mania. . . . Objects seen appear to serve chiefly as the starting-point of trains of ideas which change rapidly with slight changes in the visual surroundings.

Thinking becomes fragmented and often psychotic in acute mania. Coherence gives way to incoherence; rapid thinking proceeds to racing and disjointed thinking; distractibility becomes all-pervasive. Paranoid and grandiose delusions are common, as are illusions and hallucinations. In Kraepelin's (1921, p. 62) description, patients

show themselves sensible and approximately oriented, but extraordinarily distractible in perception and train of thought. Sometimes it is quite impossible to get into communication with them; as a rule, however, they understand emphatic speech, and even give isolated suitable replies, but they are influenced by every new impression; they digress, they go into endless details.

Kraepelin (pp. 68–69) went on to describe the progressively worsening clinical state of *delusional mania*:

The Delusions and Hallucinations, which in the morbid states hitherto described are fugitive or merely indicated, acquire in a series of cases an elaboration which calls to

mind paranoid attacks. His surroundings appear to the patient to be changed; he sees St. Augustine, Joseph with the shepherd's crook, the angel Gabriel, apostles, the Kaiser, spirits, God, the Virgin Mary.² . . . The delusions, which forthwith emerge, move very frequently on religious territory. . . . He preaches in the name of the holy God, will reveal great things to the world, gives commands according to the divine will.

Benjamin Rush (1812, pp. 244–245), author of the first major psychiatric treatise published in the United States, gave a particularly graphic account of the grandiose and “disjointed or debilitated faculties of the mind” in an acutely delusional manic patient:

The following short extract, taken down by Mr. Coats, from the constant conversation of a young man of a good education, and respectable connections, now deranged in the Pennsylvania Hospital, will exhibit an affecting specimen of this disjointed state of the mind, and of the incoherence of its operations. “No man can serve two masters. I am king Philip of Macedonia, lawful son of Mary queen of Scots, born in Philadelphia. I have been happy enough ever since I have seen general Washington with a silk handkerchief in High-street. Money commands sublunary things, and makes the mare go; it will buy salt mackerel, made of ten-penny nails. Enjoyment is the happiness of virtue. Yesterday cannot be recalled. I can only walk in the night-time, when I can eat pudding enough. I shall be eight years old tomorrow. They say R. W. is in partnership with J. W. I believe they are about as good as people in common—not better, only on certain occasions, when, for instance, a man wants to buy chincopins, and to import salt to feed pigs. Tanned leather was imported first by layers. Morality with virtue is like vice not corrected. L. B. came into your house and stole a coffee-pot in the twenty-fourth year of his majesty’s reign. Plumb-pudding and Irish potatoes make a very good dinner. Nothing in man is comprehensible to it. Born in Philadelphia. Our forefathers were better to us than our children, because they were chosen for their honesty, truth, virtue and innocence. The queen’s broad R originated from a British forty-two pounder, which makes two [sic] large a report for me. I have no more to say. I am thankful I am no worse this season, and that I am sound in mind and memory, and could steer a ship to sea, but am afraid of the thriller. ***** son of Mary queen of Scots. Born in Philadelphia. Born in Philadelphia. King of Macedonia.”

Activity and Behavior

Activity and behavior are greatly increased and diversified in mania. Patients appear to be indefatigable; they are rash, virulently opinionated, and interpersonally

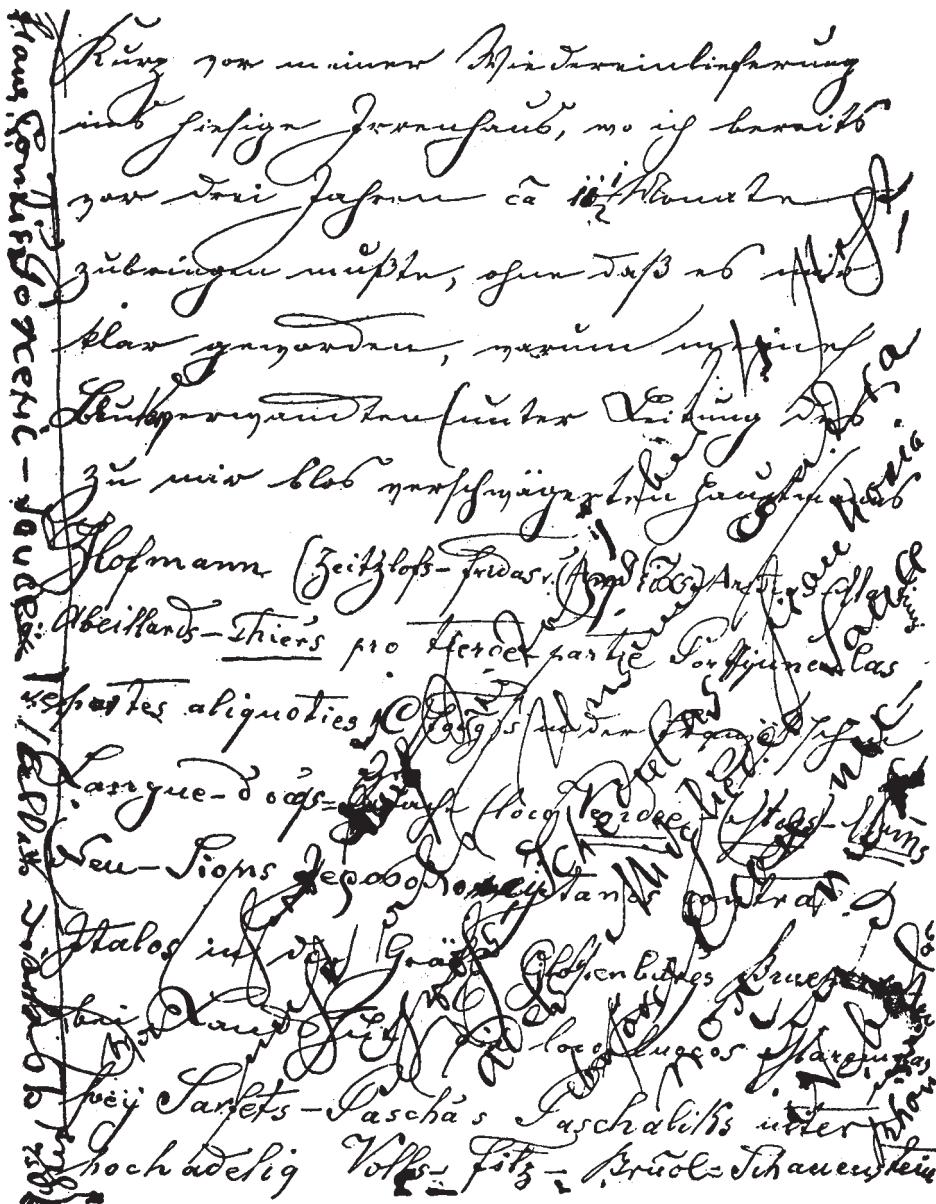

aggressive. Additionally, as Campbell (1953, pp. 152, 154–155) wrote:

The manic patient may expend a considerable amount of his energy and pressure of ideas in writing. His writing is demonstrative, flashy, rhetorical and bombastic. He insists that the physician must read every word, even though the content is biased, full of repetition, rambling and circumstantial. Capital letters are used unnecessarily, sentences are underscored and flight of ideas and distractibility destroy the coherence of the theme. The subject of the manic's writing often pertains to the correction of wrongs, religious tangents, gaining his freedom, institution of lawsuits. . . . One patient made three visits to

Washington to obtain a patent on a cotton-chopping machine; another attempted to speak to the President by long-distance telephone to warn him that the Russians might land on the coast of Florida. Urged on by the pressure of ideas as well as an excess of physical energy the manic patient has an inner drive which will not allow him to rest.

For many patients, excessive energy translates directly into pressured writing and an inordinate production of written declarations, poetry, and artwork. Kraepelin (1921, pp. 34–36) gave a concise description of this phenomenon, along with a specimen of handwriting produced during mania (see Fig. 2-1):

Figure 2-1. Specimen of handwriting produced during mania. (Source: Kraepelin, 1921, p. 35. Reproduced with permission.)

The handwriting of the patients may at first be quite regular and correct. In consequence of the excitability, however, it usually becomes gradually always larger, more pretentious and more irregular. There is no more consideration for the reader; the letters run through one another, are scribbled; more words are underlined; there are more marks of exclamation; the flourishes become bolder. . . . The number of documents produced by manic patients is sometimes astonishing, though certainly they themselves do not count on their being read; the pleasure of writing itself is the only motive.

The progression from hypomania to acute mania is usually accompanied not only by instability of mood and a sense of impending doom or premonitions of madness, but also by increasingly erratic behavior. Rush (1812, p. 142) made this clear in his monograph *Medical Inquiries and Observations upon the Diseases of the Mind*:

Its premonitory signs are, watchfulness, high or low spirits, great rapidity of thought, and eccentricity in conversation, and conduct; sometimes pathetic expressions of horror, excited by the apprehension of approaching madness; terrifying or distressing dreams; great irritability of temper; jealousy, instability in all pursuits; unusual acts of extravagance, manifested by the purchases of houses, and certain expensive and unnecessary articles of furniture, and hostility to relations and friends.

Sexual or erotic excitement is common in mania. Aretaeus of Cappadocia (150 AD) (quoted in Jelliffe, 1931, p. 20), for example, wrote that “a period of lewdness and shamelessness” exists in mania. Likewise, Kraepelin (1921, p. 22) noted that sexual excitability “is increased and leads to hasty engagements, marriages by the newspaper, improper love-adventures, conspicuous behaviour, fondness for dress, on the other hand to jealousy and matrimonial discord.” Tuke (1892, pp. 764–765) described this as well:

A very common symptom in maniacal conditions is erotic excitement. This varies from a mere coquetry, a somewhat extended application of the command “love one another,” an undue attention to the opposite sex, and so forth, up to the extreme of salacity, when the mind is wholly occupied by the urgent sexual appetite, and all restraint is abandoned.

Particularly dramatic and extreme among the clinical features of acute mania are the frenetic, seemingly aimless, and occasionally violent activities of manic patients. Bizarre, driven, paranoid, impulsive, and grossly inappropriate behavior patterns are typical. Kraepelin (1921, pp. 64–65) provided a graphic overview of these behaviors:

The patient cannot sit or lie still for long, jumps out of bed, runs about, hops, dances, mounts on tables and benches, takes down pictures. He forces his way out, takes off his clothes, teases his fellow patients, dives, splashes, spits, chirps and clicks. . . . [There are] discharges of inner restlessness, shaking of the upper part of the body, waltzing about, waving and flourishing the arms, distorting the limbs, rubbing the head, bouncing up and down, stroking, wiping, twitching, clapping and drumming. . . . [Death may be caused] by simple exhaustion with heart failure (collapse) in long continuing, violent excitement with disturbance of sleep and insufficient nourishment, by injuries with subsequent blood-poisoning.

Delirious mania, or Bell’s mania, is a relatively rare, grave form of mania characterized by severe clouding of consciousness. When Bell (1849) described the syndrome in the mid-nineteenth century, he noted its sudden onset and symptoms of severe insomnia, loss of appetite, disorientation, paranoia, and extremely bizarre hallucinations and delusions.³ Kraepelin (1921, pp. 70, 71) also remarked upon the syndrome’s acute onset and noted that patients were “stupefied, confused, bewildered,” in addition to being completely disoriented as to time and place. At the core of the illness he found a “dreamy and profound clouding of consciousness, and extraordinary and confused hallucinations and delusions.” Griesinger (1867) also emphasized the acute onset of the syndrome and observed that the primary emotion experienced by patients is anxiety. Bond (1980) noted that acute delirious mania can be distinguished by its precipitous onset, with or without premonitory signs of irritability, insomnia, or emotional withdrawal; the presence of the hypomanic or manic syndrome at some point during the illness; development of the signs and symptoms of delirium; a personal and/or family history of either mania or depression; and responsiveness to standard treatments for mania. (Patients with delirious mania often respond to electroconvulsive therapy, despite the delirium [Mann et al., 1986; Fink 1999].)

Mayer-Gross and colleagues (1960, pp. 213–214) gave a general overview of extreme manic confusion, emphasizing the medical gravity of the untreated clinical situation:

These states are seriously debilitating and may endanger life. *Sleep* is severely disturbed in these graver psychoses, but it is also shortened in the milder forms. Another bodily symptom is the exhaustion which supervenes on months of hyper-activity and reduced sleep. The intake of food may be seriously interfered with, for the manic may never take an uninterrupted meal, being constantly diverted to something else. *Body-weight*, which increases in the milder stages, rapidly drops, and very careful nursing

is required. . . . The possibility that the atypical features in manic confusion or delirium are due to nutritional deficiencies of the same kind as those sometimes causing delirium in infective illness, cannot be excluded.

Mood during delirious mania may shift rapidly between extreme melancholia and mania, suggesting a clinical link to mixed states. In Kraepelin's (1921, p. 71) words, mood is "very changing, sometimes anxiously despairing ('thoughts of death'), timid and lachrymose, distracted, sometimes unrestrainedly merry, erotic or ecstatic, sometimes irritable or unsympathetic and indifferent." The extreme cognitive and perceptual changes during delirious mania are manifested primarily through clouding of consciousness, hallucinations, and delusions. The profoundly disturbed and psychotic behavior of delirious mania underscores the origin of the phrase "raving maniac." Kraepelin (1921, pp. 71–72) graphically described this behavior:

At the beginning the patients frequently display the signs of senseless raving mania, dance about, perform peculiar movements, shake their head, throw the bedclothes pell-mell, are destructive, pass their motions under them, smear everything, make impulsive attempts at suicide, take off their clothes. A patient was found completely naked in a public park. Another ran half-clothed into the corridor and then into the street, in one hand a revolver in the other a crucifix. . . . Their linguistic utterances alternate between inarticulate sounds, praying, abusing, entreating, stammering, disconnected talk, in which clang-associations, senseless rhyming, diversion by external impressions, persistence of individual phrases, are recognised. . . . Waxy flexibility, echolalia, or echopraxis can be demonstrated frequently.

More recently, Fink (1999, pp. 57–58) described a series of modern cases of delirious mania:

Patients with delirious mania are excited, restless, fearful, paranoid, and delusional. They sleep poorly, are often confused and disoriented, and they confabulate. The onset develops within a few hours or a few days. Fever, rapid heart rate, tachycardia, hypertension, and rapid breathing are common. Patients hide in small spaces, close the doors and blinds on the windows, remove their clothes, and run nude from their home. Garrulous, incoherent, and rambling speech alternates with mutism. Negativism, stereotypy, grimacing, posturing, echolalia, and echopraxia occur. When examined, they are poorly oriented for place, date and time, are unable to recall their recent experiences, or numbers given them.

Fink argued that we do not know the true incidence of delirious mania, nor do we have adequate diagnostic criteria

to distinguish it reliably from malignant catatonia, excited catatonia, rapid-cycling mania, or mania with psychotic features.

Chronic mania was observed and described by many early clinicians, including Pinel (1801), Esquirol (1838), Griesinger (1865), Schott (1904), Kraepelin (1921), and Wertham (1929). According to Schott, only the lack of recovery distinguished the chronic from the acute form of the illness (see also Chapter 4). A first manic episode after the age of 40 was thought to put the patient at much higher risk for chronicity than one occurring earlier (Henderson and Gillespie, 1956), an observation consistent with the results of subsequent research (see Chapter 4). Wertham (1929) outlined the central features of chronic mania: reduced intellectual productivity and general activity levels, increased behavioral stereotypy, and an overall intellectual weakening. Hare (1981), in an excellent historical review of the concept of mania, discussed the declining interest in the subject of chronic mania after the nineteenth century. He attributed this in part to the decreasing morbidity of manic illness, and maintained that improvements in general health and hygiene had resulted in significant changes in the manifestation, severity, and consequences of mania. He acknowledged, however, that there still existed "the ghost as it were, of a process of mental enfeeblement which can occur in affective psychosis and which generally did occur, to a more severe degree, until towards the end of the nineteenth century" (p. 97).

Kraepelin (1921, pp. 161–162) provided an overview of the intellectual and emotional blunting in chronic mania; he also drew a distinction between chronic mania and extreme, continuous, rapid cycling and discussed possible contributory factors:

Here manic features dominate the picture. The patients are in general sensible and reasonable, and perceive fairly well; memory and retention are also fairly well preserved. On the other hand there exist increased distractibility, wandering and desultoriness of thought, a tendency to silly plays on words, poverty of thought. The patients have no understanding of their state, consider themselves perfectly well and capable of work.

Mood is exalted, but no longer exultant, enjoying activity, but silly and boastful; occasionally it comes to flaring up without strength or durability. The finer emotions are considerably injured. . . . Only the coarser enjoyments, eating, drinking, smoking, snuffing, still arouse in them vivid feelings, further the satisfaction of their personal wishes and wants; everything else has become to them more or less indifferent. . . .

At this point we have to mention in a few words another group of cases, in which the psychic decline

reveals itself in continual, abrupt fluctuation between lachrymose anxiety, irritability, and childish merriment. States of this kind sometimes appear to be developed from a continuous accumulation of short circular attacks.

Subjective Experiences of Patients

Mood

In his memoir *Wisdom, Madness, and Folly: The Philosophy of a Lunatic*, John Custance (1952, p. 30), a writer and former Royal Navy intelligence officer who suffered from bipolar illness, described the sense of well-being at the beginning of his manic episodes:

First and foremost comes a general sense of intense well-being. I know of course that this sense is illusory and transient. . . . Although, however, the restrictions of confinement are apt at times to produce extreme irritation and even paroxysms of anger, the general sense of well-being, the pleasurable and sometimes ecstatic feeling-tone, remains as a sort of permanent background of all experience during the manic period.

As it progresses, this feeling of well-being often is accompanied by a sense of benevolence and communion with nature; frequently it is associated with what Henderson and Gillespie (1956) and others have called a “heightened sense of reality.” These feelings, analogous to the beatific and mystical experiences of saints and other religious leaders, share certain features with contemporary experiences of “universal communion” induced by mescaline, LSD, and other hallucinogenic substances. The interaction among emotional, cognitive, and sensory-perceptual changes is complex, as we see in the following passages by Custance (1952, pp. 37, 40):

It is actually a sense of communion, in the first place with God, and in the second place with all mankind, indeed with all creation. It is obviously related to the mystic sense of unity with the All. . . .

A feeling of intimate personal relationship with God is perhaps its paramount feature. . . .

The sense of communion extends to all fellow-creatures with whom I come into contact; it is not merely ideal or imaginative but has a practical effect on my conduct. Thus when in the manic state I have no objection to being more or less herded together—as is inevitable in public Mental Hospitals—with men of all classes and conditions. Class barriers cease to have any existence or meaning.

Likewise, poet Theodore Roethke (quoted in Seager, 1991, p. 101) captured the mystical merging of identity in

his description of the early, euphoric stage of one of his manic episodes:

For no reason I started to feel very good. Suddenly I knew how to enter into the life of everything around me. I knew how it felt to be a tree, a blade of grass, even a rabbit. I didn't sleep much. I just walked around with this wonderful feeling. One day I was passing a diner and all of a sudden I knew what it felt like to be a lion. I went into the diner and said to the counter-man, “Bring me a steak. Don't cook it. Just bring it.” . . . I went to the Dean [at the university where Roethke taught] and said, “I feel too good. Get me down off this.” So they put me into the tubs.

Cognition and Perception

During hypomanic and manic states, thinking becomes very fluid and productive—to the point of loosening of normal patterns of association, as well as racing thoughts and flight of ideas. The dendritic, branching-out quality of manic thinking was described by nineteenth-century art critic and writer John Ruskin (quoted in Rosenberg, 1986, p. 151):

I roll on like a ball, with this exception, that contrary to the usual laws of motion I have no friction to contend with in my mind. . . . I am almost sick and giddy with the quantity of things in my head—trains of thought beginning and branching to infinity, crossing each other, and all tempting and wanting to be worked out.

Perhaps most pathognomonic of hypomanic and manic cognitive patterns are flight of ideas and the subjective experience of racing thoughts. The overwhelming and often terrifying nature of racing thoughts is expressed below in one patient's account of manic illness. Grandiosity of delusional proportions and a compelling sense of moral and social awareness also are described (Reiss, 1910):

The condition of my mind for many months is beyond all description. My thoughts ran with lightning-like rapidity from one subject to another. I had an exaggerated feeling of self importance. All the problems of the universe came crowding into my mind, demanding instant discussion and solution—mental telepathy, hypnotism, wireless telegraphy, Christian science, women's rights, and all the problems of medical science, religion and politics. I even devised means of discovering the weight of a human soul, and had an apparatus constructed in my room for the purpose of weighing my own soul the minute it departed from my body. . . .

Thoughts chased one another through my mind with lightning rapidity. I felt like a person driving a wild horse with a weak rein, who dares not use force, but lets him run his course, following the line of least resistance. Mad

impulses would rush through my brain, carrying me first in one direction then in another. To destroy myself or to escape often occurred to me, but my mind could not hold on to one subject long enough to formulate any definite plan. My reasoning was weak and fallacious, and I knew it.

Russian poet Velimir Khlebnikov (quoted in Markov, 1975, pp. 362–363), hospitalized for his erratic behavior and wild mood swings, described a euphoric grandiosity that ratcheted upwards into a delusional system of cosmic proportions. He was convinced that he possessed equations “for the stars, equations for voices, equations for thoughts, equations of birth and death.” The artist of numbers, he believed, could draw the universe:

Working with number as his charcoal, he unites all previous human knowledge in his art. A single one of his lines provides an immediate lightninglike connection between a red corpuscle and Earth, a second precipitates into helium, a third shatters upon the unbending heavens and discovers the satellites of Jupiter. Velocity is infused with a new speed, the speed of thought, while the boundaries that separate different areas of knowledge will disappear before the procession of liberated numbers cast like orders into print throughout the whole of Planet Earth.

Here they are then, these ways of looking at the new form of creativity, which we think is perfectly workable.

The surface of Planet Earth is 510,051,300 square kilometers; the surface of a red corpuscle—that citizen and star of man’s Milky Way—0.000,128 square millimeters. These citizens of the sky and the body have concluded a treaty, whose provision is this: the surface of the star Earth divided by the surface of the tiny corpuscular star equals 365 times 10 to the tenth power (365×10^{10}). A beautiful concordance of two worlds, one that establishes man’s right to first place on Earth. This is the first article of the treaty between the government of blood cells and the government of heavenly bodies. A living walking Milky Way and his tiny star have concluded a 365-point agreement with the Milky Way in the sky and its great Earth Star. The dead Milky Way and the living one have affixed their signatures to it as two equal and legal entities.

The perceptual and somatic changes that almost always accompany hypomania and mania reflect the close and subtle links among elevated mood, a physical sense of well-being, expansive and grandiose thoughts, and heightened perceptual awareness. Custance (1952, p. 16) described the temporal ordering of somatic, mood, and cognitive symptoms during the initial phases of his manic episodes:

Thus at the onset of phases of manic excitement I have sometimes noticed the typical symptoms, the pleasurable

tingling of the spinal chord [*sic*] and warm sense of well-being in the solar plexus, long before any reaction in the mental sphere occurred. The same thing happens with the sinking feeling of fear and horror which accompanies extreme depression.

Clearly, as with virtually all signs and symptoms of bipolar illness, perceptual and somatic changes vary in degree and kind—from mild increases in awareness of objects and events actually present in the individual’s environment to total chaotic disarray of the senses, resulting in visual, auditory, and olfactory experiences unrelated to existing physical phenomena. At the milder end of perceptual change, one patient described the relationship of heightened awareness, strongly charged but normal emotional reactions, and psychotic perceptions (Coate, 1964, p. 1):

In normal life at times of strong emotion, and especially at moments of great fear, we find that we are more keenly aware than usual of the external details of our world. The sunshine on wet roofs across the way, the faded edge to the blue window curtain, a scent of pipe tobacco in the room, the way the man in the armchair clasps and unclasps his hands—all is more clearly etched in consciousness because of the feeling aroused by the nearness of enemy bombers, or the gravity of an operation taking place next door, or the tenseness of waiting until an expected person, acutely loved or deeply hated, will walk in. In psychotic states, where the fate of the whole universe may be at stake, awareness of material objects and of trivial events can be heightened to an extent that is outside the range of sane experience.

Custance wrote of his sensory experiences while in the preliminary stage of a manic episode (1952, pp. 31–32):

The first thing I note is the peculiar appearances of the lights—the ordinary electric lights in the ward. They are not exactly brighter, but deeper, more intense, perhaps a trifle more ruddy than usual. Moreover, if I relax the focusing of my eyes, which I can do very much more easily than in normal circumstances, a bright star-like phenomenon emanates from the lights, ultimately forming a maze of iridescent patterns of all colours of the rainbow, which remind me vaguely of the Aurora Borealis. . . . Connected with these vivid impressions is a rather curious feeling behind the eyeballs, rather as though a vast electric motor were pulsing away there.

All my other senses seem more acute than usual. Certainly my sense of touch is heightened; my fingers are much more sensitive and neat. . . .

My hearing appears to be more sensitive, and I am able to take in without disturbance or distraction many different sound-impressions at the same time.

Custance (1952, p. 59) also described specific physical sensations he experienced during his manic episodes. His perceived imperviousness to pain and cold, as well as his delusional beliefs about electrical and other influences, occur in many manic patients:

Metabolism is rapid. I can stand cold without difficulty or discomfort; an inner warmth seems to pervade me. I can, for example, walk about naked out of doors on quite cold nights—to throw off my clothes is incidentally a strong impulse and presumably symbolises the freedom from restraint which is a feature of the whole condition. My skin seems peculiarly resistant; I have walked barefooted on stony and thorny ground, squeezed myself naked through furze fences and so on without suffering discomfort. Perhaps this is akin to the strange feats of fire walkers or dancing Dervishes. It certainly seems to show the influence of mind over matter. I fear nothing—freedom from fear is another notable symptom—so nothing seems to hurt me.

Activity and Behavior

Behavioral changes during mania include increases in psychomotor activity and in the pressure and rate of speech; heightened irritability and aggressive behaviors; increases in spending and other impulsive behaviors; hypersexuality; and frenzied, bizarre, often aimless activity. Detailed clinical descriptions of these behavioral changes—especially those by Kraepelin—were given earlier in this chapter, and specific discussions of hypomanic and manic behavior can be found elsewhere in the volume. We present here first-person accounts of only a few common or especially interesting behavioral changes in manic states. Two passages describe increased enthusiasm for and involvement in a wide variety of creative interests and activities. The first, from Coate (1964, pp. 84–85), reflects the clear influence of mood and grandiosity on thinking and behavior. The sense of time urgency and the special significance of events and objects also are evident:

I must record everything and later I would write a book on mental hospitals. I would write books on psychiatric theory too, and on theology. I would write novels. I had the libretto of an opera in mind. Nothing was beyond me. My creative impulse had found full outlet and I had enough now to write to last me for the rest of my life.

I made notes of everything that happened, day and night. I made symbolic scrap-books whose meaning only I could decipher. I wrote a fairy tale; I wrote the diary of a white witch; and again I noted down cryptically all that was said or done around me at the time, with special reference to relevant news bulletins and to jokes which were broadcast in radio programmes. The time, correct to the

nearest minute, was recorded in the margin. It was all vitally important. The major work which would be based on this material would be accurate, original, provocative, and of profound significance. All that had ever happened to me was now worthwhile.

Because her thinking was not yet psychotically fragmented or delusional, Coate was able to concentrate intensely and to keep in order a broad diversity of ideas and sensations. This ability is not uncommon in hypomania, although many bipolar patients who experience scattered thinking early in their episodes never go through this hyperalert but concentrated phase. Those who do and who also possess creative ability find this stage can be an exceptionally productive one (see Chapter 12). For Custance (1952, pp. 244–245), both creativity and learning were heightened:

In some forms of insanity, including especially mania, this ripening of the instinct, this eager readiness to absorb and learn new things, to become interested in fresh games, sports and forms of work, seems to recur. It certainly does in my own case. I have, in actual fact, learnt more while confined in Mental Hospitals than anywhere else, including my School and University. I have learnt drawing, shorthand, some languages, studied philosophy and psychology as deeply as I was able, collected and systematically written down and filed innumerable scraps of information on all sorts of subjects, and, above all, read in the book of human nature, which is as it were exposed in the raw. I know the history, background and medical diagnosis of many of the patients in the wards I have been in. Finally I have written this book.

A common aspect of the manic state is impulsive and irrational financial behavior. The psychological and interpersonal consequences, as well as the economic ones, can be devastating. The return of postmanic reason and subsequent awareness of financial extravagances and other painfully embarrassing actions often occur in the harsh context of severe postmanic depression. The humorous aspects of many manic purchases often obscure the acute shame and dire financial consequences experienced by patients with bipolar illness:

When I am high I couldn't worry about money if I tried. So I don't. The money will come from somewhere; I am entitled; God will provide. Credit cards are disastrous, personal checks worse. Unfortunately, for manics anyway, mania is a natural extension of the economy. What with credit cards and bank accounts there is little beyond reach. So I bought twelve snake bite kits, with a sense of urgency and importance. I bought precious stones, elegant and unnecessary furniture, three watches within an hour of one another (in the Rolex rather than Timex

class: champagne tastes bubble to the surface, are the surface, in mania), and totally inappropriate siren-like clothes. During one spree in London I spent several hundred pounds on books having titles or covers that somehow caught my fancy: books on the natural history of the mole, twenty sundry Penguin books because I thought it could be nice if the penguins could form a colony, five Puffin books for a similar reason, on and on and on it went. Once, I think, I shoplifted a blouse because I could not wait a minute longer for the woman-with-molasses feet in front of me in line. Or maybe I just thought about shoplifting, I don't remember, I was totally confused. I imagine I must have spent far more than \$30,000 during my two major manic episodes, and God only knows how much more during my frequent milder manias.

But then back on lithium and rotating on the planet at the same pace as everyone else, you find your credit is decimated, your mortification complete: mania is not a luxury one can easily afford. It is devastating to have the illness and aggravating to have to pay for medications, blood tests, and psychotherapy. They, at least, are partially [tax] deductible. But money spent while manic doesn't fit into the Internal Revenue Service concept of medical expense or business loss. So, after mania, when most depressed, you're given excellent reason to be even more so. (Jamison, 1995, pp. 74–75)

Clinical Studies

Mania is a complex, volatile, and fluctuating cauldron of symptoms. "The form and ways which mania manifests are manifold," said Aretaeus (translated by Jelliffe, 1931, p. 20) nearly 2000 years ago. "Some are cheerful and like to play . . . others passionate and of destructive type, who seek to kill others as well as themselves." Although classically described as a state of extraordinary energy and activity, mania can also present clinically as manic stupor and "catatonia." Manic mood, frequently characterized as elated and grandiose, as often as not is riddled with depression, panic, and extreme irritability; mania without significant mixed features is what is known as "classic" mania. For years, mania was differentiated mistakenly from schizophrenia because it reputedly lacked a thought disorder. It now is recognized as an often floridly psychotic condition, as we shall see below.

Manic episodes differ from person to person and in the same individual from time to time, although Falret (1854, cited in Sedler, 1983) and Kraepelin (1921) noted a tendency for constancy in symptom patterns across episodes in the same individual. While few systematic data are available on this latter point, Wellner and Marstal (1964, p. 176), reporting on a study of 279 manic episodes in 221 patients, concluded that "atypical attacks are followed by atypical, and typical by typical significantly more often than not

($p=0.002$), indicating the patients' inclination to reproduce the type of their psychoses." Beigel and Murphy (1971a) found that patients with multiple manic attacks tended to exhibit similar behavior and mood patterns during subsequent episodes. Two more recent studies (Cassidy et al., 2001a; Woods et al., 2001) demonstrated that manic and mixed episodes show diagnostic stability over time; the interepisode stability of depressive mixed states, while significant, is considerably less pronounced than is the case for manic states (Sato et al., 2004). Francis and colleagues (1997) found that the symptom profile of catatonia is highly consistent across episodes, while Cassidy and colleagues (2002), who evaluated 77 bipolar patients during two distinct manic episodes separated, on average, by 2 years, concluded that manic symptomatology remains generally consistent from episode to episode. Specifically, they found that severity of mania, dysphoria, hedonic activation, psychosis, and irritable aggression tends to correlate across episodes; psychomotor symptoms do not.

Regardless of the degree of constancy of the clinical picture across attacks, it is clear that symptoms vary widely during any given manic episode as it progresses through various stages. These stages, characterized by Carlson and Goodwin (1973) and discussed more fully below, begin with elation or irritability, evolve into a more severe form as arousal and hyperactivity escalate, and culminate in floridly psychotic disorganization.

Mood

Research on mood symptoms in mania, summarized in Table 2-1, demonstrates that most patients, on average, are depressed (46 percent) or labile (49 percent) nearly as often as they are euphoric (63 percent) or expansive (60 percent); they are irritable (71 percent) even more often. The depression, irritability, and mood lability are generally seen less often in early stages of an episode, although few studies have specified the stage, level, or severity of mania at the time of observation.

Winokur and colleagues (1969) observed depressed mood in 68 percent of their manic patients, as well as more severe depressive symptoms (including depressive delusions and psychomotor retardation) in a significant subgroup. They found that "short depressive contaminations in the manic episode" were significantly more common in women (79 percent) than in men (49 percent) (p. 64). Like many investigators, they were particularly impressed by the volatility of mood during manic episodes:

In our series of patients, the degree of mood elevation varied from patient to patient and from time to time during the same episode. The changes in mood were capricious, responding to internal as well as external stimuli

and so very changeable that they defied measurement. . . . In only 5% was the mood unchanging over a period of hours or days. (p. 62)

As noted earlier, Carlson and Goodwin (1973) described progressive stages of mania, from mild hypomania to

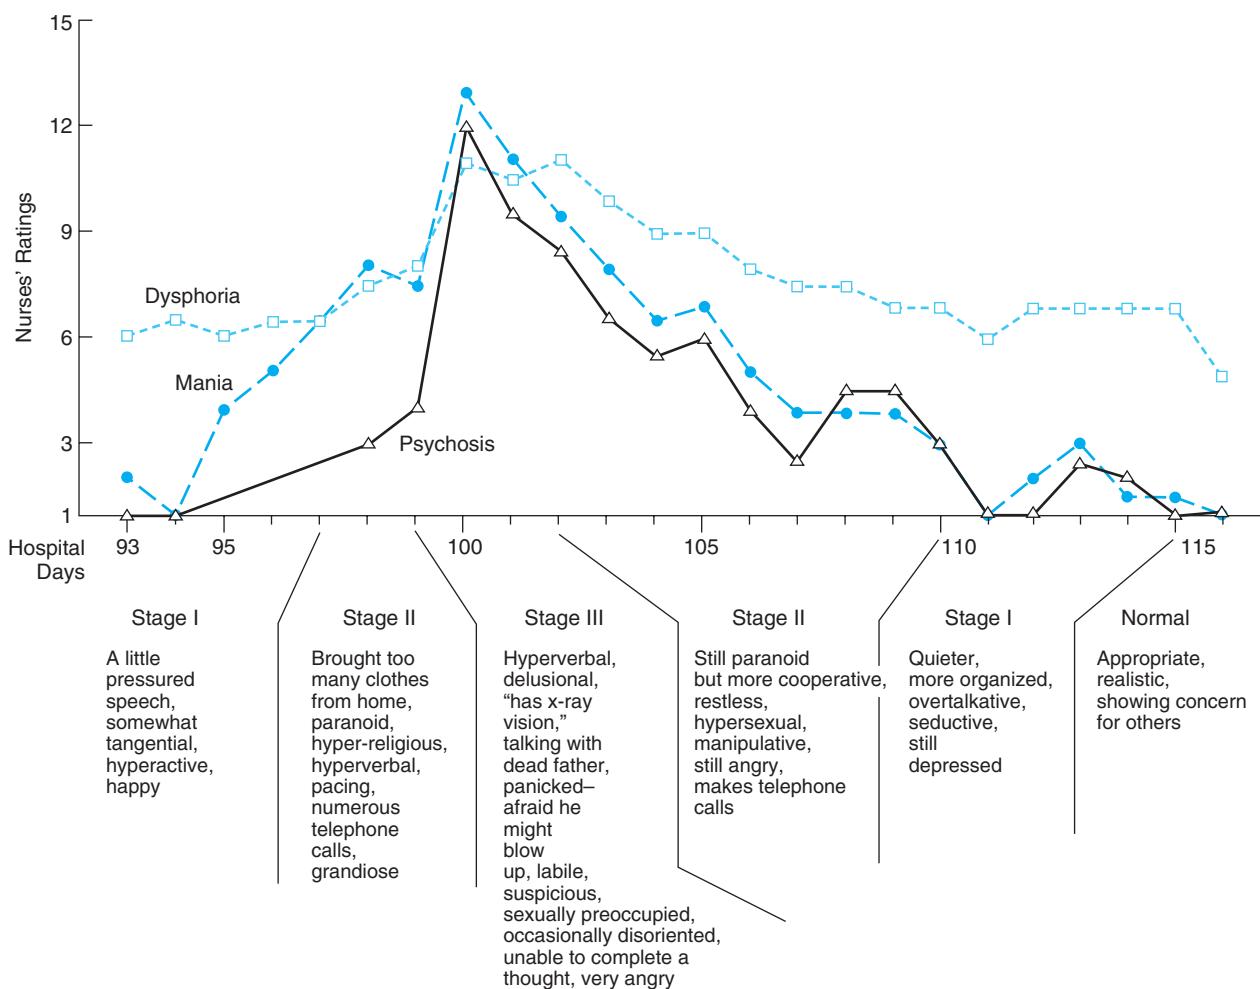

delirious psychotic mania. The principal features of the three stages are outlined in Table 2–2; the relationship of these stages to daily behavioral ratings is illustrated in Figure 2–2. The stages were inferred from a study of 20 hospitalized, unmedicated bipolar patients who had experienced a manic episode at some time during their hospitalization.

TABLE 2–2. Clinical Features of the Stages of Mania

	Stage I	Stage II	Stage III
Mood	Lability of affect; euphoria predominates; irritability if demands not satisfied	Increased dysphoria and depression; open hostility and anger	Clearly dysphoric; panic-stricken; hopeless
Cognition	Expansivity, grandiosity, overconfidence; thoughts coherent but occasionally tangential; sexual and religious preoccupation; racing thoughts	Flight of ideas; disorganization of cognitive state; delusions	Incoherent, definite loosening of associations; bizarre and idiosyncratic delusions; hallucinations in one-third of patients; disorientation as to time and place; occasional ideas of reference
Behavior	Increased psychomotor activity; increased initiation and rate of speech; increased spending, smoking, telephone use	Continued increased psychomotor acceleration; increased pressured speech; occasional assaultive behavior	Frenzied and frequently bizarre psychomotor activity

Source: Adapted from Carlson and Goodwin, 1973.

Figure 2–2. Relationship between states of a manic episode and daily behavior ratings. (Source: Carlson and Goodwin, 1973.)

Manic episodes were identified by means of global mania ratings determined twice a day by consensus of the nursing research team, and were corroborated by the psychiatrists' and nurses' written descriptions of patients' affect, psychomotor activity, and cognitive state. The sequence of mood, cognitive, and behavioral symptoms over the course of the episode was recorded. Based on analysis of this information, the patients' longitudinal course was divided into three stages, with predominant mood as the primary criterion—from the euphoria of stage I, to the anger and irritability of stage II, to the severe panic of stage III. In some of the patients, the onset of mania (the switch) was gradual, clearly unfolding in a sequence until the full syndrome had developed. In others, the onset was sudden and dramatic; even in these cases, however, the earlier stages were present, if transient.

As Carlson and Goodwin elaborated, the initial phase of mania (stage I) typically is characterized by increased activity; by a labile mood that can be euphoric, irritable, or both; and by expansive, grandiose, and overconfident thoughts. Thinking remains coherent but is often tangential. Patients describe this change as “going high” and frequently report racing thoughts. In some instances, the “high” does not go beyond stage I, which corresponds to hypomania.

Many episodes progress to the next stage, however. Psychomotor activity increases—evident in the even more rapid speech—and the mood state becomes more labile, characterized by a mix of euphoria and dysphoria. Irritability turns into open hostility and anger, and the accompanying behavior often is explosive and assaultive. As racing thoughts progress to a definite flight of ideas, cognition becomes increasingly disorganized. Preoccupations intensify, with grandiose and paranoid trends that are apparent as frank delusions. This level, which corresponds to acute mania, is designated as stage II.

In some patients, the manic episode progresses further to an undifferentiated psychotic state (stage III), experienced by the patient as clearly dysphoric, usually terrifying, and accompanied by frenzied movement. Thought processes that earlier had been only difficult to follow become incoherent, and definite loosening of associations often is seen. Delusions commonly are bizarre and idiosyncratic, and some patients experience ideas of reference, disorientation, and a delirium-like state. This phase of the syndrome is difficult to distinguish from other acute psychoses, at least superficially. In general, as the manic episode unfolds, stage I is dominated by elation (or irritability) and grandiosity, stage II by increasing hyperactivity and arousal, and stage III by florid psychotic disorganization.

In the Carlson and Goodwin study, many of the rated items showed graded continuous distributions, whereas

others evidenced definite thresholds involving apparently qualitative shifts. The level of psychomotor activity escalated continuously through all three stages, and ratings for manic mood increased in like manner through stages I and II. Ratings of psychosis, by contrast, were not clearly distributed along a continuum. This point is illustrated by the case example presented in Figure 2–2. As can be seen, stage III mania was characterized by the relatively abrupt and initial appearance of hallucinations, formal thought disorder in the Schneiderian sense, and organic delirium.

In their study of mania, Kotin and Goodwin (1972) found depressive affect to be pervasive. Indeed, in 10 of their 20 manic patients the mean depression rating was significantly higher during the manic episode than during nonmanic, depressed periods in the hospital. The authors noted that mania and depression ratings were correlated positively in a majority of patients both during manic periods and for the entire hospital stay. These findings, observed the authors, “are contrary to the common view that a patient is either manic or depressed” (p. 683). Recent studies of mania, discussed later, bear out its mixed nature.

Cognition and Perception

Nonpsychotic cognitive symptoms are common during mania. Grandiosity and flight of ideas—experienced subjectively as racing thoughts—were observed in approximately three-quarters of the manic patients described in the clinical studies summarized in Table 2–3. Less clearly and more variably defined were distractibility, poor concentration, and confusion, a fact that may account in part for the broader range of results on these variables—16 to 100 percent for distractibility, for example, and 8 to 58 percent for confusion. Definitions were especially wide-ranging for confusion—from “somewhat confused and unable to follow the gist of a conversation” to the more severe clinical usage of the term to denote disorientation and serious memory disturbance.

Thought Disorder. There is no single or comprehensive definition of formal thought disorder. Instead, thought disorder has been used as a general phrase to describe problems with the ability to attend to, abstract, conceptualize, express, or continue coherent thought. Deficits in thought and language were at one time described in general terms; today these deficits are defined by specific measures (e.g., the Thought Disorder Index or the Scale for the Assessment of Thought, Language and Communication). This increased specificity makes it possible to disentangle, at least in part, disorders of thought from those of language or speech (accordingly, we discuss the

latter separately below). Although difficult, this distinction is important, since it is possible to have either disorder without the other (Holzman et al., 1985). Much of thought is nonverbal, and individuals often say one thing while thinking another. Here we use as a working definition of thought disorder one provided by Solovay and colleagues (1987, p. 13): thought disorder “is not intended to denote a unitary dimension or process; rather, it refers to any disruption, deficit, or slippage in various aspects of thinking, such as concentration, attention, reasoning, or abstraction.”

Certain psychotic features of mania and bipolar depression—delusions and hallucinations—are relevant but not central to the concept of thought disorder. The

specificity of thought disorder to the major psychoses—mania and schizophrenia—represents an important conceptual issue and is a major focus here. Results of recent genetic studies indicate that psychosis may be an overlapping feature of bipolar illness and schizophrenia (see Chapter 13); therefore, studies that address the similarities and dissimilarities in the psychotic presentation of the two illnesses are of particular interest. Holzman and colleagues (1985, p. 228) asked: “Is thought disorder a non-specific accompaniment of psychotic behavior, whatever the etiology of that psychosis, just as fever is nonspecific for a variety of systemic conditions; or is there a set of specific disorders of thinking that accompanies specific psychotic conditions?”

Several methods have evolved for studying thought and communication disorders in schizophrenia and affective illness. These methods were categorized by Harvey (1983) as (1) clinical (the examination of speech patterns on the basis of clinical interactions, e.g., in the manner of Kraepelin and Bleuler); (2) laboratory (the study of underlying cognitive processes that result in or contribute to disordered speech); and (3) natural-language (the examination of speech samples from a variety of sources in an attempt to “identify the discourse processes that lead to the problems listeners have in understanding the speech of psychotics” [p. 368]). Several specific measures have been developed, three of which, summarized below, form the basis for most of the research relevant to the study of thought disorder in bipolar illness. Taken together, these three measures can provide a reasonably comprehensive assessment of formal thought disorder.

Holzman and colleagues (1985) developed the Thought Disorder Index using verbal protocols (most typically verbatim responses to the Rorschach test). Based on earlier indices (Watkins and Stauffacher, 1952; Rapaport et al., 1968), the Thought Disorder Index comprises 23 categories of thinking disturbances evaluated at four levels of severity (Johnston and Holzman, 1979; Shenton et al., 1987; Solovay et al., 1987). The least severe level includes vagueness and peculiar verbalizations; the most severe includes thought contamination and neologisms.

Andreasen (1979a,b) characterized different language behaviors that she considered to be subtypes of thought disorder and developed them into another measure, the Scale for the Assessment of Thought, Language and Communication. Some subtypes occur frequently in psychotic speech (e.g., poverty of content of speech, pressure of speech, tangentiality, derailment, loss of goal, and perseveration), whereas others are relatively uncommon and, correspondingly, less useful (e.g., clanging, blocking, echolalia, neologisms, and word approximations).

Finally, Harrow and colleagues⁴ have used a battery of measures taken from the Wechsler Adult Intelligence Scale (WAIS) (Social Comprehension Subtest), the Goldstein-Scheerer Object-Sorting Test, and the Gorham Proverbs Test to assess bizarre and idiosyncratic thinking and behavior, as well as conceptual style. Detailed discussions of the development, reliability, and validity of their test battery are provided elsewhere.⁵

Virtually all studies of formal thought disorder in mania and schizophrenia, the results of which are summarized in Table 2–4, have found comparably high levels in both diagnostic groups.⁶ In fact, although Resnick and Oltmanns (1984) observed more thought disorder in schizophrenic patients, Harrow and colleagues (1982) found a trend toward greater levels in manic patients.⁷ There is,

therefore, no indication that thought disorder per se is in any way specific to schizophrenia. This observation is consistent with the evidence for the strong presence in mania, as well as in schizophrenia, of psychotic features, such as hallucinations and delusions. (See Chapter 13 for discussion of potential genetic factors underlying psychosis in both bipolar disorder and schizophrenia.) Findings of qualitative comparisons of manic and schizophrenic thought disorder are less consistent, although increased pressure of speech appears to be more characteristic of mania,⁸ as are increased derailment, loss of goal, and tangentiality (Andreasen, 1984; Simpson and Davis, 1985). Poverty of speech and other negative symptoms were reported by Andreasen (1984) to be more characteristic of schizophrenic thought, although Ragin and Oltmanns (1987), using the same scale, did not confirm this finding. More recent studies have found greater poverty of thought, less complexity of speech, and less overall quantity of speech in schizophrenic than in manic patients.⁹

Studies of differences between manic and schizophrenic patients on measures of idiosyncratic and/or bizarre thinking have yielded mixed results, with some authors finding higher levels in manic patients (Andreasen and Powers, 1975; Harrow et al., 1982) and others higher levels in schizophrenic patients (Simpson and Davis, 1985; Shenton et al., 1987; Docherty et al., 1996). In general, investigators have found that those with mania have more complex speech than those with schizophrenia (Thomas et al., 1996; Lott et al., 2002). Simpson and Davis (1985) made the useful distinction that manic patients appear to be more disordered in *thought structure*, whereas schizophrenic patients appear to be more disordered in *thought content*. Jampala and colleagues (1989, p. 462) argued that manic patients with formal thought disorder may “have a more severe rather than a different condition than manic patients without formal thought disorder. The fact that more manic patients with formal thought disorder had a first-degree relative with affective illness supports this interpretation.”

Qualitative differences in thought disorder between mania and schizophrenia are more distinct in the use of combinatory thinking, the “tendency to merge percepts, ideas, or images in an incongruous fashion” (Shenton et al., 1987, p. 23). In a study of 20 manic patients, 43 schizophrenic patients, and 22 normal subjects, Solovay and colleagues (1987), using the Thought Disorder Index, found no significant difference in the quantity of thought disorder in manic and schizophrenic patients, but did note that manic thought disorder was “extravagantly combinatory, usually with humor, flippancy, and playfulness.” Schizophrenic thought disorder, by contrast, was “disorganized, confused, and idealistically fluid, with many peculiar words and

TABLE 2–4. Thought Pathology in Mania and Schizophrenia: Similarities and Differences

Study	Thought Disorder Measure	Similarities	Differences
Breakey and Goodell, 1972	Bannister Grid Test	Same frequency of thought disorder	
Andreasen and Powers, 1975	Goldstein-Scheerer Object Sorting Test		Manic patients: ↑ behavioral overinclusion; ↑ conceptual overinclusion, ↑ idiosyncratic thinking Schizophrenic patients: ↑ underinclusiveness
Grossman et al., 1981	Gorham Proverbs Test Goldstein-Scheerer Object Sorting Test Wechsler Adult Intelligence Scale (WAIS), Social Comprehension Subtest	Similar in overall level of severity, course of disturbance, and loose association of ideas; intermingling of inappropriate personal ideas or concerns into responses to neutral stimuli; gaps in communication of ideas, odd outlooks, and other manifestations of bizarre thinking	Manic patients: ↑ behavioral activity and responsiveness, ↓ response time on word association test, ↓ deficits in behavioral activity or impoverished activity, ↑ grandiose ideas
Harrow et al., 1982	Gorham Proverbs Test Goldstein-Scheerer Object Sorting Test WAIS, Social Comprehension Subtest		Manic patients: may be more thought disordered than schizophrenics, “although the results are not conclusive”; ↑ bizarre-idiosyncratic thinking
Andreasen, 1984	Scale for the Assessment of Thought, Language and Communication	Similar in number of abnormalities	Manic patients: more positive thought disorder; ↑ tangentiality, ↑ derailment, ↑ incoherence, ↑ illogicality, ↑ pressure of speech Schizophrenic patients: more negative thought disorder, ↑ poverty of speech, ↑ poverty of content Schizoaffective patients: thought disorder is midway between that of manic and schizophrenic patients
Resnick and Oltmanns, 1984	Global ratings of thought disorder		Manic patients: less overall thought disorder; ↑ pressure of speech

Simpson and Davis, 1985	Scale for the Assessment of Thought, Language and Communication Brief Psychiatric Rating Scale		Manic patients: more disordered thought structure; ↑ loss of goal, ↑ tangentiality, ↑ derailment, ↑ circumstantiality, ↑ illogicality, ↑ pressure of speech, ↑ incoherence Schizophrenic patients: more disordered thought content; ↑ hallucinatory statements, ↑ hallucinatory behavior, ↑ unusual thought content
Ragin and Oltmanns, 1987	Scale for the Assessment of Thought, Language and Communication	Similar levels of poverty of speech, derailment, loss of goal	Manic patients: ↑ pressure of speech
Shenton et al., 1987	Thought Disorder Index	High level of thought disorder in both manic and schizophrenic patients	Manic patients: ↑ combinatory thinking Schizophrenic patients: overall higher level of thought disorder; ↑ idiosyncratic and autistic thinking, ↑ absurdity, ↑ confusion Schizoaffective patients: thinking disorders more similar to those of schizophrenic patients than to those of manic patients
Solovay et al., 1987	Thought Disorder Index	Equal amount of thought disorder	Manic patients: Thought disorder “extravagantly combinative, usually with humor, flippancy and playfulness” Schizophrenic patients: “disorganized, confused, and ideationally fluid, with many peculiar words and phrases”
Jampala et al., 1989	Authors' measures of thought disorder		Manic patients: ↑ flight of ideas Schizophrenic patients: ↑ non sequiturs, ↑ tangentiality, ↑ driveling, ↑ neologisms, ↑ private use of words, ↑ paraphasias

TABLE 2–4. Thought Pathology in Mania and Schizophrenia: Similarities and Differences (*continued*)

Study	Thought Disorder Measure	Similarities	Differences
Docherty et al., 1996	Communication Disturbance Index	Structural unclarities; confused, wrong words and vague references	Manic patients: ↑ amount of speech; ↑ ambiguous word meanings Schizophrenic patients: ↑ references to information unknown to listener
Thomas et al., 1996	Brief Syntactic Analysis		Schizophrenic patients: ↓ complexity of speech
Lott et al., 2002	Authors' measures of thought, language, and communication	Most measures of deviant speech	Manic patients: ↑ complexity of speech Schizophrenic patients: ↑ poverty of speech

phrases." The authors elaborated further on these differences (pp. 19–20):

[M]anic thought disorder manifests itself as ideas loosely strung together and extravagantly combined and elaborated . . . appearance of irrelevant intrusions into social discourse that may at times appear inappropriately fliprant and playful. . . . Schizophrenic thought disorder, on the other hand, seems devoid of the playful, compulsively elaborative, and ideationally loose constructions of the manic patients. Characteristic of the schizophrenic patients in this study were fluid thinking, interpenetrations of one idea by another, unstable verbal referents, and fragmented and elliptical communications.

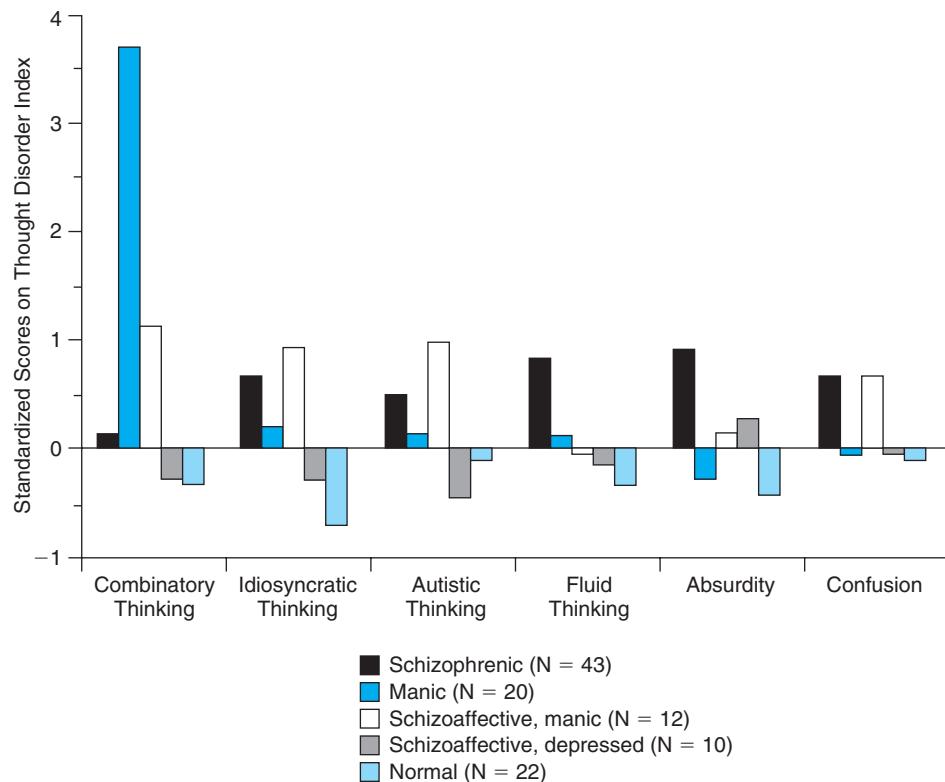

These differences are portrayed in Figure 2–3, which shows standardized Thought Disorder Index scores (on factors derived from a principal components analysis) for 12 schizoaffective (manic) and 10 schizoaffective (depressed) patients, as well as for the manic, schizophrenic, and normal subjects discussed earlier (Shenton et al., 1987). Of note, on the one "manic" factor (combinatory thinking), schizoaffective manic patients were most similar to the manic group, but on the five "schizophrenic" factors (idiosyncratic thinking, autistic thinking, fluid thinking, absurdity, and confusion), they performed more like

the schizophrenic patients. The schizoaffective depressed patients more strongly resembled the normal subjects. Andreasen (1984) found that her schizoaffective patients were midway in thought disorder between the manic and schizophrenic patients. Jampala and colleagues (1989) observed a greatly increased rate of flight of ideas in their manic patients (72 percent) compared with schizophrenic patients (10 percent).

In summary, although the overall amount of thought disorder does not differentiate manic from schizophrenic patients, qualitative differences do exist. Manic patients are more likely than schizophrenics to exhibit more pressured and complex speech; grandiosity; flight of ideas; combinatorial and overinclusive thinking; and a strong affective component to thought that is characterized by humor, playfulness, and flippancy. The causal relationships among affect, psychomotor acceleration, and the often strikingly different manifestations of the underlying thought disorders in mania and schizophrenia remain unclear.

A few studies have followed the course of manic thought disorder over time. Andreasen (1984) observed that most manic patients, unlike schizophrenic patients, demonstrated a reversible thought disorder. Other than a continuing pressure of speech, they showed nearly complete recovery over time. Schizoaffective patients, to a lesser

Figure 2–3. Standardized Thought Disorder Index scores on factors derived from principal components analysis for five groups of subjects. (Source: Shenton et al., 1987.)

extent than the manic patients, also recovered. Ragin and Oltmanns (1987), on the other hand, found that manic patients displayed moderate levels of derailment and loss of goal at initial testing and, unlike other thought-disordered subjects, did not show significant decreases in either of these features at follow-up. The most extensive longitudinal studies of manic thought disorder were conducted by Harrow and colleagues (Harrow et al., 1982, 1986; Grossman et al., 1986). Using a battery of cognitive tests designed to assess bizarre–idiosyncratic thinking (Goldstein–Scheerer Object Sorting Test, Gorham Proverbs Test, and WAIS Social Comprehension Subtest), the investigators tested manic thought disorder in the acute phase (Harrow et al., 1982), 1 year after hospitalization (Harrow et al., 1986), and 2 to 4 years after hospitalization (Grossman et al., 1986). Initial levels of manic thought pathology and changes over time were compared with those obtained for schizophrenic and nonpsychotic psychiatric patients and normal subjects. The results of these comparisons are summarized in Figure 2–4 and presented in further detail below.

In the acute phase, manic patients were extremely thought disordered; 94 percent showed some definite evidence of abnormal thinking, and 73 percent of hospitalized manic patients demonstrated severe levels of bizarre–idiosyncratic thinking. There were no significant differences

in levels of thought disorder between medicated and unmedicated manic patients. Manic patients were at least as thought disordered as, if not more so than, schizophrenic patients (Harrow et al., 1986).

In the short-term follow-up phase (7 weeks), manic thought disorder in medicated patients improved, although some patients continued to show severe thought disorder. Manic patients did not show a more rapid reduction in thought pathology relative to the schizophrenic patients (Harrow et al., 1982).

One year after hospital discharge, a “surprisingly large number” of manic patients showed relatively severe bizarre–idiosyncratic thinking or positive thought disorder (Fig. 2–4). There was also a significant reduction in severity of thought pathology for both manic and schizophrenic patients at follow-up. Manic patients showed a greater reduction in pathology (from 73 to 27 percent rated as severe or very severe) relative to the schizophrenic patients (from 50 to 27 percent) (Harrow et al., 1986).

Two- to 4-year follow-up data revealed that of the manic patients, 30 percent had severe or very severe thought disorder, and another 30 percent had definite signs of abnormal thinking. Of the 14 formerly hospitalized manic patients who showed severe or very severe thought disorder, only 4 were rehospitalized at the time of the follow-up assessment.

Positive thought disorder was associated with manic behavior; that is, those patients who showed more manic behaviors had more severe thought disorder (see Table 2–5). There was a significant correlation between thought disorder and psychosis, but psychotic symptoms alone did not account for all of the variance associated with thought disorder at follow-up. Manic patients with more than one previous hospitalization or with a more chronic manic course had significantly more thought disorder than patients with only one or no previous hospitalizations (Grossman et al., 1986).

These findings of Harrow's group are indicative of the fact that manic thought disorder can prevail long past an acute episode, a point suggesting the need for caution in accepting assumptions of a relatively benign course of illness or of a return to normality for all patients with bipolar illness (see Chapter 4 for further discussion of the problematic course of bipolar disorder). The findings must be tempered, however, by certain methodological constraints, especially one relevant to recent investigations. In the current era, manic-depressive patients seen and treated in university teaching hospitals represent a disproportionately ill and treatment-refractory group. Bipolar patients with a more typical (i.e., salutary) course are now treated, for the most part, by the general psychiatric community. Those patients less responsive to standard medical interventions are more frequently referred to research centers

for evaluation and treatment. Further confounding interpretation of the above findings are issues of patient nonadherence to medication regimens (see Chapter 21), medication side effects, and seasonal biases (e.g., annual assessments, if completed 1, 2, or 4 years after an acute episode, may increase the likelihood of testing during a periodic recurrence rather than a remission). The continuance of significant thought pathology in many manic patients is of both clinical and theoretical relevance and is an important area for further research (see Perugi et al., 1998a, for a discussion of cognitive decline in chronic mania).

Linguistic and Communication Patterns. Investigators have found differences in linguistic patterns between manic and schizophrenic patients (Kagan and Oltmanns, 1981; Harvey, 1983; Ragin and Oltmanns, 1987). Hoffman and colleagues (1986) found that total speech deviance and utterance length were greater in manic than in schizophrenic patients. The authors concluded that "manic speech difficulties were due to shifts from one discourse structure to another, while schizophrenic speech difficulties reflected a basic deficiency in elaborating any discourse structure" (p. 836). In a related study, Fraser and colleagues (1986) found that schizophrenic patients had less syntactically complex speech than manic patients. This finding is consistent with those of the more recent work of Thomas and colleagues

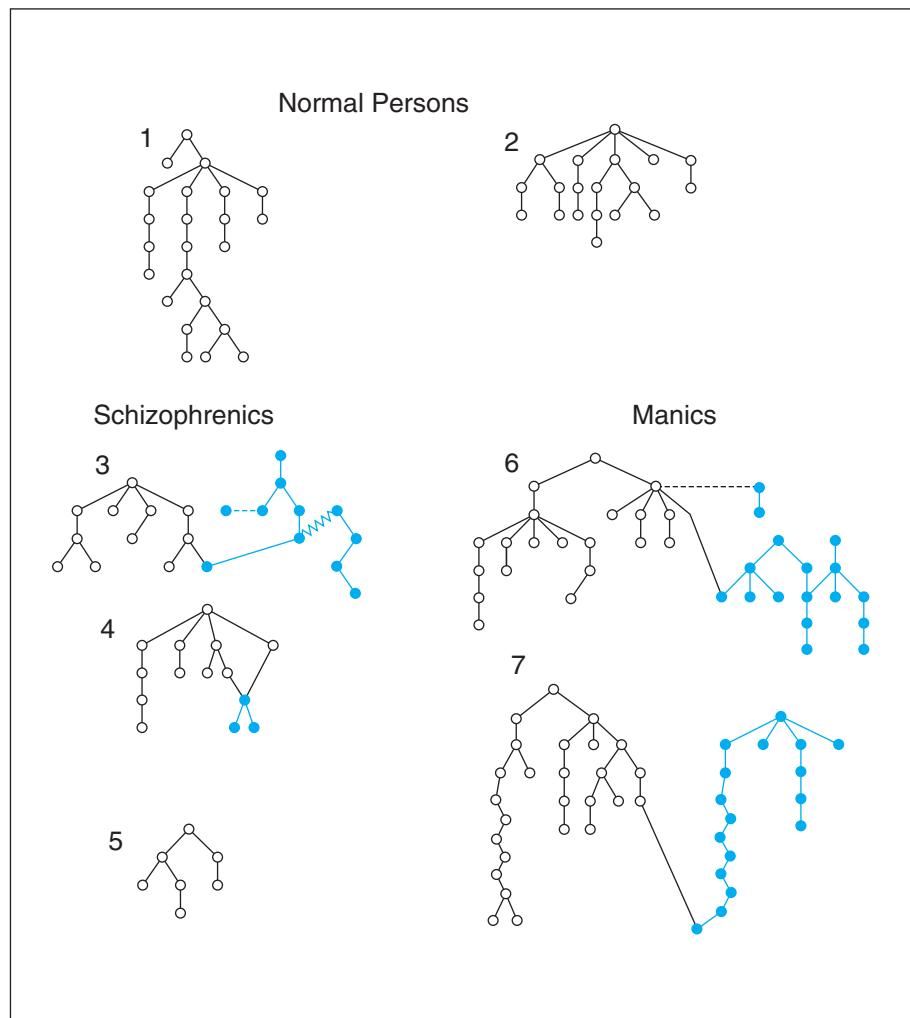

Figure 2–5. Sample of discourse structures taken from three groups. Note: Nodes correspond to statements generated by text. Linkages are formed from dependency relations. Substructures identified by open circles correspond to largest subtree embedded in segment. Jagged line indicates nontransitive dependency; broken lines represent nondependent associations. Upward branching nodes can be seen to receive more than one chain of superordinate statements. Two manic patients have larger subtrees compared with three schizophrenic patients. 1, 2, and 5 are well-formed trees. (Source: Hoffman et al., 1986.)

(1996) and Lott and colleagues (2002), who also found that manic speech was more complex. The structural differences in language are schematized in Figure 2–5. Hoffman and colleagues (1986) speculated that the shift from one discourse structure to another is related to the manic patient's increased distractibility and general level of overactivation, each of which involves both verbal and nonverbal behavior. Distractibility in bipolar illness, which is pervasive and often severe, is discussed in detail in Chapter 9.

Predictability of verbal communication has been studied through close analysis, a measure of the ability of normal subjects to guess words deleted from transcripts of speech samples. Using this technique, Ragin and Oltmanns (1983) found that depressed speech was the most predictable,

schizophrenic the least, and manic somewhere in between. Andreasen and Pfahl (1976) analyzed the frequency of syntactical elements in speech samples taken from 16 manic and 15 depressed patients. Their results are summarized in Table 2–6 and as follows by the authors (p. 1366):

The analysis of syntactical elements was particularly useful in distinguishing between the two groups . . .

[D]epressive speech tends to be more vague, qualified, and personalized, while manic speech is more colorful and concrete . . . [D]epressed patients tend to qualify more, to talk more in terms of a "state of being," and to talk more both about themselves and other people. Manics, on the other hand, tend to talk more about things

than about people, to discuss them in terms of action, and to use more adjectives to describe them.

Delusions and Hallucinations. Problems in the assessment of delusions and hallucinations are many and troublesome. Orvaschel and colleagues (1982) found that family reports of affective delusions identified only 18 percent of probands who admitted such symptoms on direct interview with the Schedule for Affective Disorders-Lifetime (SADS-L). In a study of psychosis in 89 bipolar patients, Rosen and colleagues (1983a) found that 49 (55 percent) emerged as psychotic on the basis of interviews (SADS) alone. After a review of all interviews and prior records, however, 63 were identified as psychotic. Price and colleagues (1984), like Orvaschel and colleagues (1982), found a lack of reliability in reports from family members. Yet as Pope and Lipinski (1978) observed in their early review of the literature, the general findings of all these studies, despite wide differences in time, setting, and sample selection, are reasonably consistent.

Table 2–7 summarizes findings from 33 studies of psychotic features in mania. Approximately two-thirds of the bipolar patients in these studies were found to have a lifetime history of at least one psychotic symptom (phase of illness usually unspecified, but when specified, more often manic). The range of rates was 47 to 90 percent. These results are consistent with Carlson and Goodwin's (1973) finding that 30 percent of their bipolar-I patients (i.e., those with a history of mania) did not progress to stage III mania. Rosenthal and colleagues (1979) also observed that 33 percent of their bipolar-I patients never became formally psychotic during mania. The high prevalence of psychotic features in these studies is consistent with the presence of a psychosis factor in most factorial studies of mania and with Koukopoulos's (2005) assertion that the manic syndrome is basically a psychotic condition.

Some evidence suggests that early age at onset of bipolar illness is likely to be associated with an increased rate

of psychotic symptoms. Carlson and Strober (1979) found that bipolar illness first appearing during adolescence was characterized by especially florid psychotic symptoms. Rosenthal and colleagues (1980) observed that those bipolar-I patients who also met Research Diagnostic Criteria (RDC) for schizoaffective illness had a younger age at onset and more non-Schneiderian delusions and hallucinations. Rosen and colleagues (1983b) found a negative correlation of 0.4 between age at onset and psychotic symptom score. The authors also suggested that their findings raise the possibility that RDC schizoaffective disorders are really a form of bipolar-I disorder. More recent, larger studies have not found a significant correlation between early age at onset and psychotic symptoms, however (Perugi et al., 2000; Toni et al., 2001; Baethge et al., 2005). Age-specific issues relevant to delusions and hallucinations are discussed more fully in Chapter 6.

Akiskal and colleagues (1983) reported that in patients who switched from depression to mania during a prospective observation period of 3–4 years, the index depressive episode was often psychotic. Findings of a new study (Othmer et al., in press) based on more than 1,000 outpatients confirm the strong association between early-onset psychotic depression and eventual manic switch.

Some evidence relates the presence of psychotic symptoms to severity of illness. Abrams and Taylor (1981) found "only a trend" toward an association between severity of manic syndrome and "schizophrenic features," including delusions and hallucinations. Carlson and Goodwin (1973), however, reported covariance between ratings of psychosis and ratings of manic severity. Likewise, Young and colleagues (1983) found a positive relationship between total score on the Mania Rating Scale and the presence of psychotic symptoms. More recently, Baethge and colleagues (2005) found that hospitalizations for bipolar patients who had hallucinations averaged 17 percent longer than those for bipolar patients who did not.

^aLifetime or course of illness.

^b100 episodes, 61 patients.

^cPhase of illness not specified.

^dBipolar fraction unclear.

^e38 reported psychotic symptoms during manic phase only, 6 during both manic and depressed phases, and 5 during depressed phase only.

^f(71) refers to total % psychotic (only 55% were considered psychotic on the basis of interview alone).

^gBipolar I patients only.

^hLow and high symptom threshold values.

ⁱMixed mania figures are in parentheses.

^jWinokur et al. not included in calculation because units are in episodes, not in patients.

The relationship between the presence or a history of psychotic features and the long-term course of illness is unclear. While several studies have not found a correlation between psychosis and poorer outcome,¹⁰ many more have.¹¹ There is even more agreement that mood-incongruent psychotic features predict a less positive course.¹² Only one early investigation (Abrams and Taylor, 1983) and a single recent study (Keck et al., 2003) found otherwise. Keck and colleagues hypothesized that their findings, which are at variance with most others, may reflect the high morbidity and poor functional outcome in the great majority of the patients they studied. There does not appear to be a significant correlation between psychosis and an increased likelihood of attempting suicide (Grunebaum et al., 2001; Black et al., 2003; Keck et al., 2003; see Chapter 8).

Young and colleagues (1983) examined the relationship between psychotic features and other manic symptoms. They found no association of psychotic features with insight, disruptive-aggressive behavior, appearance, and rate and amount of speech, or with demographic variables, such as age, gender, and race. They did find, however, that psychotic patients were significantly more likely than nonpsychotic patients to have grandiose and expansive mood, increased psychomotor activity and energy, and increased sexual interest, and were also more likely to report sleep-disturbance symptoms. Baethge and colleagues (2005), who studied hospitalized bipolar patients, found that those who reported hallucinations were less well educated and had higher anxiety scores, longer hospitalizations, and less insight into their illness. Comparisons of bipolar-I and -II patients have found, as one would expect, a greatly elevated rate (nearly three-fold) of psychotic symptoms in those with bipolar-I (Vieta et al., 1997; Suppes et al., 2001; Serretti et al., 2002).

Finally, Endicott and colleagues (1986) studied 1,084 first-degree relatives of 298 probands with schizoaffective, psychotic, and nonpsychotic unipolar and bipolar major depressive disorders. They found that over the course of a lifetime, bipolar disorder and psychosis were positively associated in both probands and relatives. Bipolar illness in a proband did not predict psychosis in relatives, however, whereas psychosis in a proband was related to increased risk of psychosis (but not to bipolarity) in relatives. According to Endicott and colleagues, these findings suggest that, although bipolarity and psychosis often occur in the same individuals, they may not reflect the same genetic influence. The authors speculated that “the risk for the ‘expression’ of psychotic symptoms is increased in individuals who also have had a bipolar disorder” (p. 11). Interestingly, Winokur and colleagues (1986; Winokur and Kadrmas, 1989) showed that the risk for psychosis, as well as polyepisodic course in bipolar

patients, is predicted by a history of mania and polyepisodic course in the family.

Delusions, like thought disorder, vary widely in severity, fixedness, content, and effect on overt behavior (Jaspers, 1913; Kraepelin, 1921; Garety, 1985). The degree to which they are contingent upon fluctuating affect also varies.

Manic delusions are usually grandiose and expansive in nature, often religious, and not infrequently paranoid. They generally can be differentiated from schizophrenic delusions by their tendency to be wish-fulfilling in nature and oriented more toward communion than segregation (Lerner, 1980). Winokur and colleagues (1969, p. 70) distinguished the presentations of delusions in the two illnesses as follows:

The delusions that are seen in schizophrenia usually last for months or years and are often primary; that is, they do not explain a real or disordered perception. They fulfill the definition of a delusion as a fixed, false belief. In mania the delusions are quite different. They are often evanescent, appearing or disappearing during the course of a day, or even during an interview. They also vary with the patient's total state, being more frequent when he is more active; and his flights of ideas become more pronounced and fading as he becomes more quiet. Frequently they are extensions of the patient's grandiosity.

At times the patient can be talked out of his delusion, and at other times he gives the impression that he is only being playful rather than really being deluded. In our group the delusions were often secondary to the patient's exalted affect. This was especially true of those patients who felt their mood could be described only as a religious experience.

The most subtle and earliest distortions of reality are manifest in the frequent extravagance and grandiose self-image expressed by the patients.

Kraepelin (1921, pp. 68–69) also emphasized the changing nature of manic delusions (especially when contrasted with those expressed during the depressive phase, which he thought were for the most part “uniformly adhered to”): manic delusions “change frequently, emerge as creations of the moment and again disappear”; they “move very frequently on religious territory,” tending to be grandiose; and “patients often narrate all sorts of journeys and adventures, secret experiences.” He also reported that the same delusional ideas often appeared again in subsequent attacks. Winokur and colleagues (1969, p. 72), like Kraepelin, suggested that delusions of mania are “not well systematized and, apart from grandiose optimism, tend not to be acted upon.” They attributed the fact that manic patients seldom act on their delusions (a point perhaps worth disputing) to

the brief duration of the delusions and the patient's "inability to make any sort of concerted action." They noted further that both manic and depressive delusions, which occur primarily in the most disturbed patients, tend to be appropriate to the patient's mood and not to be systematized. The same investigators found that religious themes were the most common manic delusions in both men (27.0 percent) and women (30.1 percent). Political themes were more common in men (18.9 percent) than in women (3.2 percent), and sexual and financial themes were about equally common (13.5 and 9.5 percent, respectively, in men; 5.4 and 7.9 percent, respectively, in women).

Hallucinations, or perceptions of sensory impressions without the existence of external physical stimuli, represent a fascinating, not uncommon, and yet relatively unstudied part of the clinical phenomenology of affective illness. They occupy a portion of the continuum of dream-state–illusory–hallucinatory phenomena, which ranges from distortions and misperceptions on the one hand to the total conjuring of fully developed images on the other. Hallucinations can vary in a wide range of aspects, such as their extent (frequency and duration), location, constancy, intensity, effect on overt behavior, affect produced, content, and causal attributions (Lowe, 1973). Yet despite these complexities, hallucinations are most commonly presented in the psychiatric research literature as simply present or absent in a given sensory modality (e.g., auditory or visual).

Hallucinations generally occur less frequently than delusions in both the manic and depressed phases of bipolar illness, although Carlson and Strober (1979) reported a significantly higher rate of hallucinations in bipolar depression. Baethge and colleagues (2005) found comparable rates of hallucinations in mania and depression, but twice as high a rate in bipolar mixed patients (see Table 2-8). The lifetime history data presented earlier in Table 2-7 suggest that at least half of all patients report a history of delusions, but only about a fifth report the experience of hallucinating while depressed or manic. Auditory hallucinations, averaged across the data-based studies, are more common than visual ones.

Kraepelin (1921, pp. 5–6) found that in mania, the perception of external impressions was "invariably encroached upon" and that defective perceptions often were related to "extraordinary distractibility of attention." He described not only the blurring of illusions, hypnagogic phenomena, and hallucinations, but also their overlap with mood and thinking in the bipolar form of manic-depressive illness (pp. 8, 11):

Isolated hallucinations are observed frequently and in the most different states, although they do not very often

appear conspicuously in the foreground. It is generally a case of illusionary occurrences, the appearance of which is favoured by the incompleteness and slightness of perception, but especially by the lively emotions peculiar to the disease. The substance of the illusions therefore is invariably in close connection with the trains of thought and the moods of the patients. . . .

Auditory hallucinations frequently appear only in the night-time, or at least much more often. They seem, as a rule, not to possess complete sensory distinctness. They are voices "as in a dream" Their origin is relatively seldom referred to the external world. . . . Much more frequently the hallucinations have their seat in the patient's own body.

In an early study, Bowman and Raymond (1931–1932b) compared hallucinations in 1,009 patients with manic-depressive psychoses, 1,408 with schizophrenia, and 496 with general paresis. They found an overall tendency for more women than men to have a history of hallucinations (especially of a visual nature), and observed that women with "seclusive personalities" were at particularly high risk for auditory and visual hallucinations. A recent study of hallucinations in bipolar patients also found that women were more likely than men to report hallucinations (Baethge et al., 2005). Bowman and Raymond found no significant relationship between the presence of hallucinations and religion, age at admission, or level of intelligence. They did observe a close relationship between the clinical nature of the hallucinations in bipolar illness and those present in patients with general paresis. This latter finding is consistent with Lowe's (1973) conclusion that bipolar hallucinations resemble more those of the organic psychoses than those of schizophrenia or paranoia. (This similarity to organic psychosis [toxic versus defect] is also discussed in Chapters 3, 9, and 15.)

Winokur and colleagues (1969) found that manic hallucinations tended to be brief, grandiose, often part of a delusional idea, usually religious ("the face of God," "Heaven in all its glory"), and frequently in the form of a command from God. Manic and depressive hallucinations shared a fragmented and fleeting quality and usually occurred in the most severely disturbed patients. The authors stressed the theoretical importance of a severity profile in bipolar illness, after noting that hallucinations—the least common of symptoms—were also the first symptoms to disappear during recovery from a manic episode, followed in turn by delusions, flight of ideas, push of speech, and distractibility (a general pattern later confirmed by Carlson and Goodwin, 1973).

Although finding hallucinations of generally limited use in differential diagnosis, D.W. Goodwin and colleagues

(1971), in one of the few (albeit small) phenomenological studies, were able to draw several conclusions about the nature of hallucinations in their 28 patients (7 bipolar) with affective illness: (1) the modality of hallucinations (e.g., auditory or visual) was not consistent from one affective episode to another; (2) patients with affective illness were far more likely than those with schizophrenia to hallucinate only when no other person was there; (3) color was usually normal; (4) the people who appeared in the hallucination were usually of normal size and appearance; (5) the hallucinations were intermittent; (6) they were often in several sensory modalities; and (7) accusatory voices were not specific to affective illness—indeed, they were more common in schizophrenia.

Lowe (1973) studied 22 bipolar patients in a particularly intensive and interesting investigation of hallucinations. In comparing these patients with others who had organic, paranoid, or schizophrenic psychoses, he found that they reported mainly auditory and visual hallucinations when manic; that these hallucinations were less frequent and briefer than those occurring in other neuropsychiatric conditions; that in retrospect, the hallucinations were believed by patients to be “less real” but were also perceived

to be less controllable; that women were more likely to report rarer types of hallucinations; and finally, that the patients always believed the hallucinations to be experienced only by themselves. Consistent with other investigators, Lowe concluded that manic hallucinations were more similar in nature to those reported by patients with organic psychoses than to those reported by patients with schizophrenia or paranoia.

Lerner (1980), who also investigated qualitative differences between the psychotic experiences of mania and schizophrenia, concluded that mania was more characterized by enhanced sensory awareness and ecstatic or beatific experiences. Manic hallucinations tended to be more of the visual type; strikingly vivid and associated with bright, colorful sensations; and often coupled with intensely pleasurable or ecstatic feelings (similar to psychedelic experiences). Silberman and colleagues (1985) compared histories of transient sensory phenomena akin to hallucinations in 44 euthymic affective patients (34 bipolar), 37 patients with a history of complex partial seizures, and 30 hypertensive controls. Affective and epileptic patients were similar in their reports of sensory changes, including visual and auditory hallucinations and altered

perceptual intensities. Epileptic patients, however, were far more likely to have experienced epigastric, vestibular, and gustatory hallucinations.

In summary, hallucinations occur less frequently than delusions in both the manic and depressed phases of bipolar illness. Hallucinatory phenomena appear to represent the extreme end of the symptomatic picture, being nonexistent in milder forms of depression and mania and most pronounced in the gravest, most delirious states. Hallucinations during mania are frequently ecstatic and religious in nature, brief and fleeting in duration, and inconstant in their modality of expression. They appear qualitatively, at least in the few studies in which they have been addressed, to be more similar to organic than to schizophrenic psychoses. Gender differences in the experience of hallucinatory phenomena are unclear, although there is some evidence that women are more likely to report having had hallucinations.

Activity and Behavior

The results of studies of activity and behavior during manic states, summarized in Table 2–9, show that disturbed sleep and speech, as well as hyperactivity, are common in mania. About 80 percent of manic patients have either insomnia or a decreased need for sleep. Virtually all, 80–90 percent, exhibit hyperverbosity and rapid or pressured speech. An overwhelming majority are hyperactive, more than half are hypersexual, and one in four exhibits catatonia. There are few studies of gender differences in manic activity and behavior, although a recent New Zealand investigation of 90 bipolar males and 121 bipolar females found that men were significantly more likely to report the presence of “problem behaviors” (the nature of which was not specified) and “excitement or inability to hold a conversation” (Kawa et al., 2005, p. 122). Gender differences in manic sexual behavior are discussed in Chapter 10.

Factorial Studies of Mania

Although a great deal of research has been done on the factorial structure of nonbipolar depressive disorders, the literature on the structure of bipolar depressive states is relatively sparse (reviewed in Azorin, 2000). Until recently, this was also the case for mania. Initially, Beigel and colleagues (1971) concluded, on the basis of a relatively small National Institute of Mental Health (NIMH) sample, that pure manic and dysphoric subtypes could be delineated. Subsequently, new data derived from large clinical samples have confirmed this conclusion, but also painted a much more complex clinical portrait of mania.¹³ The French EPIMAN study (Akiskal et al., 2003a) is multicentered, with patient information being collected by means of a standardized

protocol in at least four regions of France. The main findings of this study are generally consistent with those of earlier research in indicating that further phenomenological understanding of mania requires a multidimensional perspective. The authors of this study went beyond the euphoric–dysphoric dichotomy and proposed the existence of independent euphoric, depressive, hostile, psychotic, and deficit factors, each of which was correlated with a core activation (disinhibition–instability) factor of mania.

Like Bauer and colleagues (1994), Akiskal and colleagues (2001) concluded that, rather than euphoria/irritability, the central definitional focus of mania should be psychomotor activation. This conclusion is consistent with the emphasis of Heinroth (1818) and Koukopoulos (2005), which posits that excitement is the fundamental state of the bipolar subgroup of manic-depressive illness. By incorporating new features of mania derived from the EPIMAN study (e.g., pathological gregariousness and overfamiliarity) and using clinical expertise, different groups of investigators have developed a factorial structure of mania that incorporates psychomotor activation as the major criterion, along with mood disturbance, other signs and symptoms, and a lack of insight and judgment; this work, in conjunction with that of other investigators, has led to proposed changes in the DSM-IV criteria for mania. Ghaemi and colleagues (1995) also underscored the cognitive dysfunction in the areas of insight and judgment in mania; similar findings were reported by Dell’Osso and colleagues (2000). Interestingly, insight appears to be less impaired during mixed mania (Cassidy et al., 2001a; see Chapters 21 and 22).

Table 2–10 summarizes the findings of factorial studies of the structure of mania. It is clear that current diagnostic systems fail to reflect the actual complexity of the state. Nor do most diagnostic formulations adequately capture the essential relationship, indeed the often total overlap, between major subtypes of mania and mixed states. Virtually all investigations of the structure of mania have noted common underlying dimensions: a mood component, characterized by either predominantly euphoric or dysphoric qualities; psychomotor activation; psychotic features; and irritability and/or aggression.

There are fewer data on the structure of hypomania, but as with mania, cardinal manifestations are irritability, coupled with heightened activation and behavioral excess. Serretti and Olgati (2005) compared patterns of manic symptoms in 158 bipolar-I and 122 bipolar-II patients (see Table 2–11). The bipolar-I patients had a higher prevalence of reckless activity, distractibility, psychomotor agitation, irritable mood, and increased self-esteem. Juruena and colleagues (2006) compared 27 bipolar-I patients with

25 bipolar-II patients. Those with bipolar-I reported a higher frequency of racing thoughts, grandiosity, impaired judgment, and decreased total sleep time. Patients with bipolar-II disorder experienced 3.5 times more depressive episodes and four times the rate of lifetime substance abuse disorders. Benazzi (2005) emphasized that there are no clear boundaries between mania and hypomania and that overactive behavior during hypomania is at least as important as hypomanic mood. To date, fewer factors have been derived for hypomania: energy–activity; irritability–racing thoughts, which, as noted earlier, is putatively a

dysphoric expression of hypomania (Benazzi and Akiskal, 2003); and, more recently, an “elevated mood” factor that includes elevated mood and increased self-esteem (Benazzi, 2006). Hantouche and colleagues (2003) also found a dual structure of hypomania, although the factors were slightly different: one factor was defined by positive (driven–euphoric) features, and the other by greater irritability and risk taking.

The factorial structure of mania and hypomania is a relatively new area of clinical investigation, and future studies are needed to follow up on this preliminary work.

Source: Adapted from Serretti and Olgiati, 2005.

In particular, little is known about the longitudinal stability of these factors, although the findings of one short-term follow-up study suggest such a possibility for the manic and mixed subtypes (Cassidy et al., 2002).

DEPRESSIVE STATES

Classic Clinical Descriptions

The bipolar depressive states, in sharp contrast to the manias, are usually characterized by a slowing or decrease in almost all aspects of emotion and behavior: rate of thought and speech, energy, sexuality, and the ability to experience pleasure. As with the manic states, severity varies widely. Symptoms can range from mild physical and mental slowing, with very little distortion in cognition and perception, to profound depressive stupors, delusions, hallucinations, and clouding of consciousness. Of the three major symptomatic groups we have been examining—mood, cognition and perception, and activity and behavior—mood is perhaps the least variable across the continuum of depressive states, although, as we shall see, irritability and anger often accompany the more usual melancholic picture. Cognition and perception, on the other hand, change profoundly, as do activity and behavior. We begin with extensive classic descriptions of depressive mood, then discuss

changes in cognition and perception and activity and behavior in various depressive states (i.e., nonpsychotic, psychotic, and stuporous depressions). Cognition and perception are treated most extensively in the discussion of psychotic depression, whereas activity and behavior figure more prominently in the discussion of stuporous depression. First, however, we present an ancient description of melancholia from Aretaeus (*Extant Works*, pp. 299–300):

The patients are dull or stern, dejected or unreasonably torpid, without any manifest cause: such is the commencement of melancholy. And they also become peevish, dispirited, sleepless, and start up from a disturbed sleep.

Unreasonable fear also seizes them, if the disease tends to increase, when their dreams are true, terrifying, and clear: for whatever, when awake, they have an aversion to, as being an evil, rushes upon their visions in sleep. They are prone to change their mind readily; to become base, mean-spirited, illiberal, and in a little time, perhaps, simple, extravagant, munificent, not from any virtue of the soul, but from the changeableness of the disease. But if the illness becomes more urgent, hatred, avoidance of the haunts of men, vain lamentations; they complain of life, and desire to die. In many, the understanding so leads to insensibility and fatuousness, that they become ignorant

of all things, or forgetful of themselves, and live the life of the inferior animals. . . . They are voracious, indeed, yet emaciated; for in them sleep does not brace their limbs either by what they have eaten or drunk, but watchfulness diffuses and determines them outwardly.

Mood

Mood in all of the depressive states is bleak, pessimistic, and despairing. A deep sense of futility is often accompanied, if not preceded, by the belief that the ability to experience pleasure is permanently gone. The physical and mental worlds are experienced as monochromatic, as shades of gray and black. Heightened irritability, anger, paranoia, emotional turbulence, and anxiety are common. The frightening lack of color and the inability to experience meaningful emotional responses were described by Campbell (1953, p. 106):

General impairment in emotional feeling is another symptom often described by the manic-depressive patient in a depressive episode. In addition to distortions in sensing impressions, such as a queer, odd or unreal feeling, the patient may complain of a universal dulling of the emotional tone. This symptom, like the feeling of unreality, frightens the patient because it tends to alienate him from his environment. Indeed, it is an important constituent of the patient's fear of insanity. It is bad enough not to speak the same language as other people—it is worse not to feel the same emotions.

Mayer-Gross and colleagues (1960, p. 209) emphasized the negative cognitive and affective tone of depressed patients:

There is a diminished capacity for normal affective response to sad as well as happy events, a phenomenon which is merely one aspect of a *generalized insufficiency of all mental activities*. . . . Whatever is experienced seems to be painful. Even enjoyable experiences have this effect, partly by making the patient more acutely aware of his incapacity for normal appreciation, partly because he is at once sensible of any unfortunate aspect they may have; he may in fact show considerable ingenuity in seeing the bad side of everything. Past, present, and future are alike seen through the same dark and gloomy veil; the whole of life seems miserable and agonizing. The depth of the affect cannot easily be measured from its *outward expression*. The silent shedding of tears may be seen in an otherwise expressionless face; another patient will mock at himself and at his complaints with a grim and sardonic but surprising humour or call himself a fraud or a fool: in another a sudden smile or expression of gaiety will deceive the physician about the severity of the underlying emotion.

Cognition and Perception

Most mental activity is markedly slowed during depression. By definition, patients with nonpsychotic depression do not manifest clouding of consciousness, nor do they experience delusions or hallucinations. Suicidal thinking, however, is often of dangerous proportions, and morbidly ruminative and hypochondriacal thinking is common. The profoundly slowed but nonpsychotic nature of this type of depressive thought and its indecisive and ruminative quality are portrayed in the following passage from Kraepelin (1921, p. 75)¹⁴:

Thinking is difficult to the patient, a disorder, which he describes in the most varied phrases. He cannot collect his thoughts or pull himself together; his thoughts are as if paralyzed, they are immobile. . . . He is no longer able to perceive, or to follow the train of thought of a book or a conversation, he feels weary, enervated, inattentive, inwardly empty; he has no memory, he has no longer command of knowledge formerly familiar to him, he must consider a long time about simple things, he calculates wrongly, makes contradictory statements, does not find words, cannot construct sentences correctly.

Jaspers (1997, p. 597; first published in 1913) described the profound impairment of will, pervasive gloom, and dearth of ideas in depression. The central core of pure depression, he wrote, is formed from

an equally unmotivated and profound sadness to which is added a retardation of psychic events, which is as subjectively painful as it is objectively visible. All instinctual activities are subjected to it. The patient does not want to do anything. The reduced impulse to move and do things turns into complete immobility. No decision can be made and no activity begun. Associations are not available. Patients have no ideas. They complain of a complete disruption of memory. They feel their poverty of performance and complain of their inefficiency, lack of emotion and emptiness. They feel profound gloom as a sensation in the chest or body as if it could be laid hold of there. The depth of their melancholy makes them see the world as grim and grey. They look for the unfavourable and unhappy elements in everything. They accuse themselves of much past guilt (self-accusations, notions of having sinned). The present has nothing for them (notions of worthlessness) and the future lies horrifyingly before them (notions of poverty, etc.).

Activity and Behavior

Like thought and verbal expression, activity and behavior are slowed in bipolar depression. Fatigue, lack of activity, withdrawal from the company of others, impairment in

the volition of will, and profoundly altered sleep and eating patterns are hallmarks of this type of depression (see Chapter 16 for detailed discussion of altered sleep and activity patterns). Campbell (1953, p. 85) described the fatigued, psychomotorically retarded appearance of depressed patients:

Depressed mood is often suggested by the bearing, gait or general appearance of the patient. The depressed individual usually walks slowly and reacts sluggishly. He appears to push himself along, as if he were being held back, rather than propelling himself with normal agility. There are no unnecessary movements with the hands or feet, the patient sitting in a languorous but not restful posture. The shoulders sag, the head is lowered and the entire body seems to droop; loosely hanging clothes sometimes suggest the weight loss often present in the melancholic individual. Everyone is acquainted with the tendency of the angles of the mouth to turn down in the saddened person; a smile, when it occurs, must be forced, and even then there is something sickly or distorted in its expression. The facial musculature of the depressed individual lacks tone, giving the face an inert, myasthenic appearance. The upper eyelids also manifest this careworn expression....

The eyes, which normally portray the spark, vitality and curiosity of the personality, are dull and lustreless. In some individuals the eyes have a faraway, unnatural stare, which even the layman recognizes as a mark of extreme pre-occupation or mental illness.

Disturbances in both the quality and quantity of sleep during depression can be profound but variable. Jaspers (1997, p. 234) noted that depressive sleep is

sometimes abnormally deep, so that patients sometimes feel as if they had been dead. It may however be abnormally light and the patients never feel refreshed, but have vivid, restless and anxious dreams, and feel as if only half of their being had been asleep, the other half had stayed awake and watched. *Duration of Sleep* may be very lengthy . . . in some depressed states. The patients are always wanting to sleep and sometimes sleep twelve hours uninterruptedly. On the other hand we find sleep abnormally curtailed. The patients go to sleep but are awake again soon after and then lie awake all night long. Or they only manage to get off to sleep towards morning.

Suicide is an all-too-frequent outcome of bipolar depression (see Chapter 8). In the words of Kraepelin (1921, pp. 25, 87–88):

The torment of the states of depression, which is nearly unbearable, according to the perpetually recurring state-

ments by the patients, engenders almost in all, at least from time to time, weariness of life, only too frequently also a great desire to put an end to life at any price. . . .

The extraordinarily strong tendency to suicide is of the greatest practical significance. Sometimes it continually accompanies the whole course of the disease, without coming to a serious attempt owing to the incapacity of the patients to arrive at a decision. . . . Sometimes the impulse to suicide emerges very suddenly without the patients being able to explain the motives to themselves. . . .

Occasionally after indefinite prodromata the first distinct morbid symptom is a suicidal attempt. Only too often the patients know how to conceal their suicidal intentions behind an apparently cheerful behaviour, and then carefully prepare for the execution of their intention at a suitable moment.

Psychotic depression (Kraepelin's *melancholia gravis*) is characterized by the same signs and symptoms as those present in nonpsychotic depression, usually in worsened form, with the addition of delusions and/or hallucinations. The following is Bleuler's (1924, pp. 475–476) description of the nature and extent of depressive delusions, hallucinations, and paranoia, as well as their primary content areas of expression (somatic, religious, and financial):

In the severer cases delusions are invariably present and may stand in the foreground. At the same time the hallucinations usually but not always increase. . . . The devil appears at the window, makes faces at the patients. They hear themselves condemned, they hear the scaffold erected on which they are to be executed, and their relatives crying who must suffer on their account, or starve or otherwise perish miserably.

But the *delusions* especially are never absent in a pronounced case and always as delusions of economic, bodily, and spiritual ruin. The patients think that they became poor, and it does no good to show them their valuables or their balance in the bank; that has no significance for them. Debts are there anyway, or demands are to be expected that will wipe out everything.

A more severe form of psychotic depression, although still less severe than delirious depression, was termed by Kraepelin *fantastic melancholia* (equivalent to Griesinger's *melancholia with delusions*, or what other clinicians have called *depressive insanity*). Delusions and hallucinations are more pronounced, some clouding of consciousness usually occurs, and violent excitement can alternate with mild stuporous states. As described by Kraepelin (1921, pp. 89–95):

[a] further, fairly comprehensive group of cases is distinguished by a still greater development of *delusions*. We

may perhaps call it "fantastic melancholia." Abundant *hallucinations* appear. . . . [T]here are also multifarious delusional interpretations of real perceptions. The patient hears murderers come; some one is slinking about the bed; a man is lying under the bed with a loaded gun; an electro-magnet crackles. . . . The trees in the forest, the rocks, appear unnatural, as if they were artificial, as if they had been built up specially for the patient, in fact, even the sun, the moon, the weather, are not as they used to be. . . .

Hypochondriacal delusions usually reach a considerable development; they often completely resemble those of the paralytic. . . .

Consciousness is in this form frequently somewhat clouded. The patients perceive badly, do not understand what goes on, are not able to form clear ideas. They complain that they cannot lay hold of any proper thought, that they are beastly "stupid," confused in their head, do not find their way, also perhaps that they have so many thoughts in their head, that everything goes pell-mell. . . .

The Volitional Disorders are also not quite uniform. The activity of the patients is frequently dominated by volitional inhibition; they are taciturn, even mute, cataleptic; they lie with vacant or strained expression of countenance in bed. . . .

At times more violent states of excitement may be interpolated. The patients scream, throw themselves on the floor, force their way senselessly out, beat their heads, hide away under the bed, make desperate attacks on the surroundings. . . . Serious attempts at suicide are in these states extremely frequent.

Delirious melancholia represents the most severe stage of cognitive and perceptual distortion and disorientation. Delusional thought becomes progressively unclear and fragmented, and hallucinations are particularly vivid, bizarre, and frightening. It is a depressive state characterized predominantly by clouding of consciousness. Kraepelin (1921, pp. 95–97) wrote more than anyone since about the mental and physical aspects of this stage of depression:

Gradual transitions lead to a last, delirious group of states of depression, which is characterized by *profound visionary clouding of conscience*. Here also numerous, terrifying hallucinations, changing variously, and confused delusions are developed. . . .

During these changing visionary experiences the patients are outwardly for the most part strongly inhibited; they are scarcely capable of saying a word. They feel confused and perplexed; they cannot collect their thoughts, know absolutely nothing any longer, give contradictory, incomprehensible, unconnected answers, weave in words which they have heard into their detached,

slow utterances which they produce as though astonished. . . . For the most part the patients lie in bed taking no interest in anything.

Depressive stupor, the most severe form of psychomotor retardation, often constitutes an acute medical emergency. Although it is rarely seen today, it is an important clinical presentation and one that provides insight into the severity of the illness prior to the modern treatment era. The state was described by Henderson and Gillespie (1956, p. 258):

This condition may be defined as a state of intense psychic inhibition during which regression may occur to an infantile, if not more primitive level. The patient, usually, is confined to bed, is mute, inactive and unco-operative. His bodily needs require attention in every way; he has to be fed, washed and bathed. Precautions have to be taken to prevent the retention of faeces, urine and saliva. In some cases all attempts at movement are strongly resisted. In other cases the muscles are more flaccid, and the body and limbs can be moulded into any position. On the surface it may seem as if there was a total absence of feeling or emotion, but that is often more apparent than real, for, after recovery, many patients give a vivid account of the distress which they have experienced. The idea of death is believed by some to be almost universal in stupor reactions, and may be regarded as a form of expiation for the wickedness for which they hold themselves responsible. Some patients may have a clear appreciation of their position and surroundings throughout the whole period of the stupor, but in the majority a considerable dulling of consciousness occurs.

During all these stages of depression the *physical health* suffers greatly. The patient becomes weak, loses weight, has a poor appetite, a coated tongue, and constipation. The circulation is enfeebled, and there is cyanosis, especially of the extremities.

Subjective Experiences of Patients

Mood

Mood in bipolar depression tends to be dominated by a dull, flat, and colorless sense of experience; by despair, hopelessness, and pessimism, often fueled by marked physical and mental lethargy; and by a sharp decrease in the pleasure obtained from ordinarily gratifying events, interests, and people.

Depression is paralyzing and suffocating to those in its grasp. Five years before she killed herself, Sylvia Plath (1982, p. 240) wrote of this in her journal: "I have been and am battling depression. I am now flooded with despair, almost hysteria, as if I were smothering. As if a great muscular owl were sitting on my chest, its talons

clenching and constricting my heart.” British writer Alan Garner (1997, pp. 208–209) portrayed the deadening and the horror of the beginning of his manic-depressive breakdown:

The next thing I remember is that I was standing in the kitchen, the sunlit kitchen, looking over a green valley with brook and trees; and the light was going out. I could see, but as if through a dark filter. And my solar plexus was numb.

Some contraption, a piece of mechanical junk left by one of the children, told me to pick it up. It was cylindrical and spiky, and had a small crank handle. I turned the handle. It was the guts of a cheap musical box, and it tinkled its few notes over and over and over again, and I could not stop. With each turn, the light dimmed and the feelings in my solar plexus spread through my body. When it reached my head, I began to cry with terror at the blankness of me, and the blankness of the world.

A scene from Eisenstein’s “Alexander Nevsky” swamped my brain: the dreadful passage in which Nevsky dupes the Teutonic Knights onto the frozen lake, and the ice breaks, and their faceless armour takes them under. The cloaks float on the water before being pulled down, and the hands clutch at the ice floes, which flip over and seal in the knights.

All that helplessness, cold and horror comprised me. I was alone in the house, and throughout the afternoon I turned the tinkle tinkle tinkle of the broken toy, which became the sound of the ice. My body was as heavy as the armour and the waterlogged cloaks as I slid beneath the ice.

When the family came home, I was lying on the kitchen settle, in a foetal position, without moving or speaking, until I went to bed at midnight. Sleep was unconsciousness without rest. . . .

I was incapable of emotion except that of being incapable of emotion. I had no worth. I poisoned the planet.

Composer Hugo Wolf’s account of his depression (quoted in Walker, 1968, p. 322) focused, as have many descriptions written by depressed or formerly depressed individuals, on the painful contrast between the subjective experience of an arid, sterile reality and a perception of the external world as an unobtainable, visible but not habitable world of light, warmth, and creation:

What I suffer from this continuous idleness I am quite unable to describe. I would like most to hang myself on the nearest branch of the cherry trees standing now in full bloom. This wonderful spring with its secret life and movement troubles me unspeakably. These eternal blue skies, lasting for weeks, this continuous sprouting and budding in nature, these coaxing breezes impregnated

with spring sunlight and fragrance of flowers . . . make me frantic. Everywhere this bewildering urge for life, fruitfulness, creation—and only I, although like the humblest grass of the fields one of God’s creatures, may not take part in this festival of resurrection, at any rate not except as a spectator with grief and envy.

The sense of lost energy is of singular importance in understanding the subjective experience of depression. The ebb and flow of life’s force or vitality and its painful absence in depression were described by F. Scott Fitzgerald in *The Crack-Up* (1956, p. 74; first published in 1936), a harrowing account of his nervous breakdowns:

[O]f all natural forces, vitality is the incommunicable one. In days when juice came into one as an article without duty, one tried to distribute it—but always without success; to further mix metaphors, vitality never “takes.” You have it or you haven’t it, like health or brown eyes or honor or a baritone voice. “*Ye are the salt of the earth. But if the salt hath lost its savour, wherewith shall it be salted?*”—Matthew 5:13¹⁵

Cognition and Perception

Cognitive changes during depression can be subtle or profound and often are a combination of both. Depressed patients frequently complain that their process of thinking has slowed down. They are confused and ruminative, cannot concentrate, and feel inadequate and useless. John Custance (1952, p. 62) wrote:

I seem to be in perpetual fog and darkness. I cannot get my mind to work; instead of associations “clicking into place” everything is inextricable jumble; instead of seeming to grasp a whole, it seems to remain tied to the actual consciousness of the moment. The whole world of my thought is hopelessly divided into incomprehensible watertight compartments. I could not feel more ignorant, undecided, or inefficient. It is appallingly difficult to concentrate, and writing is pain and grief to me.

Irrational fears, which can range from fear and panic to obsession and delusion, are common in depression. Fitzgerald (1956, p. 75) summed up the experience as “the dark night of the soul”:

Now the standard cure for one who is sunk is to consider those in actual destitution or physical suffering—this is an all-weather beatitude for gloom in general and fairly salutary day-time advice for everyone. But at three o’clock in the morning, a forgotten package has the same tragic importance as a death sentence, and the cure doesn’t work—and in a real dark night of the soul it is always three o’clock in the morning, day after day.

Robert Schumann (quoted in Niecks, 1925, p. 142) was even more explicit about his terror:

I was little more than a statue, neither cold nor warm; by dint of forced work life returned gradually. But I am still so timid and fearful that I cannot sleep alone. . . . Do you believe that I have not courage to travel alone to Zwicken for fear that something might befall me? Violent rushes of blood, unspeakable fear, breathlessness, momentary unconsciousness, alternate quickly.

Preoccupation with sin and perceived religious transgressions are not uncommon in severe depression, and many deeply depressed patients would empathize with Cowper's "strong sense of God's wrath, and a deep despair of escaping it." William James wrote definitively of this preoccupation, as well as of religious ecstasies, in *The Varieties of Religious Experience* (1902).

Finally, as noted above, thoughts of suicide often accompany the despair, apathy, guilt, and feelings of inadequacy associated with depression. Extensive discussion of suicidal thoughts and behaviors is given in Chapter 8; here we present one woman's description of the depression leading up to a nearly lethal suicide attempt (Jamison, 1995; pp. 110–111, 113):

A floridly psychotic mania was followed, inevitably, by a long and lacerating, black, suicidal depression; it lasted more than a year and a half. From the time I woke up in the morning until the time I went to bed at night, I was unbearably miserable and seemingly incapable of any kind of joy or enthusiasm. Everything—every thought, word, movement—was an effort. Everything that once was sparkling now was flat. I seemed to myself to be dull, boring, inadequate, thick brained, unlit, unresponsive, chill skinned, bloodless, and sparrow drab. I doubted, completely, my ability to do anything well. It seemed as though my mind had slowed down and burned out to the point of being virtually useless. The wretched, convoluted, and pathetically confused mass of gray worked only well enough to torment me with a dreary litany of my inadequacies and shortcomings in character, and to taunt me with the total, the desperate, hopelessness of it all. What is the point in going on like this? I would ask myself. Others would say to me, "It is only temporary, it will pass, you will get over it," but of course they had no idea how I felt, although they were certain that they did. Over and over and over I would say to myself, If I can't feel, if I can't move, if I can't think, and I can't care, then what conceivable point is there in living?

The morbidity of my mind was astonishing: Death and its kin were constant companions. I saw death everywhere, and I saw winding sheets and toe tags and body

bags in my mind's eye. Everything was a reminder that everything ended at the charnel house. My memory always took the black line of the mind's underground system; thoughts would go from one tormented moment of my past to the next. Each stop along the way was worse than the preceding one. . . .

At the time, nothing seemed to be working, despite excellent medical care, and I simply wanted to die and be done with it. I resolved to kill myself. I was cold-bloodedly determined not to give any indication of my plans or the state of my mind; I was successful.

Activity and Behavior

Although social isolation, psychomotor retardation or agitation, and other behavioral changes accompany depression, changes in sleep patterns are among the most pervasive, quantifiable, and pathognomonic symptoms. They are also highly distressing for patients. (Research on sleep disturbances is discussed in detail in Chapter 16.) Sylvia Plath—probably bipolar, certainly hospitalized and treated for severe depression—described her experience thus in her autobiographical novel *The Bell Jar* (1971, pp. 142–143):

I hadn't washed my hair for three weeks. . . .

I hadn't slept for seven nights.

My mother told me I must have slept, it was impossible not to sleep in all that time, but if I slept, it was with my eyes wide open, for I had followed the green, luminous course of the second hand and the minute hand and the hour hand of the bedside clock through their circles and semicircles, every night for seven nights, without missing a second, or a minute, or an hour.

The reason I hadn't washed my clothes or my hair was because it seemed so silly.

I saw the days of the year stretching ahead like a series of bright, white boxes, and separating one box from another was sleep, like a black shade. Only for me, the long perspective of shades that set off one box from the next had suddenly snapped up, and I could see day after day after day glaring ahead of me like a white, broad, infinitely desolate avenue.

It seemed silly to wash one day when I would only have to wash again the next.

It made me tired just to think of it.

I wanted to do everything once and for all and be through with it.

Likewise for Scott Fitzgerald (1956, pp. 72–73; first published in 1936), sleep and hating to face the night became sources of terror:

[E]very act of life from the morning toothbrush to the friend at dinner had become an effort . . . hating the night

when I couldn't sleep and hating the day because it went towards night. I slept on the heart side now because I knew that the sooner I could tire that out, even a little, the sooner would come that blessed hour of nightmare which, like a catharsis, would enable me to better meet the new day.

Clinical Studies

There has been much less quantitative study of the clinical features of bipolar depression than is the case for either mania or nonbipolar depression. In fact, the substantial literature on depression seldom differentiates bipolar from unipolar depression,¹⁶ and until recently, bipolar depression was usually excluded from study and discussion. Further complicating matters, bipolar depression has frequently been misdiagnosed as unipolar depression, or not discussed in the context of its often mixed forms. For our data-based clinical description of bipolar depression, we have relied primarily upon the early monograph of Winokur and colleagues (1969), Benazzi's series of outpatient studies,¹⁷ and the work of several other researchers (Perugi et al., 1998a; Koukopoulos and Koukopoulos, 1999; Mitchell et al., 2001). Specific comparisons of bipolar and unipolar depression are presented in Chapter 1.¹⁸ In this section we present the findings of data-based studies with regard to symptom presentation in bipolar depression, psychotic features, depressive mixed states, and bipolar–unipolar differences in depressive symptomatology.

Mood

Winokur and colleagues (1969) studied the symptomatology and clinical course of 21 treated bipolar depressed patients (5 men and 16 women, with a combined total of 33 separate depressive episodes). They described the onset of depression as abrupt in 5 episodes (15 percent) and gradual in 28 (85 percent). Mood was observed to be melancholic or tearful in virtually all patients (100 and 94 percent, respectfully), with approximately half (52 percent) displaying hopelessness. Fully three-fourths of bipolar depressed patients were described as irritable, almost as high a percentage (85) as was found by the same authors in manic patients (see Table 2–1). Irritability, which is pervasive during bipolar depression (Deckersbach et al., 2004; Benazzi and Akiskal, 2005), is considered more extensively later in this section, as well as in the subsequent discussion of mixed depressive states.

Cognition and Perception

Winokur and colleagues (1969) found widespread cognitive and perceptual changes during bipolar depression. Self-deprecatory and self-accusatory thoughts were present in almost all patients (97 and 91 percent, respectively).

With few exceptions, patients also reported substantially impaired cognitive ability: 91 percent reported poor concentration, diminished clarity of thought, and/or diminished speed of thought. Half complained of poor memory. Suicidal thoughts were common (82 percent), a figure in close agreement with the rate (83 percent) found in a later study of bipolar depressed adolescents (Carlson and Strober, 1979).

Frequencies of thought disorder in manic, depressed, and normal subjects (as measured by the Scale for the Assessment of Thought, Language and Communication) were analyzed in three early studies (Ianzito et al., 1974; Andreasen 1979a, 1984). Manic patients were more likely than depressive patients to exhibit pressured speech, distractibility, derailment, illogicality, loss of goal, perseveration, and a higher overall global rating of thought disorder. Depressed patients, by contrast, were more likely than manic patients to demonstrate poverty of speech. There were no differences between manic and depressed patients in ratings of poverty of content of speech, tangentiality, clanging, neologisms, word approximations, circumstantiality, echolalia, blocking, or stilted speech. When compared with normal subjects, depressed patients displayed greater poverty of content of speech, as well as increased tangentiality, circumstantiality, and self-reference. Normal subjects were more likely than depressed patients to exhibit derailment. Andreasen (1979a,b, 1984) found less evidence of thought disorder in her depressed patients than in schizophrenic patients, perhaps reflecting either true differences or differences in illness severity, assessment techniques, and diagnostic criteria (bipolar–unipolar differences were not specified).

Delusions and hallucinations often occur in severe bipolar depression, but they are less frequent than psychotic symptomatology in mania. Depressive delusions tend to focus on fixed ideas of guilt and sinfulness, poverty, hypochondriacal and somatic concerns, and feelings of persecution.¹⁹ As shown in Table 2–8 (presented earlier), delusions were present in 12 to 66 percent of bipolar depressive episodes versus 44 to 96 percent of manic episodes. Hallucinations, less common in both mania and depression, were relatively more frequent in manic episodes. Several investigators have found a constancy in the presence or absence of psychotic symptoms across major depressive episodes,²⁰ although generalizability from unipolar to bipolar depression has not been demonstrated. Charney and Nelson (1981) found that 95 percent of their delusional patients but only 8 percent of their nondelusional patients had experienced prior delusional episodes. Among patients whose index admission was psychotic, 89 percent of all previous episodes had been psychotic as well. Helms and Smith (1983) reported that 92 percent of their psychotic

depressive patients with recurrent illness had experienced another admission for psychotic depression, while Lykouras and colleagues (1985) found that 92 percent of their delusional depressive patients had experienced previous episodes with delusional ideation, compared with 36 percent of their nonpsychotic depressive patients. Nelson and colleagues (1984, p. 298) observed:

It would appear that the presence of delusions during an index episode of depression may be not merely an indicator of severity of that episode, but additionally a distinct stable trait which would be expressed in the biologically vulnerable individual during prior and subsequent episodes.

Aronson and colleagues (1988), studying bipolar as well as unipolar delusional depressive patients, also found a consistency of psychotic expression across episodes, as well as an association with a marked rate of relapse. They noted that psychoticism may be an independent variable that can present in either bipolar or nonbipolar depression. The question of whether psychoticism is to some extent independent of polarity and diagnosis (for example, schizophrenia and bipolar illness) is discussed in Chapter 13, as are family-history studies of bipolar and unipolar delusional depression; additional reviews of clinical correlates of unipolar delusional depression are presented elsewhere.²¹ A recent large-scale analysis ($N=4,274$) of three family studies found that the diagnosis of bipolar-I was far more predictive of psychotic symptoms during depression than was the diagnosis of recurrent major depression (odds ratio [OR] = 5.13) (Goes et al., *in press*).

Bipolar patients who experience psychotic depressions tend to have a more severe and more chronic course than those who do not. They also have fewer atypical features and less Axis I comorbidity (Benazzi, 1999c).

Activity and Behavior

Activity, behavior, and somatic symptoms during bipolar depression as noted by Winokur and colleagues (1969) are summarized in Table 2-12; comparison figures from Carlson and Strober (1979) and Casper and colleagues (1985) also are given. Sleep difficulties are pronounced and pervasive. Fatigue and psychomotor retardation are seen in approximately three-fourths of bipolar depressed patients; loss of appetite and sexual drive are common as well. Women are more likely than men to report weight and appetite changes during periods of bipolar depression (Benazzi, 1999; Kawa et al., 2005). Most patients have somatic complaints, and the majority report a diurnal mood variation (most feel worse in the morning and better in the evening).

MIXED STATES

Mixed states, in which symptoms of depression and mania combine, represent a complex and often confusing aspect of the clinical presentation of bipolar illness. They can be conceived of as transitional states from one phase of illness to another or as independent clinical states combining various mixes of mood, thought, and activity components. To a considerable extent, mixed states are even more vulnerable to the inadequacies of modern diagnostic systems than other types or stages of affective illness. Indeed, systematic diagnostic criteria, impressively standardized for most other types and phases of affective disorders, are least validated for mixed states. Differential diagnosis—especially among mixed states, agitated depressions, and borderline pathologies—can be a difficult clinical problem (see Chapter 3).

Mixed states are broadly defined as the simultaneous presence of depressive and manic symptoms. Yet we know, for example, as noted earlier, that mania frequently is accompanied by moderate to severe depression. Should depression during mania be conceptualized as a mixed state, a typical mania, an atypical mania, or a severe (stage-related) form of mania? Should a mixed depressive episode be defined by the presence of four manic symptoms or only two? Are the diagnostic criteria of DSM-IV prohibitively strict, as most researchers think? (According to DSM-IV, a diagnosis of mixed states requires that all of the criteria, except duration, for both a manic and a depressive episode be met “nearly every day” during at least a 1-week period, and that the symptoms be severe enough to cause “marked impairment” or necessitate hospitalization, or that there be psychotic features.) Until more systematic and discriminating definitions and criteria are developed, the pragmatism of the immediate clinical or research issue will determine the answers to such questions.

Classic Clinical Descriptions

Mixed states are important for both theoretical and clinical reasons. (Their implications for pathophysiology are discussed in Chapter 17 and for treatment in Chapters 18 and 19.) Despite the diagnostic difficulties noted above, their existence has been recognized for centuries. A seventeenth-century physician (Broughier, 1679; cited in Dewhurst, 1962, p. 122) described the alternating and combining qualities of mania and melancholy in one of his patients, a Lady Grenville. Characterizing the illness as “her Ladyship’s annual raving,” he wrote to her husband:

For there are twin symptoms, which are her constant companions, Mania and Melancholy, and they succeed each other in a double and alternate act; or take each other’s place like the smoke and flame of a fire; so that the

TABLE 2–12. Activity, Behavior, and Somatic Symptoms in Bipolar Depression

noble patient is first melancholy, while her animal spirits are unable to disentangle themselves from the dense cloud of fumes which surround them; and then maniacal, when the saline and sulphureous atoms of the blood are stirred up and loosened by the immoderate heat of their surroundings.

Heinroth (1818) delineated, in detail, mixed states of exaltation and depression (see Marneros, 2001). Later in the mid-nineteenth century, Falret (cited in Sedler, 1983) noted the strong depressive quality often observed before, during, and after manic episodes, as well as *mélancolie anxieuse*. The latter state, he wrote, is “characterized by constant pacing and inner turmoil, which incapacitates these patients

so they cannot concentrate, and this state sometimes ends up as manic agitation.” Kraepelin (1921, pp. 4, 191–192) described mixed states and their similarities and dissimilarities to manic and depressive states as follows:

We observe also clinical “mixed forms,” in which the phenomena of mania and melancholia are combined with each other, so that states arise, which indeed are composed of the same morbid symptoms as these, but cannot without coercion be classified either with the one or with the other. . . . The mixed states frequently fall outside the limits of the ordinary states in a very conspicuous way. . . . Our customary grouping into manic and melancholic attacks does not fit the facts, but requires substantial

enlargement, if it is to reproduce nature. At the same time it turned out that this enlargement ran out in the direction not of the fitting in of fresh morbid symptoms, but only of the different combination of morbid symptoms known for long. Further, it was seen that the mixed states, even when they appeared not as interpolations but as independent attacks, behaved with regard to their course and issue quite similarly to the usual forms, and lastly, that they might in the same morbid course simply take the place of the other attacks especially after a somewhat long duration of the malady.

Kraepelin conceptualized mixed states as primarily transitional phenomena, but recognized their existence as individual attacks that frequently occur in later stages of the illness, often associated with poor outcome. Table 2–13 summarizes Kraepelin's classification and description of mixed states, which he conceptualized as different combinations of the manic and depressive symptoms of mood, activity, and thought. Below is Kraepelin's (1921, pp. 103–104) description of two of the most important kinds of these mixed states, *depressive or anxious mania* and *excited depression*:

Depressive or Anxious Mania—If in the picture depression takes the place of cheerful mood, a morbid state arises, which is composed of flight of ideas, excitement, and anxiety. The patients are distractible, absent-minded, enter into whatever goes on round them, take themselves up with everything, catch up words and continue spinning out the ideas stirred up by these; they do not acquire a clear picture of their position, because they are incapable of systematic observation, and their attention is claimed by every new impression. They complain that they must think so much, their thoughts come of themselves, they have a great need of communicating their thoughts, but easily lose the thread, they can be brought out of the connection by every interpolated question, suddenly break off and pass to quite other trains of thought. Many patients display a veritable passion for writing, and scrawl over sheets and sheets of paper with disorderly effusions. At the same time ideas of sin and persecution are usually present, frequently also hypochondriacal delusions, as we have formerly described them.

Mood is anxiously despairing; it gives itself vent in great restlessness, which partly assumes the form of movements of expression and practical activity, but partly also passes over into a wholly senseless pressure of activity. The patients run about, hide away, force their way out, make movements of defense or attack; they lament, scream, screech, wring or fold their hands, beat them together above their head, tear out their hair, cross themselves, slide about kneeling on the floor. With these are associated rhythmical, rubbing, flourishing, snatching,

turning, twitching movements, snapping with the jaw, blowing, barking, growling. If one will, one might here speak of a “depressive” or “anxious” mania.

Excited Depression—if in the state described the flight of ideas is replaced by inhibition of thought, there arises the picture of excited depression. It is here a case of patients who display, on the one hand, extraordinary poverty of thought but, on the other hand, great restlessness. They are communicative, need the doctor, have a great store of words, but are extraordinarily monotonous in their utterances. To questions they give short answers to the point, and then immediately return to their complaints again, which are brought forth in endless repetition, mostly in the same phrases. About their position in general they are clear; they perceive fairly well, understand what goes on, apart from delusional interpretation. Nevertheless they trouble themselves little about their surroundings, they are only occupied with themselves.

Mood is anxious, despondent, lachrymose, irritable, occasionally mixed with a certain self-irony. Sometimes one hears from the patients witty or snappish remarks. Delusions are frequently present, but they are usually scantier and less extraordinarily spun out than in the form just described. The excitement of the patients also is usually not so stormy or protean. They run hither and thither, up and down, wring their hands, pluck at things, speak loud out straight in front of them, give utterance to rhythmic cries and torment themselves as well as their surroundings often to the uttermost by continuous, monotonous lamenting.

Jaspers, while noting occasional ambiguity in Kraepelin's nosology of mixed states, acknowledged its clinical utility. The many possible combinations of components—euphoria, flight of ideas, and pressure of movement on the one hand, and sadness and retardation of thought and of movement on the other—made possible a better understanding of the wide variety of affective states seen in clinical practice. Thus, Jaspers (1997, p. 598; first published in 1913) described a mixed melancholia, one that he suggested might be characterized as a “querulant mania” or “nagging depression” in some, and as a “wailing melancholia” in others:

In this state the over-valued or compulsive depressive ideas become delusionlike. They are fantastically elaborated (the patients are the cause of all the misfortune in the world; they are thought to be beheaded by the devil, etc.). The ideas are believed even though the patient seems relatively sensible. Underlying the experiences there are a host of *body sensations* (which soon lead to hypochondriacal delusions: the patients are filled up to the neck with excreta; the food falls through the empty body right to the bottom); then there are the most severe

TABLE 2–13. Kraepelin's Classification of Mixed States

	I. Depressive or Anxious Mania	II. Excited or Agitated Depression	III. Mania with Poverty of Thought	
Mood	Anxiety Anxiously despairing.	Anxiety Anxious, despondent, lachrymose, irritable, occasional self-irony.	Elation Cheerful, pleased, unrestrained; somewhat irritated, repellent, or afterwards breaking into a merry laugh.	
Activity	Overactivity Great restlessness; wholly senseless pressure of activity.	Overactivity They run hither and thither, wring their hands, pluck at things; loud rhythmic cries; monotonous lamenting.	Overactivity Excitement is often limited to making faces, dancing about, throwing things, changes in dress; many conduct themselves so quietly and methodically that superficial excitement does not appear at all; incapable of regular occupation, very abrupt, short-lived, impulsive outbursts of violence.	
Thought	Flight of Ideas Distractible, absent-minded; incapable of systematic observation; veritable passion for writing with disorderly effusions; thoughts come of themselves.	Inhibition of Thought Delusions are frequently present; extraordinary poverty of thought; extraordinarily monotonous in utterances; perceive well, understand what goes on, apart from delusional interpretation.	Inhibition of Thought Perceive slowly and inaccurately; cannot immediately call things to mind. Their conversation is monotonous, not infrequently making an impression of weak-mindedness; state is subject to great fluctuation.

TABLE 2–13. Kraepelin's Classification of Mixed States (*continued*)

	IV. Manic Stupor	V. Depression with Flight of Ideas	VI. Inhibited Mania
Mood	<i>Elation</i> Cheerful; smile without recognizable cause; supportive, erotic.	<i>Depression</i> Cast-down and hopeless; anxiety; sad and moody.	<i>Elation</i> More exultant, occasionally irritable, distractible, inclined to jokes.
Activity	<i>Gross Motor Retardation</i> Usually inaccessible; lie quiet in bed; decorate themselves, without sign of restlessness or excitement. Not infrequently cataplexy can be demonstrated. Unexpectedly give utterance to loud and violent abuse, throw their food, suddenly take off their clothes, and immediately sink back into inaccessibility.	<i>Motor Retardation</i> They read much, show interest in, and have understanding of their surroundings, although almost mute, and rigid in their whole conduct.	<i>Motor Retardation</i> In outward behaviors, conspicuously quiet; it appears, however, as if a great inward tension existed, as patients may suddenly become very violent.
Thought	<i>Inhibition of Thought</i> Occasionally isolated delusions of changing content find utterance; for the most part they prove themselves fairly sensible and well oriented.	<i>Flight of Ideas</i> Incited by delusions; occasionally patients who cannot give utterance in speech are capable of writing; often desultory, full of ideas of sin and delusional fears; heaping up of synonymous phrases, jumping off to side thoughts, show flight of ideas, recognizable only in writings.	<i>Flight of Ideas</i> They easily fall into chattering talk with flight of ideas and numerous clang associations.

forms of *depersonalization* and *derealisation*: the world is no more, they themselves no longer exist, but still since they seem to exist they will have to live for ever (nihilistic delusions); finally there is extreme *anxiety*: the patients seek relief from this by keeping constantly on the move and indulging in a monotonous pressure of talk which almost becomes verbigeration: ‘God, God, what will come of it, all, everything is gone, everything is gone, everything is gone, what will come of it?’ etc. Even when the anxiety and melancholy have lifted, the patterns of movement, the facial expression and pressure of talk seem to maintain an *ossified* state until—often after a considerable time—the phase finally abates and recovery commences.

Manic stupor, according to Kraepelin’s student and colleague Weygandt (1899, translated into English in the *Harvard Review*, 2002, p. 276), is the most important of the mixed states:

Manic stupor as a phase of manic-depressive insanity is characterized by psychomotor inhibition and manic, elevated mood, with inhibition of thought (which usually occurs in a depressive state) instead of flight-of-ideas. This condition can occur transiently during a manic or depressive episode, particularly during switching from the manic phase to the depressive, when a shift has already taken place in psychomotor activity but not in affect

The psychopathological condition is usually characterized by psychomotor manifestations (specifically stupor) as the prominent feature: some patients lie [in bed] showing very severe inhibition for a long time. Their limbs are cold; they refuse food, and every attempt to feed them is vain due to their opposition; for months they are mute. Only the facial expression, which shows no trace of depression and often shows a slight smile, reveals that a case is not typical circular [manic-depressive] stupor with depressed mood. In other cases, the [psychomotor] block is less intense: such patients may answer if asked questions, but they speak in a soft voice and hesitate before replying. They prefer not to speak spontaneously at all. Furthermore, these patients want to stay in bed all the time and refuse to work. Considerable retardation in their movements can be observed immediately: the gait is heavy and leaden; they hesitate to shake hands; and their writing is clearly slowed down. In less severe cases, the [psychomotor] block is occasionally interrupted by a fast, goal-directed movement.

Campbell (1953, pp. 144, 146), with his characteristic and important emphasis on the ever-fluctuating nature of moods, reiterated the mixed nature of most of the emotional and physical states associated with bipolar illness:

There are more mixed reactions of this disease than is generally realized. It could truly be stated that, to some extent, all manic-depressive reactions are “mixed” types, in that the symptomatology is anything but static.

The mixed type of manic-depressive psychosis epitomizes the entire cyclothymic process, in that it contains the symptoms characteristic of the various phases. Whether it is a sustained reaction or represents a phase of metamorphosis between the major forms, the mixed type emphasizes the underlying similarities between the depressive and hypomanic, the fact that the manic and depressive reactions may be superimposed, and that the same individual possesses the potentialities for either form. . . . Manic-depressive is a dynamic, constantly changing process which, at times, may manifest symptoms of both phases simultaneously. It is in the mixed form that the observer graphically realizes the homogeneity of the entire process.

Subjective Experiences of Patients

The extreme mental anguish often experienced during mixed states, including the terrifying thoughts and feelings associated with racing thoughts, delusions, and auditory hallucinations, was described by one bipolar patient whose mixed state was experienced at the height of a manic episode that, prior to that point, had been purely euphoric (as had countless hypomanias). Despite the strong and prolonged preponderance of classic euphoric mania in each of her episodes, the occasional transition into a mixed state was a potent feature of her illness. The simultaneous existence of suicidal thinking and mania is clearly portrayed in this description (Jamison, 1995, pp. 82–83):

I felt infinitely worse, more dangerously depressed, during this first manic episode than when in the midst of my worst depressions. In fact, the most dreadful I have ever felt in my entire life—one characterized by chaotic ups and downs—was the first time I was psychotically manic. I had been mildly manic many times before, but they had never been frightening experiences—ecstatic at best, confusing at worst. I had learned to accommodate quite well to them. I had developed mechanisms of self-control, to keep down the peals of singularly inappropriate laughter, and had set rigid limits on my irritability. I avoided situations that might otherwise trip or jangle my hypersensitive wiring, and I learned to pretend I was paying attention or following a logical point when my mind was off chasing rabbits in a thousand directions. My work and professional life flowed. But nowhere did this, or my upbringing, or my intellect, or my character, prepare me for insanity.

Although I had been building up to it for weeks, and certainly knew something was seriously wrong, there was

a definite point when I knew I was insane. My thoughts were so fast that I couldn't remember the beginning of a sentence halfway through. Fragments of ideas, images, sentences raced around and around in my mind like the tigers in a children's story. Finally, like those tigers, they became meaningless melted pools. Nothing once familiar to me was familiar. I wanted desperately to slow down but could not. Nothing helped—not running around a parking lot for hours on end or swimming for miles. My energy level was untouched by anything I did. Sex became too intense for pleasure, and during it I would feel my mind encased by black lines of light that were terrifying to me. My delusions centered on the slow painful deaths of all the green plants in the world—vine by vine, stem by stem, leaf by leaf they died and I could do nothing to save them. Their screams were cacophonous. Increasingly, all of my images were black and decaying.

At one point I was determined that if my mind—by which I made my living and whose stability I had assumed for so many years—did not stop racing and begin working normally again, I would kill myself by jumping from a nearby twelve-story building. I gave it twenty-four hours. But, of course, I had no notion of time, and a million other thoughts—magnificent and morbid—wove in and raced by. Endless and terrifying days of endlessly terrifying drugs—Thorazine, lithium, valium, and barbiturates—finally took effect. I could feel my mind being reined in, slowed down, and put on hold. But it was a very long time until I recognized my mind again, and much longer until I trusted it.

In the nineteenth century, composer Hector Berlioz (1966, translated by Cairn, 1970, pp. 226–228), described his episodes of “spleen,” or depression, one type of which he characterized as an agitated and deeply “malignant” state:

The fit fell upon me with appalling force. I suffered agonies and lay groaning on the ground, stretching out abandoned arms, convulsively tearing up handfuls of grass and wide-eyed innocent daisies, struggling against the crushing sense of absence, against a mortal isolation.

Yet such an attack is not to be compared with the tortures that I have known since then in ever-increasing measure. What can I say that will give some idea of this abominable disease? . . .

There are . . . two kinds of spleen; one mocking, active, passionate, malignant; the other morose and wholly passive, when one's only wish is for silence and solitude and the oblivion of sleep.

George Gordon, Lord Byron (in a letter dated August 1819) described his agitated and fluctuating moods during one of his many mixed depressive episodes:

I am so bilious—that I nearly lose my head—and so nervous that I cry for nothing—at least today I burst into tears all alone by myself over a cistern of Gold fishes—which are not pathetic animals. . . . I have been excited—and agitated and exhausted mentally and bodily all this summer—till I really sometimes begin to think not only “that I shall die at top first”—but that the moment is not very remote—I have had no particular cause of grief—except the usual accompaniments of all unlawful passions.

In a letter to a friend (written in December 1793), Scottish poet Robert Burns, who was also afflicted with a vexacious melancholia on and off throughout his life, provided a particularly graphic description of the terrible agitation that can accompany depression (*The Letters of Robert Burns*, ed. G.R. Roy, 1985):

Here I sit, altogether Novemberish, a damn'd mélange of Fretfulness & melancholy; not enough of the one to rouse me to passion; nor of the other to repose me in torpor; my soul flouncing & fluttering round her tenement, like a wild Finch caught amid the horrors of winter newly thrust into a cage.

Clinical Studies

To date, the best historical discussions of mixed states are those of Weygandt (1899), Kraepelin (1921), Campbell (1953), Winokur and colleagues (1969), Himmelhoch (1979), and Koukopoulos (Koukopoulos et al., 1992; Koukopoulos and Koukopoulos, 1999). These authors described the clinical course, presentation, and correlates of mixed states, as well as hypotheses regarding their etiology and nature (including their relationship to the continuum hypothesis of affective illness, kindling and rapid cycling, and mixed-heredity hypotheses).

Reported rates of mixed states vary as a function of the inclusion criteria—that is, whether the diagnostic criteria are narrow or broad—and the nature of the rating scales employed,²² as reflected in the wide range of rates reported by the 18 studies summarized in Table 2–14. An average of 28 percent of affectively ill patients experienced mixed states across these studies. By any standard, mixed states are not as rare as they once were reputed to be. (Kraepelin and Weygandt, of course, were fully aware of how common mixed states are. In a study of 150 manic-depressive patients at the Heidelberg Psychiatric Clinic, 36 percent were diagnosed with a form of mixed states: 15 percent with sustained mixed episodes, 8 percent with agitated depression, 7 percent with manic stupor, and 6 percent with unproductive mania [Weygandt, 1899].)

Symptomatic presentations of mixed states range from a single opposite-state symptom found in the midst of an

otherwise “pure” manic or depressive syndrome (such as depressive mood during mania or racing thoughts during depression) to more complex mixes of mood, thought, and behavior. Documentation of the frequent occurrence of depressive mood during mania was presented earlier in Table 2–1. Kotin and Goodwin (1972) systematically inves-

tigated the relationship of depression to mania in 20 hospitalized patients. Through an analysis of nurses’ and physicians’ behavioral ratings and notes, they found a statistically significant positive association between mania and depression in the majority of cases.

Racing thoughts during depression can be considered another type of mixed state, one observed by earlier clinicians (Kraepelin, 1921; Lewis, 1934). More recently, this state was examined by Ianzito and colleagues (1974) and Braden and Qualls (1979). Ianzito’s group found a relatively low rate of racing thoughts in their 89 depressed inpatients (5 percent), but they used the Present State Exam, which emphasizes the pleasurable and exciting quality as well as the rapidity of thought. Braden and Qualls, by contrast, found that one-third to one-half of their depressed inpatients reported racing thoughts, with a definite diurnal variation (worsening in the evening, greatest severity at bedtime). They drew the following conclusion (pp. 17–18):

In bipolar patients and cyclothymics, the racing thoughts may occur in both “high” and “low” states. The symptom may thus be related more to the underlying pathology of the affective illness than to the characteristics of either “pole.”

Other authors (Akiskal and Mallya, 1987; Koukopoulos and Koukopoulos, 1999; Benazzi and Akiskal, 2001) have favored the interpretation that racing—especially “crowded”—thoughts are indicative of mixed depressive states, and have invoked a significant excess of bipolar family history as validation of the bipolar nature of the phenomenon.

The symptomatic presentation of severe mixed states has been characterized in a variety of studies as dysphoric mood alternating with elevated mood, racing thoughts, grandiosity, suicidal ideation, persecutory delusions, auditory hallucinations, severe insomnia, psychomotor agitation, and hypersexuality (Cassidy et al., 1998; Perugi et al., 2001a; Brieger et al., 2003). Kotin and Goodwin (1972, p. 60) summarized their clinical impressions of mixed states as follows:

Mania was nevertheless clearly identifiable by pressure of speech, increased motor activity, anger, intrusiveness, grandiosity, and mood instability. Depression during mania was frequently evidenced by expressed feelings of helplessness and hopelessness and thoughts of suicide. Sleep disturbance, irritability, anorexia, and many other symptoms are common to both conditions.

In their early study, Winokur and colleagues (1969) documented the course and symptoms of mixed states; the quantitative results of their work are given in Table 2–15. They concluded that the single most striking feature of

mixed states was variability and lability of mood: “It is this panoply of varying and contrasting emotions which makes these patients difficult to diagnose” (p. 81). Winokur’s group observed that mixed states tended to resemble mania in push of speech, physical activity, and hyperactivity. Delusions, on the other hand, tended to be depressive in nature, as did mood and vegetative signs and symptoms. The authors found that in 79 percent of cases, mixed states were gradual; that there was prior depression of appreciable clinical proportions in 71 percent of patients; that diurnal variation occurred in 64 percent; that the average period from onset to euthymia was 24 days; and that more than half (57 percent) of mixed episodes were followed by a depression.

Women made up 60 percent of Nunn’s (1979) sample of patients with mixed states, consistent with the finding of Himmelhoch and colleagues (1976a) that 55 percent of their sample were women. Winokur and colleagues (1969) found a far more striking gender difference: 9 of their 10 patients with mixed episodes were women, and 13 of the 14 episodes they analyzed were experienced by women. The degree of this discrepancy almost certainly is due to the more stringent criteria used by these authors in defining mixed states. In the most comprehensive study to date, 908 bipolar patients were followed over a period of 7 years to assess mixed and euphoric hypomanias (Suppes et al., 2005). Mixed hypomania was more common than euphoric hypomania, and women were significantly more likely to experience a mixed symptomatic picture ($p < .001$).

Himmelhoch and colleagues (1976a) found no correlation between mixed states and severity of illness or rapidity of mood swings. They did find, however, that patients with mixed states were far more likely to have a history of substance abuse, especially alcoholism. This has been confirmed in some studies (Sonne et al., 1994; McElroy et al., 1995; Goldberg et al., 1999) but not in subsequent, larger investigations (Brieger, 2000; Cassidy et al., 2001). Current data indicate that mixed mania, unlike pure mania, which peaks in the spring, is more likely to peak in the late summer (Cassidy and Carroll, 2002), and both types of episodes tend to remain consistent over a prospective course (Cassidy et al., 2001b; Woods et al., 2001; Suppes et al., 2005). A recent study (Sato et al., 2006) found significant seasonal differences between 95 bipolar depressive patients and 77 unipolar patients with depressive mixed states when compared with 786 unipolar depressive patients without mixed states. Depressive episodes peaked in the spring in those without mixed states, but in those with mixed states (whether bipolar or unipolar), there was a significant autumn peak in depressive episodes. (It is not clear why unipolar patients with mixed states were not diagnosed as bipolar by the researchers.)

Winokur and colleagues (1969) examined the nature of delusions during mixed states and found, not surprisingly, that the type of delusion fluctuated with the patient's mood. Although depressive delusions were more frequent, manic-like delusions (nondepressed, grandiose, all religious) also occurred. Himmelhoch (1979, p. 453) emphasized the importance of manic delusions in differentiating unipolar agitated depression from mixed states:

The clue to recognizing it [a mixed state] is the presence of distinct maniacal coloration of the psychotic material in the midst of all the severe depressive symptomatology . . . [for example] . . . grandiose, radiant, beatific religious delusions . . . out of tune with the patient's misery.

Recent studies have found a significant rate of delusions (23 percent) or delusions and/or hallucinations (40 percent) in mixed states (Mantere et al., 2004; Baethge et al., 2005). As some overlap exists between depressive and manic signs and symptoms (insomnia, anorexia, psychomotor agitation), the question arises of what constitutes the depressive manifestations "uncontaminated" by mania that would be suitable for the diagnostic assessment of mixed states. On the basis of a comprehensive review of the data (McElroy et al., 1992; Bauer et al., 1994; Cassidy et al., 1998), Akiskal and colleagues (2000) proposed the following depressive symptoms to support a diagnosis of dysphoric mania: depressed and/or labile mood, irritability, anhedonia, hopelessness/helplessness, suicidal thinking or behavior, guilt, and fatigue. Nonspecific symptoms, according to these authors, include agitation, changes in weight, and insomnia.

Akiskal (1992b) proposed that mixed states arise when temperament and episodes are opposite in polarity—that is, mania arising from a depressive temperament and depression arising from a hyperthymic temperament. There has now been some preliminary validation of this view in several Italian, French, and German studies (Dell'Osso et al., 1991; Perugi et al., 1997; Brieger et al., 2003), but the diverse presentation of mixed states makes any single explanation necessarily incomplete and premature. Temperament may be decisive in determining the manifestation of mixed states in some individuals but ultimately is far less important than other factors—for example, comorbidity, chronicity of illness, medication effects—in many or even most patients.

While much of the research on mixed states has been in dysphoric or depressive mania, depressive mixed states (hypomanic behavior and/or symptoms intruding into depressive episodes) have been described since Kraepelin's (1899) and Weygandt's (1899) original contributions in this area. The most common manifestations of the excitatory

pole in depressive mixed states are psychomotor activation and/or agitation, irritability and mood lability, racing or crowded thoughts, and sexual arousal, as well as severe insomnia, panic attacks, and suicidal crises in severely complicated variants.²³ Indeed, increased suicidality and the risk of suicide are particularly associated with mixed states (Hantouche et al., 2003; Strakowski et al., 1996; Marneros et al., 2004; see Chapter 8). A recent study of bipolar adolescents found that mixed states contributed independently to the risk of suicidal behavior, but the increased risk was among the girls only (Dilsaver et al., 2005). In a meta-analysis of risk factors for suicide and attempted suicide, Hawton and colleagues (2005) at the University of Oxford also found mixed states to be a significant risk factor.

Consistent with Aretaeus, who had observed that melancholics could be "angry without reason," Mammen and colleagues (2004) found that 39 percent of their bipolar patients reported anger attacks during depression. Such attacks may well represent a form of depressive mixed state.

As discussed in Chapter 1, Benazzi and Akiskal (2005) compared the relationship between irritability and other clinical features in a large number of bipolar-II and unipolar major depressive subjects. Major depressive episodes with irritability were present in 60 percent of their bipolar-II patients and in 37 percent of their depressive patients. In the bipolar-II patients, those who presented with irritability had a significantly younger age at index episode, higher rates of atypical depressive features, and more significant Axis I comorbidity relative to those who did not. They also were more likely to meet the study criteria for depressive mixed states, defined by the investigators as a major depressive episode plus three or more concurrent intra-depressive hypomanic symptoms (whether occurring in the bipolar-II or major depressive patients). In the unipolar patients, those who presented with irritability had a significantly younger age at onset and higher rates of atypical depression; they were also more likely to meet criteria for a depressive mixed state and to have a family history of bipolar illness. According to the authors, their data demonstrate that irritability may be a good marker of depressive mixed states, a view consistent with that of others who have found high rates of irritability and anger attacks associated with these states (e.g., Fava and Rosenbaum, 1999; Deckersbach et al., 2004; Perlis et al., 2004). The relationship between age at onset and mixed states is unclear. Some investigators have found that earlier age at onset is associated with mixed states (Nunn, 1979; Post et al., 1989; McElroy et al., 1997), but others have not (Marneros et al., 1991a,b; Strakowski et al., 1996; Perugi et al., 1997).

In their discussion of depression with manic features, Koukopoulos and Koukopoulos (1999) suggested that all types of agitated depressions should be called “mixed depression.” They proposed that the following diagnostic criteria be used: (1) major depressive episode and (2) at least two of the three symptoms of motor agitation, psychic agitation or intense inner tension, and racing or crowded thoughts. Perugi and colleagues (2001) have distinguished between depressive mixed states and non-mixed bipolar depression on the basis of depressive mixed states being characterized by fewer episodes of longer duration; less cyclicity; greater likelihood of mixed state at first episode; more previous mixed episodes; less interepisode remission; more incongruent psychotic features; and more agitation, irritability, pressured speech, and flight of ideas.

CYCLOTHYmia AND MANIC-DEPRESSIVE TEMPERAMENTS

Classic Clinical Descriptions

Cyclothymia and related temperamental types represent a significant portion of the manic-depressive spectrum. The relationship of predisposing personalities (or temperaments) and cyclothymia to the subsequent development of manic-depressive illness is a fundamental one (as discussed further below, as well as in Chapters 1, 5, 6, and 10). *Cycloid temperament*, a generic term for the spectrum of manic-depressive personality types, is generally manifested as predominantly depressive, manic or hypomanic, irritable, or cyclothymic.²⁴ Campbell (1953, pp. 25–26) described these personality types and their relationship to manic-depressive illness and to one another:

The term *cycloid personality* is an overall or general appellation, indicating all forms of the prepsychotic manic-depressive personality. The cycloid personality may occur in one of three forms, with innumerable gradations and mixtures between the three. First, is the hypomanic personality, the overactive, jovial, friendly, talkative and confident individual who, if he becomes psychotic, *usually* develops the manic form of manic-depressive psychosis. . . . Second, is the depressive type, the worried, anxious, thoughtful, sorrowful, individual who, if he becomes psychotic, *usually* develops the depressive form of manic-depressive psychosis. The third form of the cycloid personality is the cyclothymic personality who may have mixed traits, or be euphoric and friendly at one time, and depressed and pessimistic at another, and who may develop either a manic or depressive reaction, or swing from one into the other. It is important to realize

that the manic reaction, melancholia, hypomanic reaction, cyclothymic personality, cycloid personality, depressive personality and periodic insanity, are all a part of the same disease process, and that any one of these may change into any other.

The generic term *cycloid personality* used by Kretschmer encompasses all types of prepsychotic personality in manic-depressive patients. Kretschmer, too, stressed the overlap among these personality types (1936; cited in Campbell, 1953, pp. 26–27):

Men of this kind have a soft temperament which can swing to great extremes. The path over which it swings is a wide one, namely between cheerfulness and unhappiness. . . . Not only is the hypomanic disposition well known to be a peculiarly labile one, which also has leanings in the depressive direction, but many of these cheerful natures have, when we get to know them better, a permanent melancholic element somewhere in the background of their being. . . . The hypomanic and melancholic halves of the cycloid temperament relieve one another, they form layers or patterns in individual cases, arranged in the most varied combinations.

Clearly, not all cyclothymic or cycloid personalities go on to develop the full manic-depressive syndrome, and here we concern ourselves primarily with clinical descriptions of the range of cycloid temperaments and cyclothymic disorders. Kraepelin (1921, pp. 119–120) described a *depressive temperament*, which is characterized by a “permanent gloomy emotional stress in all the experience of life”:

Patients, as a rule, have to struggle with all sorts of internal obstructions, which they only overcome with effort; . . . they lack the right joy in work. . . . From youth up there exists in the patients a special susceptibility for the cares, the difficulties, the disappointments of life . . . in every occurrence feel the small disagreeables much more strongly than the elevating and satisfying aspects. . . . Frequently . . . a capricious, irritable, unfriendly, repellent behaviour is developed. The patients are occupied only with themselves, do not trouble themselves about their surroundings. . . .

Every task stands in front of them like a mountain; life with its activity is a burden which they habitually bear . . . without being compensated by the pleasure of existence.

In manic temperament, Kraepelin went on to say, the patients’ “understanding of life and the world remains superficial”; their “train of thought is desultory, incoherent, aimless”; and their mood is “permanently exalted, careless, confident.” (Centuries earlier, Aretaeus [cited in

Roccatagliata, 1986, p. 229] had described a predominantly manic form of illness that arose in those "whose personality is characterized by gayness, activity, superficiality and childishness." The mania itself was manifest in "furor, excitement and cheerfulness") Kraepelin (1921, pp. 126–128) said that such patients are

convinced of their *superiority* to their surroundings. . . . Towards others they are haughty, positive, irritable, impertinent, stubborn. . . . *unsteadiness and restlessness* appear before everything. They are accessible, communicative, adapt themselves readily to new conditions, but soon they again long for change and variety. Many have belletristic inclinations, compose poems, paint, go in for music. . . . Their mode of expression is clever and lively; they speak readily and much, are quick at repartee, never at a loss for an answer or an excuse. . . . With their surroundings the patients often live in constant *feud*.

Kraepelin also discussed a milder form of manic temperament within the "domain of the normal," but still a "link in the long chain of manic-depressive dispositions," a form that progresses to what he termed the *irritable temperament*. In Kraepelin's (1921, pp. 129–131) words:

It concerns here brilliant, but unevenly gifted personalities with artistic inclinations. They charm us by their intellectual mobility, their versatility, their wealth of ideas, their ready accessibility and their delight in adventure, their artistic capability, their good nature, their cheery, sunny mood. But at the same time they put us in an uncomfortable state of surprise by a certain restlessness, talkativeness, desultoriness in conversation, excessive need for social life, capricious temper and suggestibility, lack of reliability, steadiness, and perseverance in work, a tendency to building castles in the air . . . periods of causeless depression or anxiety. . . .

The *irritable temperament*, a further form of manic-depressive disposition, is perhaps best conceived as a *mixture of the fundamental states* . . . in as much as in it manic and depressive features are associated. . . . The patients display from youth up extraordinarily great fluctuations in emotional equilibrium and are greatly moved by all experiences, frequently in an unpleasant way. While on the one hand they appear sensitive and inclined to sentimentality and exuberance, they display on the other hand great irritability and sensitiveness. They are easily offended and hot-tempered; they flare up, and on the most trivial occasions fall into outbursts of boundless fury. "She had states in which she was nearly delirious," was said of one patient; "Her rage is beyond all bounds," of another. It then comes to violent scenes with abuse,

screaming and a tendency to rough behaviour. . . . The patients are positive, always in a mood for a fight, endure no contradiction, and, therefore, easily fall into disputes with the people round them, which they carry on with great passion. . . . The colouring of mood is subject to frequent change. . . .

Their power of imagination is usually very much influenced by moods and feelings. It, therefore, comes easily to delusional interpretations of the events of life. The patients think that they are tricked by the people round them, irritated on purpose and taken advantage of.

Cyclothymic temperament is characterized, according to Kraepelin (1921, p. 131), by "frequent, more or less regular fluctuations of the psychic state to the manic or to the depressive side." He described cyclothymic individuals as follows (p. 132):

These are the people who constantly oscillate hither and thither between the two opposite poles of mood, sometimes "rejoicing to the skies," sometimes "sad as death." To-day lively, sparkling, beaming, full of the joy of life, the pleasure of enterprise, and pressure of activity, after some time they meet us depressed, enervated, ill-humoured, in need of rest, and again a few months later they display the old freshness and elasticity.

Kretschmer (1936, p. 132) pointed out a tendency of these individuals to drift toward either mania or depression:

The temperament of the cycloids alternates between cheerfulness and sadness, in deep, smooth, rounded waves, only more quickly and transitorily with some, more fully and enduring with others. But the mid-point of these oscillations lies with some nearer the hypomanic, and with others nearer the depressive pole.

Slater and Roth (1969, pp. 206–207) provided a general description of the "constitutional cyclothymic," emphasizing the natural remissions and seasonal patterns often inherent in the temperament. The alternating mood states, each lasting for months at a time, are continuous in some individuals but subside, leaving periods of normality, in others. In Slater and Roth's words, the cyclothymic constitution

is perhaps less frequent than the other two "basic states," but its existence in artists and writers has attracted some attention, especially as novelists like Björnsen and H. Hesse have given characteristic descriptions of the condition. Besides those whose swings of mood never intermit, there are others with more or less prolonged *intervals of normality*. In the hypomanic state the patient feels well, but the existence of such states accentuates his feeling of insufficiency and even illness in the depressive phases. At such times he will often seek the advice of his practitioner,

complaining of such vague symptoms as headache, insomnia, lassitude, and indigestion. . . . In typical cases such alternative cycles will last a lifetime. In cyclothymic artists, musicians, and other creative workers the rhythm of the cycles can be read from the dates of the beginning and cessation of productive work. Some cyclothymics have a *seasonal rhythm* and have learned to adapt their lives and occupations so well to it that they do not need medical attention.

According to Koukopoulos (2003, p. 202), observing a cyclothymic patient who is depressed, "one is spontaneously reminded of a machine in which the oil has run dry and the gears grind on in laborious suffering, rasping against one another until they seize up in pain." When hypomanic, on the other hand, the patient is entirely different (p. 203):

Instead of the inhibition that was previously felt, the course of thoughts is now faster, the perception of external impressions easier and more immediate, so the patient appears to be more intelligent, full of wit and more entertaining than in the healthy days. As for the increased capacity for criticizing, which as already mentioned may present itself also in the depressive state, this may now become so strong as to be considered vexing by the patient himself. It often betokens itself by an arrogant, mocking smirk. The elevated mental capacity leads in the majority of cases to a restless, non-stop activity and dynamism which develops in the widest variety of directions. It is not only the stamina of the patient, which appears greater than that of the healthy days, but the level of skill and ability that is increased in various ways. Many, for instance, who had a rather mediocre voice and in their depressive intervals—were without much musical talent—now sing not only with great eagerness, but also with a better tone of voice and a livelier expressiveness. Others display, in manual tasks and their mode of dress, a skill and taste which they did not formerly possess. And others manifest a literary bent that was quite alien to them before.

All these characteristics are, as I observed above, due to the expression of the expansive mood, which as a rule sweeps over the patient suddenly. All at once he sees the rosy side of life and at the same time feels a desire to have others partake in his joy, to help his fellow men and carry out activities that frequently bear fruit in the fields of charity and humanitarian interests.

Clinical Studies

Compelling evidence argues for including cyclothymia as an integral part of the spectrum of manic-depressive illness. The data presented here describe several aspects of

cyclothymia: its clinical presentation; symptomatic patterns of mood, cognition, and behavior; and subsequent development of full affective episodes in cyclothymic patients.²⁵ (Related issues are discussed in Chapters 1, 10, and 11.)

In his early review of the literature, Waters (1979) cited widespread agreement that mood and energy swings often precede clinical illness by years. In a study of 33 patients with definite bipolar illness, he found that one-third reported bipolar mood swings or hypomania predating the actual onset of their illness. These subsyndromal mood swings were characterized by (1) onset in early adulthood; (2) occurrence most often in spring or fall; (3) occurrence on an annual or biennial basis; (4) onset unrelated to current life events (with the exception of the first episode); (5) persistence of symptoms for 3 to 10 weeks; (6) a change in energy level, rather than the experience of dysphoria; and (7) sensitivity to lithium treatment (comparable to that for manifest bipolar illness). More recently, Kochman and colleagues (2005) assessed 80 depressed children and adolescents with the Kiddie-SADS semi-structured interview and a newly developed questionnaire to measure cyclothymic–hypersensitive temperament. At the end of the 2- to 4-year follow-up period, 43 percent of the sample had been diagnosed as bipolar. Of the children and adolescents who had been categorized as cyclothymic–hypersensitive, 64 percent developed bipolar disorder; of those who had not been so categorized, only 15 percent experienced a hypomanic or manic episode ($p < .001$).

In a study of the natural course or progression of cyclothymia, that is, the relationship of cyclothymic states to the subsequent development of bipolar affective episodes, approximately one-third (36 percent) of 50 cyclothymic patients, in contrast to only 4 percent of 50 nonaffective controls, developed full syndromal depression, hypomania, or mania (Akiskal et al., 1979b). Of the 25 cyclothymic patients requiring antidepressant medication for their depressive illness, 11 (44 percent) became hypomanic. This rate was comparable to the switch rate in bipolar controls (35 percent).

Akiskal and colleagues further described and quantified these "subsyndromal" mood swings. Box 2-1 presents revised operational criteria for cyclothymia based on a population study that tested the authors' clinically derived criteria (Akiskal et al., 1979a, 1998b). Their original sample of 50 cyclothymic patients was characterized by the following: a female/male ratio of 3:2; young age at onset, which is consistent with other data suggesting an onset of first symptoms between ages 12 and 14 (Akiskal et al., 1977; Depue et al., 1981); and a tendency for the first clinical presentation to be perceived as a personality rather than a mood disorder, with family members and friends describing the

BOX 2-1. Validated Criteria for Cyclothymic Temperament

Biphasic subclinical mood swings with abrupt and labile shifts, and with variability in duration, measured from hours to a few days. At least four of the following constitute the habitual long-term baseline of the subject:

- Lethargy alternating with eutonia
- Shaky self-esteem alternating between low self-confidence and overconfidence
- Decreased verbal output alternating with talkativeness
- Mental confusion alternating with sharpened and creative thinking
- Unexplained tearfulness alternating with excessive punning and jocularity
- Introverted self-absorption alternating with uninhibited people seeking

patient as “high-strung,” “explosive,” “moody,” “hyperactive,” or “sensitive.”

Mood, cognitive, and behavioral patterns in 46 patients with cyclothymia were studied by Akiskal and colleagues (1977); although based on a small sample, their findings are useful in providing an overall view of cyclothymic states. As might be expected, the mood and cognitive aspects parallel, in milder form, those for mania and depression. Three-fourths of Akiskal and colleagues’ patients met criteria for alternating patterns of sleep disorder, fluctuating levels in the quality and quantity of work or school productivity, and financial disinhibition. One-half of the patients reported periods of irritability or aggressiveness, patterns of frequent shifts in interests or plans, drug or alcohol abuse, or fluctuating levels of social interaction. Episodic promiscuity or extramarital affairs were reported by 40 percent of the sample, and joining new movements with zeal, followed by disillusionment, by 25 percent. Although frequencies of specific behavior patterns are of interest, replicated and comparison population figures are necessary. Thus we await more detailed studies of cognitive and perceptual changes across mood states, much larger sample sizes, and replications utilizing more standardized measures.

Cyclothymia is a common temperamental variant, occurring in 0.4 to 6.3 percent of the population (Depue et al., 1981; Placidi et al., 1998; Chiaroni et al., 2005). According to Akiskal (1998), the most frequent subtypes of cyclothymia are *pure cyclothymia* (equal proportion of depressive and hypomanic swings, alternating in an irregular fashion), *predominantly depressed cyclothymia* (depressive periods dominating the clinical picture,

interspersed with “even,” “irritable,” and occasional hypomanic periods), and *hyperthymia* (hypomanic traits—decreased need for sleep, expansive behavior, “wild lifestyle”—dominating, with occasional depressive and irritable episodes). Systematic qualitative data to verify this taxonomy do not exist, however.

Discriminatory criteria for the irritable temperament have remained elusive (Akiskal, 1992a; Akiskal et al., 1998b). The hyperthymic type, by contrast, is probably distinct from the cyclothymic (Akiskal, 1992a). Indeed, in a factor analytic study of temperaments in an Italian student population, the cyclothymic and hyperthymic types emerged as separate superfactors (Akiskal et al., 1998b). The hyperthymic type is best described as adaptive-trait hypomania (which distinguishes it from hypomanic episodes), consisting of the triad of high energy, overconfidence, and cheerfulness, with virtually no depressive dips (which distinguishes this type from the cyclothymic type proper). Again, while such speculations are interesting, they need greater validation and replication.

The validated criteria for the cyclothymic type summarized in Box 2-1 portray a temperament with greater instability than the hyperthymic type, and for that reason one perhaps more proximal to bipolar disorder; indeed, cyclothymia often precedes or underlies bipolar-II disorder (Hantouche et al., 1998; Perugi and Akiskal, 2002). Of the affective temperaments, cyclothymia is the most correlated with emotional and behavioral problems (Signoretta et al., 2005).

On the other hand, the hyperthymic type represents a more adaptive set of traits. The criteria for hyperthymic temperament, as validated by Akiskal and colleagues (1998a), require that four of the following traits (which constitute the habitual long-term functioning of the individual) be present: (1) warm, people seeking, or extraverted; (2) cheerful, overoptimistic, or exuberant; (3) uninhibited, stimulus seeking, or risk taking; (4) overinvolved and meddlesome; (5) vigorous, overenergetic, and full of plans; (6) self-assured, overconfident, or boastful; and (7) overtalkative or articulate. Researchers in Italy (Maremmani et al., 2005) compared responses from 1,010 students aged 14 to 26 on Cloninger’s revised Tridimensional Personality Questionnaire (TPQ) (Cloninger, 1987) and on the semi-structured affective temperament interview (TEMPS-I) (Placidi et al., 1998). The TPQ constructs of gregariousness, exploratory excitability, uninhibited optimism, attachment, confidence, extravagance, independence, vigor, and impulsiveness correlated highly with the temperamental construct of hyperthymia. Jamison (2004) has discussed at length the relationship among exuberant, hyperthymic, and extraverted temperaments, as well as the relationship

between such temperaments and psychological resilience (see also Chapter 10).

Psychiatric studies of temperament would benefit enormously from the addition of the perspectives and methodologies used by developmental psychologists who have studied early manifestations of temperament and the development of temperament over time, from infancy to adulthood. Particularly relevant here is the paradigm used by Jerome Kagan and colleagues in their important studies of inhibited and uninhibited temperaments.²⁶ At present, we lack the sophisticated developmental and genetic approaches that ultimately will provide the kind of information needed to adequately understand the manic-depressive spectrum of temperaments.

CONCLUSIONS

This chapter has presented a clinical description of manic-depressive illness (with emphasis on the bipolar form) that combines three methods of observation: descriptions of both ancient and modern clinical observers, first-person accounts from patients with manic-depressive illness, and results obtained from clinical studies. Each method is unique, invaluable, but incomplete. Good clinical description is beholden to all three perspectives.

Pathognomonic cycles of mood and activity serve as a background for ongoing fluctuations in thinking, perception, and behavior. The bipolar form of manic-depressive illness encompasses the extremes of human experience. Moods swing between euphoria and despair, irritability and panic. Cognition can range from psychosis or delirium to a pattern of fast, clear, and sometimes creative associations; it can also manifest as retardation so profound that consciousness is clouded. Behavior can be seductive, hyperactive-expansive, and dangerous; or it can be reclusive, sluggish, and suicidal.

The rapid undulations and combinations of such extremes result in an intricately textured clinical picture. It is important to note that the designation "mixed states" is often arbitrary. Indeed, manic patients are depressed and irritable at least as often as they are elated, and bipolar depressed patients are frequently agitated and may have racing thoughts.

NOTES

1. Falret, 1854 (translated by Sedler, 1983); Kraepelin, 1921; Campbell, 1953; Wellner and Marstal, 1964; Beigel and Murphy, 1971a; Cassidy et al., 2001a, 2002; Woods et al., 2001; Sato et al., 2004.

2. Kraepelin continued:

Statues salute him by nodding; the moon falls down from the sky; the trumpets of the Day of Judgment are sounding. He hears the voice of Jesus, speaks with God and the poor souls, is called by God dear son. There are voices in his ears; the creaking of the floor, the sound of the bells take on the form of words. The patient has telepathic connection with an aristocratic fiancée, feels the electric current in the walls, feels himself hypnotized; transference of thought takes place.

3. As discussed later in this chapter, Carlson and Goodwin (1973), in their systematic study of the stages of mania, found that mania usually evolves gradually. In their hospitalized patients, the early stages of mania could be discerned in nurses' recordings of mood and behavior reviewed after the apparently sudden onset of manic episodes.

Diagnosis

The symptom-complexes of pure mania and depression seem extraordinarily “natural” to us because of the thread of meaningful connection which runs through their individual features, but very many of these patients do not correspond at all to these “natural” complexes which are only ideal types of construct.

—Karl Jaspers (1913, p. 597)

The history of psychiatric diagnosis has been notable for its confusion, reflected in the myriad overlapping systems for classifying and subdividing depressive disorders. As discussed in Chapter 1, however, Kraepelin brought order to the diagnosis of depression by grouping all of the recurrent affective disorders under the rubric of manic-depressive illness, a broad category later divided into unipolar and bipolar subgroups. Although the original meaning of *unipolar* as a form of recurrent affective disorder has been obscured in our current diagnostic system, bipolar illness has remained a relatively consistent and stable diagnostic category; characterizing patients as bipolar leads to valid predictions about family history, course, prognosis, and treatment response. In this chapter, we review the formal criteria for the diagnosis of manic-depressive illness, focusing on the bipolar form. With the category thus defined, we then reexamine the boundaries it shares with other major diagnostic categories, some of which were introduced in our earlier discussion of the manic-depressive spectrum (see Chapter 1). Here the focus is on clinical decision making.

A reading of the relevant literature makes clear that reliable diagnosis of manic-depressive illness requires a longitudinal as well as a cross-sectional view of the patient.¹ This literature also charts a course for clinicians, underscoring the need to meet repeatedly with the patient and to seek out other people, particularly family members, who can help in forming an accurate picture of the patient's history, symptoms, and behavior. Such practices decrease the clinician's dependence on cross-sectional data and increase the reliability of diagnoses. Clinicians will need to remain careful and skilled diagnosticians even if future genetic and biological studies provide more clues as to the

etiology of manic-depressive illness. This is so because both the bipolar and highly recurrent unipolar forms of manic-depressive illness undoubtedly involve complex interactions among genetic and environmental factors that do not allow for the kinds of direct cause-and-effect relationships seen, for example, with inborn errors of metabolism.

The first section of this chapter summarizes the development of contemporary diagnostic systems. This is followed by a review of the diagnostic criteria for those disorders salient to diagnosis of manic-depressive illness. We then examine findings of recent studies addressing the key issue of whether psychotic conditions should be classified as separate conditions or as falling along a continuous spectrum. Finally, we look at the problem of differential diagnosis of bipolar disorder and other disorders with which it shares overlapping features.

DEVELOPMENT OF CONTEMPORARY DIAGNOSTIC SYSTEMS

Successive versions of the *International Classification of Diseases* (ICD), now in its tenth revision (Sato et al., 2002), represent the official diagnostic system used by clinicians throughout most of the world. The major exception, of course, is the United States, where clinicians use the American Psychiatric Association's (APA) *Diagnostic and Statistical Manual*, the fourth edition of which (DSM-IV) was published in 1994. The different diagnostic systems are illustrated in Boxes 3-1a and 3-1b. Two European systems of classification are also important—the Present State Examination (PSE)-Catego (Wing and Nixon, 1975) and the system developed by the Association for Methodology and Documentation in Psychiatry (Guy and Ban, 1982).

BOX 3-1a. DSM-IV Mood Disorders**Depressive Disorders**

2.96	Major depressive disorder .2x single episode .3x recurrent
300.4	Dysthymic disorder —specify if: early onset/late onset —specify: with atypical features
311	Depressive disorder not otherwise specified
Bipolar Disorders	
296	Bipolar I disorder .0x single manic episode —specify if mixed .40 most recent episode hypomanic .4x most recent episode manic .6x most recent episode mixed .5x most recent episode depressed .7 most recent episode unspecified
296.89	Bipolar II disorder —specify (current or most recent episode) hypomanic/depressed
301.13	Cyclothymic disorder
296.8	Bipolar disorder not otherwise specified
293.83	Mood disorder due to (indicate the general medical condition) —specify type: with depressive/manic/mixed features —specify if: with onset during intoxication/withdrawal —see substance-related disorders for codes for specific drugs of abuse for other agents (including antidepressants)
292.84	Code as other substance-induced mood disorder
296.90	Mood disorder not otherwise specified
295.70	Schizoaffective disorder —specify: bipolar type/depressive type
295.40	Schizophreniform disorder —specify: with or without good prognostic features
298.8	Brief psychotic disorder —specify: with or without marked stressor, with postpartum onset
298.9	Psychotic disorder not otherwise specified

BOX 3-1b. ICD-10 Mood Disorders (Affective Disorder)

F 32	Depressive episode
F 33	Recurrent depressive disorder
F 34	Persistent mood (affective) disorders
F 34.1	Dysthymia
F 34.8	Other persistent mood (affective) disorders
F 34.9	Persistent mood (affective) disorders, unspecified
F 38	Other mood (affective) disorders
F 38.0	Single mixed affective episode
F 38.1	Recurrent brief depressive episode
F 31	Bipolar affective disorder (BAD)
F 30	Manic episode —specify if hypomania, mania with or without psychosis
F 31.0	BAD, current episode hypomania
F 31.1, 31.2	BAD, current episode manic with or without psychosis
F 31.6	BAD, current episode mixed
F 31.3, 31.4, 31.5	BAD, current episode depressed with or without psychotic symptoms
F31.8	Other bipolar affective disorders —specify if bipolar-II disorder or recurrent manic episodes
F 34.0	Cyclothymia
F 31.9	BAD, unspecified
F 10-19	Mental and behavioral disorders due to psychoactive substance abuse
F 25.0	Schizoaffective disorder, manic type
F 25.1	Schizoaffective disorder, depressive type
F 25.2	Schizoaffective disorder, mixed type
F 25.9	Schizoaffective disorder, unspecified
F 23	Acute and transient psychotic disorder
F 23.2	Acute schizophrenic-like psychotic disorder

Classification of Causes of Death. The ICD was designed as a system that could be applied throughout the world; thus its developers attempted to encompass a great variety of conceptual backgrounds, which in turn resulted in overlap among many of its categories. The 16 different subtypes of affective disorder in ICD-9, grouped under eight different main headings, cannot readily be compared with the descriptive diagnostic systems that have recently evolved from systematic research on these disorders.

The APA's first diagnostic manual (DSM-I) was published in 1952. Although developed independently of the ICD, the American system likewise was not derived from

ICD-6 through ICD-9 and DSM-I and DSM-II

The first effort to establish a universal diagnostic system for psychiatric illnesses was made by the World Health Organization (WHO) in its 1948 ICD-6, formerly the International

systematic research. In DSM-I, manic-depressive reaction appeared along with psychotic depressive reaction as sub-categories of affective reactions, which in turn formed one of four categories of psychosis.

In 1968, the eighth revision of the ICD appeared, as did the revised APA manual (DSM-II); the two generally paralleled each other. Manic-depressive reaction became manic-depressive illness and, with involutional melancholia, was classified under major affective disorders. Psychotic depressive reaction was removed from the affective disorders category and became a separate class. As was true of prior versions, the categories in ICD-9, which appeared in 1978, overlapped conceptually.

Empirically Based Systems: Research Diagnostic Criteria, DSM-III-R, and ICD-10

The transition from DSM-II to DSM-III and more recent systems has been characterized by a movement from psychiatric dogmas to greater reliance on empirical research. ICD-9 and DSM-II were fundamentally flawed, despite their greater use of descriptive material and implicit recognition of the bipolar–unipolar distinction, because they were essentially compromises constructed around isolated, mutually exclusive belief systems about etiology. In DSM-II, each school of psychiatric thought appeared to be assigned its own category, which reflected its own etiologic assumptions. For example, a presumed psychosocial etiology was the defining characteristic for depressions not associated with physiological disturbances or major functional impairment. Depressions associated with these latter features were presumed to be endogenous, that is, biological in origin. In both ICD-9 and DSM-II, manic-depressive illness stayed in the “endogenous” column. Neurotic (reactive) depression and psychotic depressive reaction (or reactive depressive psychoses) were excluded from the manic-depressive illness

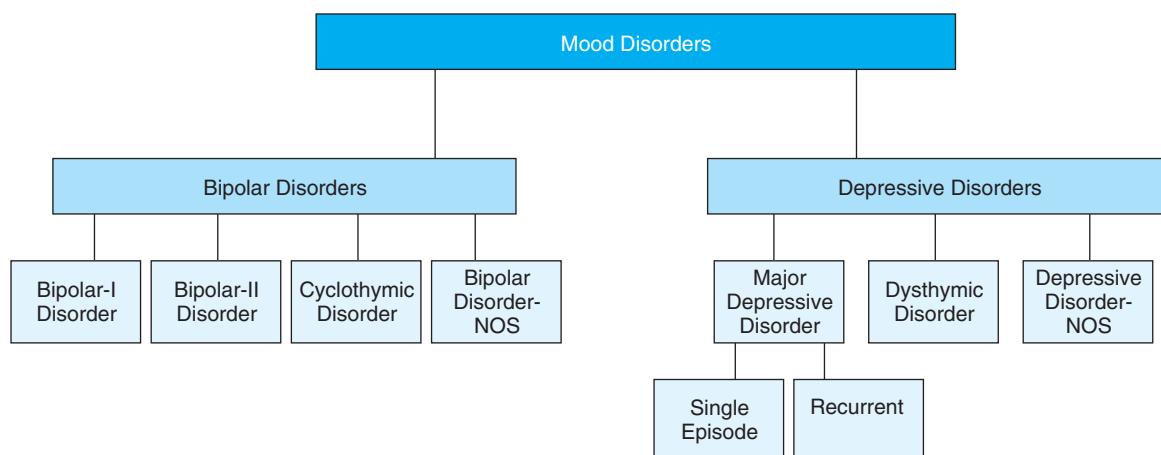

category, implying that the presence of precipitating factors was incompatible with such a diagnosis.

Clearly, what was desperately needed was a nosological system that was etiologically neutral, a system that would allow independent assessment of the types and severity of symptoms, the presence of precipitating events, the extent of functional impairment, personality characteristics, and the presence of other psychiatric diagnoses. Without such a system, the long-standing debate pitting biological predispositions against psychological causes and social influences would remain an exercise in polemics. Likewise, attempts to foster understanding of manic-depressive illness by bridging these insular schools of thought would continue to flounder, as would efforts to clarify the relationship between affective illness and schizophrenia.

The evolution of psychiatric nosology toward DSM-III was propelled by the rise in influence of the “neo-Kraepelinian” school, based in the United States at Washington University at St. Louis. The shift was toward descriptive criteria, based to the extent possible on empirical evidence, with no etiologic commitments. Since diagnostic validity was and remains elusive, the framers of DSM-III sought to at least establish diagnostic reliability—agreed-upon empirically testable definitions—which is a prerequisite to validity. A precursor to DSM-III was the Research Diagnostic Criteria (RDC)² (Spitzer et al., 1978).

The systems as they have evolved thus far are by no means ideal. For example, as illustrated in Figure 3-1, the organization of both DSM-III and DSM-IV implies that bipolar disorder is distinct from all forms of major depression. This division discourages consideration of underlying unifying relationships between bipolar and the more highly recurrent forms of unipolar disorder, including the possibility that they fall along a continuum (Angst et al., 2003; Smith et al., 2005; see also Chapter 1). It appears that

Figure 3-1. DSM-IV classification of mood disorders. NOS = not otherwise specified.

the designers of DSM-III and -IV arbitrarily chose polarity over cyclicity or recurrence as the primary principle for organizing a diagnostic system. This approach left the depressive disorder category as hopelessly heterogeneous, defined only by not being bipolar (see Chapter 1). Another drawback of DSM-III, DSM-III-R, and DSM-IV is that they lack the rich clinical descriptiveness of ICD-9.

Other criticisms can be made of the DSM-IV system in general, not just of the bipolar category. First, natural course, longitudinal patterns, and family history in recurrent affective illness are not included in the DSM-IV criteria, despite their clear importance. The lack of attention to course means that the DSM-IV schema often results in defining an episode more reliably than the disorder. For example, in longitudinal studies of patients with mixed affective and schizophrenic symptoms, numerous investigators³ have noted a significant proportion who undergo syndrome shifts; that is, at one point in their history they can be diagnosed as schizophrenic, and at another as having an affective disorder.

Other studies of diagnostic stability—defined as the degree to which a diagnosis is confirmed at subsequent assessment points (Fennig et al., 1994)—have shown a similar propensity to diagnostic shifting, with an original diagnosis of unipolar depression later changing to one of bipolar disorder.⁴ In a 20-year follow-up of 406 hospitalized depressed patients initially diagnosed as unipolar (Angst et al., 2005), the diagnoses were changed to bipolar at a rate of approximately 1.5 percent per year (1 percent to bipolar-I, 0.5 percent to bipolar-II), cumulatively 39.2 percent over the 20-year follow-up period; those with six or more depressive episodes were especially likely to be re-diagnosed as bipolar. In an interesting study of the relationship of diagnostic criteria to the stability of the bipolar diagnosis, Amin and colleagues (1999) found that 91 percent of those diagnosed as bipolar according to ICD-10 maintained that diagnosis at a 3-year follow-up, compared with only 78 percent of those so diagnosed using DSM-IV (see also Chapter 3).

Another problem with DSM-IV is that since all criteria are weighted equally, a DSM-IV diagnosis cannot by itself replicate the complex process of pattern recognition by which the experienced clinician arrives at a diagnosis. The limitations of the system were emphasized by van Praag (1993, p. 97):

One can witness a standardized interview degenerating into a question-and-answer game: answers being taken on face value, not caring for the meaning behind the words, disregarding the as-yet-unspoken and oblivious to the emotional content of the communication. . . . There is the danger of the desk researcher studying rating scale and standardized

interview results rather than actual patients. These may be data collected not by himself, but by a research assistant with little psychiatric experience and training.

ICD-10 became official in 1993. Heavily influenced by the development of DSM-IV, it groups all mood disorders together by replacing manic-depressive psychosis with bipolar affective disorder and recurrent depressive disorders. ICD-10 does stay more true to the original Kraepelinian vision by linking the two recurrent forms of major affective disorder.⁵ Neurotic depression, reactive depressive psychosis, and affective (cyclothymic) personality disorder are relocated to the major groups of affective disorders. The classification scheme for ICD-10 is reviewed in Box 3-1b, presented earlier.

Transition from DSM-III-R to DSM-IV

DSM-III-R was criticized for its definitions of mood disorders on a number of grounds. First, bipolar-II disorder was only a residual category and not recognized as a distinct presentation. Second, there was no operational definition of rapid cycling or mixed states. Third, there was no duration requirement for manic, mixed, or depressive episodes in bipolar disorder, leading to some confusion in distinguishing among rapid cycling, mixed episodes, and cyclothymic disorder. Fourth, certain system-level flaws from prior DSM criteria persisted, such as an absence of clinical description and no information regarding age at onset, course, or family history.

DSM-IV was introduced in 1994. Major revisions are as follows:

- Bipolar-II is designated as a diagnostic entity in its own right.
- Antidepressant-induced mood states are excluded from the diagnosis of bipolar disorder.
- Episodes are descriptive but not formally categorized with codes; instead, mood disorders are coded as either recurrent or single episode. This simple distinction between recurrent and single episode is still too broad since it includes everyone with more than one episode; more useful would be a further distinction between those with two to four (recurrent) and more than four (highly recurrent) episodes.
- Information on course, age, and gender is included. A time specification of 1 week is given for manic or mixed episodes.
- Criteria for mixed states are explicitly stated.
- A separate definition of rapid cycling is provided, based on empirical data supporting a definition of four or more episodes per year (see Chapter 4).

DSM-IV makes no change in the overall diagnostic schema for major depressive disorder.

Of the above changes, perhaps the most important clinically are the introduction of bipolar-II disorder, the definition of rapid cycling, the definition of mixed episodes, and the exclusion of antidepressant-induced mood states from the diagnosis of bipolar disorder. In general, it would appear that the DSM-IV task force attempted to balance the expansion of the bipolar diagnosis to include type II and a clearly defined rapid-cycling course with more restrictive definitions of mixed states and antidepressant-induced mania.

On the latter point, there is indeed significant evidence that antidepressant-induced mania is a predictive marker for bipolar disorder (Akiskal and Benazzi, 2003; Akiskal et al., 2003). The exclusion of this diagnostic group is not supported clinically or empirically by most of the available evidence. To quote Dunner (1998) (a member of the DSM-IV task force):

There was a sense from the Task Force that bipolar conditions should not be overdiagnosed in the community; if they are, lithium might be too broadly applied to patients with mood disorders. . . . The criteria for bipolar II were defined in a way that is somewhat restrictive. . . . Hypomanic episodes occurring in response to treatment with antidepressant pharmacotherapy would not count toward the diagnosis of bipolar II but would instead be termed substance-induced hypomania. Frankly, this latter option makes little sense to me and is inconsistent with the natural course of bipolar disorder. . . . It is difficult to induce mania or hypomania in a true unipolar patient; there is a likelihood that patients who develop hypomania in response to treatment are actually bipolar.

Given the (probably unfortunate) reality that the majority of patients with bipolar disorder take antidepressants most of the time, it can be difficult to be sure about the identification of true spontaneous manic or hypomanic episodes.

The definition of mixed episodes (discussed further below) in DSM-IV requires that complete criteria for a major depressive episode and a manic episode be met simultaneously for 1 week. This strict definition can exclude many classic descriptions of dysphoric mania and agitated depression that have historically been referred to as mixed states and appear to share characteristics distinct from pure depression or pure mania (see Chapter 2). As discussed below, these more broadly defined mixed states may be valid categories that are, unfortunately, excluded from DSM-IV.

Finally as noted above, DSM-IV continues to leave unaddressed Kraepelin's original observation of the essential unity of the recurrent affective disorders, both bipolar and unipolar, and the possibility that these two recurrent subgroups exist along a spectrum with intermediate forms.

Thus, while DSM-IV incorporates some useful new features, it leaves considerable room for improvement. It may be hoped that this will be accomplished. The APA and the National Institute of Mental Health (NIMH) have commissioned a series of white papers on various diagnostic issues as a way to launch the process of the development of DSM-V. Also, the APA and WHO are jointly sponsoring a series of conferences to stimulate and coordinate the empirical research necessary to fill key information gaps relevant to improving current diagnostic systems; the promotion of international collaborations is a key goal of the APA–WHO effort (American Psychiatric Association, 2005). Figure 3–2 presents our proposal for the organization of mood disorders in DSM-V.

We now turn to the specific diagnostic criteria set forth in DSM-IV. For mania, depression, and mixed states, the criteria define episodes; for bipolar-II disorder, cyclothymia, and schizoaffective disorder, they include a definition of the disorder. The role of biological correlates of diagnosis is reviewed in Chapters 9, 13, 14, and 15.

DIAGNOSTIC CRITERIA

When making a diagnosis, the clinician should assess presenting signs and symptoms, and weigh them together with the patient's history and prior response to treatment, as well as the family's history. Individual symptoms—even clusters of symptoms—examined at one point in time often lack diagnostic specificity, although such cross-sectional views are sometimes the only ones available. In the following sections, we use the relevant DSM-IV categories as a framework for discussing diagnostic criteria for mania and hypomania, depression, mixed states, cyclothymia, and schizoaffective disorder. We also review problems involved in applying the DSM-IV criteria.

Mania and Hypomania

The DSM-IV definition of a manic episode is given in Box 3–2. Among the criteria for mania, perhaps the most objective is decreased need for sleep. In more subtle cases of hypomania in particular, this feature—decreased need for sleep—appears to be the most reliable single indicator of the diagnosis (Rice et al., 1992) and can alert the clinician to explore for other manic features.

As detailed in Chapter 2, the structure of mania has been examined in recent phenomenological studies using factor analytic and other methods. These studies have revealed that the most common signs of mania are motor activation, flight of ideas, pressured speech, and decreased sleep, while elated mood and increased sexuality are decidedly less common. These studies have also identified four types of mania that coincide with Kraepelin's observations:

BOX 3-2. DSM-IV Definition of a Manic Episode

DSM-IV (p. 328) defines a manic episode as follows:

Criterion A: A *manic episode* is a distinct period during which there is an abnormally and persistently elevated, expansive, or irritable mood. This period of abnormal mood must last at least 1 week (or less if hospitalization is required).

Criterion B: The mood disturbance must be accompanied by at least three additional symptoms from a list that includes inflated self-esteem or grandiosity, decreased need for sleep, pressure of speech, flight of ideas, distractibility, increased involvement in goal-directed activity or psychomotor agitation, and excessive involvement in pleasurable activities with a high potential for painful consequences. If the mood is irritable (rather than elevated or expansive), at least four of the above symptoms must be present.

Criterion C: The symptoms do not meet criteria for a mixed episode.

Criterion D: The disturbance must be sufficiently severe to cause marked impairment in social or occupational functioning or to require hospitalization, or it is characterized by the presence of psychotic features.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (Copyright 2000). American Psychiatric Association.

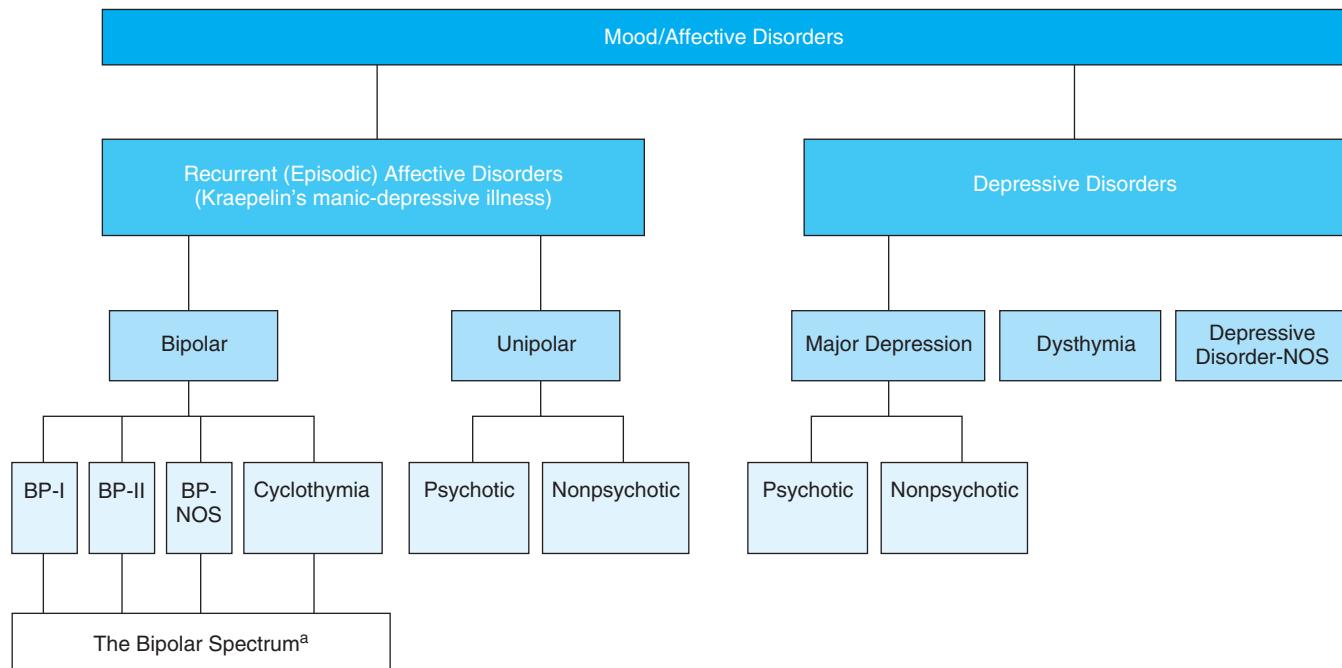

hypomania, acute mania, delusional mania, and depressive or anxious mania.

As in DSM-III-R, diagnostic criteria for manic episodes in DSM-IV include psychotic features—even the Schneiderian first-rank symptoms that some investigators have thought to be pathognomonic of schizophrenia. The framers of DSM-IV (and its DSM-III-R precursor) departed from earlier diagnostic systems because evidence had accumulated to confirm the presence of considerable thought disorder and gross psychotic content in patients clearly defined as manic by all other indicators, corresponding to Kraepelinian delusional mania. Specific exclusionary criteria are used to rule out other psychotic or secondary mental disorders, a point developed later in the section on differential diagnosis.

The diagnostic distinction between pure mania and mixed states is supported by the identification in these studies of a factor linking dysphoria in mania with depressed mood, lability, guilt, anxiety, suicidality, and the absence of elation. This finding supports the idea of frequent mixed states in manic presentations, as well as the validity of the distinction between pure mania and mixed states (see Chapter 2).

Impulsivity as a prime phenomenological feature of mania has also been underscored by the recent studies reviewed in Chapter 2. Using the Barratt Impulsiveness Scale, Swann and colleagues (2003) found that impulsivity appears to persist even outside of the acute mood state in

Figure 3-2. Mood disorders in DSM-V: a proposal. BP=bipolar; NOS=not otherwise specified.

BOX 3-3. DSM-IV Definition of a Hypomanic Episode

DSM-IV (p. 335) defines a hypomanic episode as follows:

Criterion A: *Hypomanic episode* is defined as a distinct period during which there is an abnormally and persistently elevated, expansive, or irritable mood that lasts at least 4 days.

Criterion B: Normal mood must be accompanied by at least three additional symptoms from a list that includes inflated self-esteem or grandiosity (nondelusional), decreased need for sleep, pressure of speech, flight of ideas, distractibility, increased involvement in goal-directed activities or psychomotor agitation, and excessive involvement in pleasurable activities that have a high potential for painful consequences.

Criterion C: If the mood is irritable rather than elevated or expansive, at least four additional symptoms must be present (from a list identical to that provided for a "manic episode"). . . . Hypomanic episodes must be clearly different from the individual's usual nondepressed mood, and there must be a clear change in functioning that is not characteristic of the individual's usual functioning.

Criterion D: These changes in mood and functioning must be observable by others.

Criterion E: In contrast to a manic episode, a hypomanic episode is not severe enough to cause marked impairment in social or occupational functioning or to require hospitalization, and there are no psychotic features.

bipolar disorder, suggesting that it may represent both a state and a trait feature of the illness.

Research on the structure of manic episodes indicates that they are stable, appearing with similar presentations if and when they recur. The symptom factors reviewed in Chapter 2 have been found to be highly correlated in separate episodes.

The inclusion of hypomanic episodes in DSM-IV was based on accumulating empirical evidence that hypomania could be diagnosed reliably by experienced clinicians using semistructured interviews (Dunner and Tay, 1993; Simpson et al., 2002; Benazzi, 2003); that it was stable; and that it could be distinguished from bipolar-I disorder or unipolar depression on the basis of symptoms, course, family history, and treatment response (Coryell et al., 1989; Dunner and Tay, 1993).⁶ The diagnostic criteria for a hypomanic episode in DSM-IV, which are much more specific than those in DSM-III-R, are listed in Box 3-3.

The key differentiating feature between a manic and hypomanic episode in DSM-IV is not in the manic symptoms themselves, as they are largely the same for both

diagnoses. Rather, the key difference is in the impact of those symptoms on social or occupational functioning. In a manic episode, social or occupational functioning must be characterized by "marked" impairment. In a hypomanic episode, "the episode is not severe enough to cause marked impairment in social or occupational functioning, or to necessitate hospitalization, and there are no psychotic features." In simple terms, there should be no such thing as a hypomanic hospitalized patient; if manic-like symptoms lead to hospitalization, the diagnosis must be mania, not hypomania. The same holds true if psychosis is present. With regard to functional impairment, much hinges on one's definition of the word "marked," which DSM-IV has left deliberately vague, perhaps reflecting the limited literature on the subject. Indeed, the main reason for the low reliability of a bipolar-II diagnosis in many routine clinical settings is that clinicians disagree on the limits of marked functional impairment. Hypomanic episode is one of the few if not the only major Axis I primary psychiatric diagnosis in DSM-IV in which marked impairment of social or occupational functioning is not part of the definition of the syndrome; indeed as noted, the clinician must rule out such impairment before making the diagnosis. Almost all the impairment in bipolar-II is due to the depressive phase. As Vieta and colleagues (1997, p. 100) observed:

It is worth emphasizing that although bipolar-II disorder is milder than bipolar-I disorder in terms of manic symptoms, it is not less severe in terms of depressive morbidity. In fact, bipolar-II disorder is more severe in terms of an increased propensity for rapid-cycling and a greater number of mood episodes than bipolar-I disorder.

Another important difference between the DSM-IV definitions of mania and hypomania has to do with the duration of the syndrome, defined as 1 week for the former and a minimum of 4 days for the latter. Clinical and research experience suggests that 2 to 3 days of hypomania appears to identify a cohort of patients with a variant of bipolar illness that is milder in manic symptomatology than the classic form (Angst, 1998). Duration of 1 day or less of hypomania is more controversial, often making it difficult to distinguish the state from the rapid mood alternations of borderline personality disorder or normal variants in temperament. The following is Dunner's (1992, p. 13) account of how the 4-day minimum criterion came to be set:

The initial definition proposed by Dunner et al. had posited a 3-day or longer duration of hypomania. This definition was based on a study of "normal" women who were being assessed for a premenstrual mood disturbance and who on interview were sometimes found to have 1–2 days

of hypomanic symptoms. Because 1–2 days of hypomania could occur in “normal” women, the proposed minimal criteria for the duration of hypomania for bipolar II patients became 3 days or more. There were no data to support the minimal duration criteria [*sic*] for hypomania, and the ICD-10 group had arbitrarily chosen 4 days or more as the minimal criterion. The [DSM-IV] Work Group opted for that definition in order to be consistent.⁷

Just as with mania, an exclusive focus on euphoria can miss patients in whom irritability is the primary manifestation, with hypomania, overactivity can be a more sensitive (but less specific) indicator of hypomania than euphoria (Akiskal, 2005). Angst and Cassano (2005) have argued for broadening this concept so that overactivity and/or euphoria and/or irritability are used together.

Bipolar-II disorder is defined as at least one hypomanic episode along with at least one major depressive episode. The diagnostic criteria for this condition are listed in Box 3–4. If a patient meets criteria for hypomania and has a history of depressions not severe enough to be designated as major depression, the appropriate DSM-IV diagnosis is

BOX 3-4. DSM-IV Definition of Bipolar-II

DSM-IV (p. 359) defines bipolar-II as follows:

Criterion A: The essential feature of bipolar-II disorder is a clinical course that is characterized by the occurrence of one or more major depressive episodes.

Criterion B: Accompanied by at least one hypomanic episode.

Criterion C: The individual experiences rapidly alternating moods (sadness, irritability, euphoria) accompanied by symptoms of a manic episode and a major depressive episode. The presence of a manic or mixed episode precludes the diagnosis of bipolar-II disorder.

Criterion D: Episodes of substance-induced mood disorder (due to the direct physiological effects of a medication, other somatic treatments for depression, drugs of abuse, or toxin exposure) or of mood disorder due to a general medical condition do not count toward a diagnosis of bipolar-II disorder. In addition, the episodes must not be better accounted for by schizoaffective disorder and are not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.

Criterion E: The symptoms must cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (Copyright 2000). American Psychiatric Association.

cyclothymia (discussed below), which is not easily distinguishable from bipolar-not otherwise specified (NOS).

Additional discussion relevant to the bipolar-II diagnosis is included in Chapters 1 and 2. For example, Benazzi and Akiskal (2005) have offered a definition of trait mood lability and suggested that it can be used as a screening tool for bipolar-II.

Depression

DSM-IV criteria for a major depressive episode are presented in Box 3–5. As with the criteria for mania, the boundaries of major depressive disorder were considerably broadened in DSM-III-R through the incorporation of additional psychotic features, including mood-incongruent delusions, and this broadened definition carries over into DSM-IV. We return to this issue later in the section on differential diagnosis. The required minimum 2 weeks’ duration is regarded as too short by many clinicians, who prefer the 1 month originally given in the criteria of Feighner and colleagues (1972).

As noted earlier in this chapter and in Chapter 1, one of the major, and in our opinion unfortunate, changes in the transition to ICD-10 and DSM-IV is that both of these nosologies, as a first principle, separate bipolar disorder from major depression (single or recurrent), thereby reinforcing the bipolar–unipolar dichotomy. Within the DSM-IV framework, there is no attempt to differentiate bipolar from unipolar depression on any grounds other than the presence or absence of a history of mania. Clinical features reported to differentiate bipolar from unipolar depression as described in Chapter 1 are not incorporated into the DSM-IV system. In contrast, ICD-9, under the rubric of manic-depressive psychoses—depressed type, properly emphasized the recurrent nature of endogenous forms of depression, implying that such depressions are closely related to bipolar illness (i.e., Kraepelin’s manic-depressive illness).

Mixed States

The factor analytic studies referred to earlier (and reviewed in Chapter 2) reported two types of mixed states with marked lability of mood: one displayed depression with labile periods of pressured, irritable hostility and paranoia; the other displayed an incongruous mix of elated mood and psychosis, which would switch frequently to anxiety, depression, and irritability.

Kraepelin originally viewed mixed states as the most common form of manic-depressive illness. In fact, in the 1899 edition of his textbook, he placed a great deal of emphasis on six types of mixed states, including forms that clinicians today may label as mania (dysphoric mania) or depression (agitated depression, depression with racing

BOX 3-5. DSM-IV Definition of a Major Depressive Episode

DSM-IV (p. 320) defines a major depressive episode as follows:

Criterion A1: The essential feature of a major depressive episode is a period of at least 2 weeks during which there is either depressed mood or the loss of interest or pleasure in nearly all activities. In children and adolescents, the mood may be irritable rather than sad. The individual must also experience at least four additional symptoms drawn from a list that includes changes in appetite or weight, sleep, and psychomotor activity; decreased energy; feelings of worthlessness or guilt; difficulty thinking, concentrating, or making decisions; or recurrent thoughts of death or suicidal ideation, plans, or attempts. To count toward a major depressive episode, a symptom must either be newly present or must have clearly worsened compared with the person's pre-episode status. The symptoms must persist for most of the day, nearly every day, for at least 2 consecutive weeks. The episode must be accompanied by clinically significant distress or impairment in social, occupational, or other important areas of functioning. For some individuals with milder episodes, functioning may appear to be normal, but requires markedly increased effort. The mood in a major depressive episode is often described by the person as depressed, sad, hopeless, discouraged, or "down in the dumps."

Criterion A2: Loss of interest or pleasure is nearly always present, at least to some degree.

Criterion A3: When appetite changes are severe (in either direction), there may be a significant loss or gain in weight, or, in children, a failure to make expected weight gains may be noted.

Criterion A4: The most common sleep disturbance associated with a major depressive episode is insomnia.

Criterion A5: Psychomotor changes include agitation (e.g., the inability to sit still, pacing, hand-wringing; or pulling or rubbing of the skin, clothing, or other objects) or retardation (e.g., slowed speech, thinking, and body movements; increased pauses before answering; speech that is decreased in volume, inflection, amount, or variety of content, or muteness).

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (Copyright 2000). American Psychiatric Association.

thoughts) (Marneros, 2001; Salvatore et al., 2002).⁸ Recent work has confirmed that agitated depression and dysphoric mania are distinguishable syndromes—the differences lying primarily in manic-like symptoms, with depressive and anxiety features being rather similar (Swann et al., 1993). Koukopoulos (1999) considers agitated depression to be a mixed depressive state, as did Kraepelin (1921) and Waygandt (1899). This category can include cases without motor agitation but with intense psychic agitation or inner tension. To clarify the differential diagnosis between anxiety and

inner agitation, Koukopoulos has proposed certain criteria⁹ (Koukopoulos et al., 2005).

A third kind of mixed state, unique to bipolar-II disorder, has also recently been proposed: the "depressive mixed state" (Benazzi, 2000b). This condition, described more fully in Chapters 1 and 2, reflects the occurrence of a major depressive episode and *at least three* hypomanic symptoms in an individual with bipolar-II disorder (past pure depressive and spontaneous "hypomanic" episodes).

Compared with DSM-III-R and ICD-10, DSM-IV provides a more definitive treatment of mixed episodes. DSM-IV still does not, however, provide separate empirically derived criteria for mixed states, but instead refers to the criteria for mania and depression. DSM-IV also avoids addressing criteria for the diagnosis of agitated depression or dysphoric mania. The main DSM-IV and ICD-10 criteria for bipolar-I disorder, most recent episode mixed, are provided in Box 3-6. DSM-IV's description is more extensive than in the past, whereas the ICD-10 definition is somewhat vague and spotty.

Despite the advance toward a clear definition of mixed episodes, the DSM-IV criteria remain unlinked to empirical

BOX 3-6. DSM-IV and ICD-10 Definitions of a Mixed Episode

DSM-IV (p. 333) defines a mixed episode as follows:

Criterion A: A mixed episode is characterized by a period of time (lasting at least 1 week) in which the criteria are met both for a manic episode and for a major depressive episode nearly every day.

The individual experiences rapidly alternating moods (sadness, irritability, euphoria) accompanied by symptoms of a manic episode and a major depressive episode. The symptom presentation frequently includes agitation, insomnia, appetite dysregulation, psychotic features, and suicidal thinking.

The ICD-10 definition is as follows (p. 58)^a:

Bipolar affective disorder, current episode mixed: The patient has had at least one authenticated hypomanic, manic, depressive, or mixed affective episode in the past, and currently exhibits either a mixture or a rapid alternation of manic and depressive symptoms.

^aIn the first edition, we also referred to the Vienna Research Criteria for Mixed States, which before DSM-IV provided the clearest definition. Unlike DSM-IV, the Vienna Research Criteria were derived more directly from empirical studies of mixed states. It appears the DSM-IV task force felt the need to provide a clear definition of mixed states in light of the burgeoning literature on the topic. Yet it chose to use the most restrictive definition possible, contrary to the empirical evidence supporting somewhat broader definition of mixed states (see discussion in the text).

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (Copyright 2000). American Psychiatric Association.

studies of such episodes—specifically those studies that support the validity of definitions in which criteria for mixed episodes are met by mania accompanied by as few as two or more depressive symptoms (dysphoric mania) (McElroy et al., 1992). Using this definition, for instance, one study (reviewed in Chapter 18) suggested greater treatment response with valproate than with lithium.

Some research suggests that, under the narrow DSM-IV criteria, fewer than 10 percent of episodes in patients with bipolar disorder meet criteria for a mixed episode. One study reviewed in Chapter 2 found that only 54 percent of 143 broadly defined mixed states (using Kraepelinian definitions) met DSM-III-R (or DSM-IV) criteria for a mixed episode (Perugi et al., 1997). Data suggest that using broader criteria for mixed states, incorporating the clinical concept of dysphoric mania and perhaps also agitated depression, in patients with bipolar disorder would result in more than 50 percent of episodes in bipolar disorder being diagnosable as mixed states.

Further work is needed to demonstrate empirically the appropriate boundaries for mixed states. Findings of other studies reviewed in Chapter 2 suggest that the DSM-IV criteria will need to be broadened. For instance, when dysphoric mania was defined as two or more depressive criteria plus a manic episode (McElroy et al., 1992), 36 percent of manic episodes were identified as dysphoric (Hantouche et al., 2001). In a study of the “depressive mixed state,” Perugi and colleagues (1997) found that 32 patients with depressive mixed states could be distinguished from 36 patients with pure bipolar depression by the presence of increased cyclicity with greater frequency of episodes in the latter group, as opposed to longer episodes with less interepisode recovery in the depressive mixed state group (Perugi et al., 2001).

There is also some evidence, reviewed in Chapter 19, that patients with depressive “mixed states” (analogous or perhaps identical to agitated depression), unlike those with pure depression, may not respond well to antidepressants and may even worsen with their use. Thus it would appear that depressive mixed states are distinct from pure major depression in phenomenology, course, treatment response, and family history, a supposition that may justify a broadening of DSM-IV criteria for mixed episodes. It is also important to recall the point made in Chapters 1 and 2 that, while irritability often occurs in mixed states, irritability is nonspecific, occurring also in pure mania as well as in pure depression.

Cyclothymia

Consistent with our discussion of cyclothymia in Chapter 2, DSM-IV notes that the boundaries between this disorder, bipolar disorder, and bipolar-NOS are not well de-

fined, and that many investigators believe cyclothymia to be simply a mild form of bipolar illness. The DSM-IV definition of cyclothymia is presented in Box 3-7.

Note that DSM-IV allows for a dual diagnosis of a major depressive, manic, or mixed episode and cyclothymia if such episodes occur after the described 2-year period. The clinical relevance of this provision is not clear. DSM-IV also allows for a dual diagnosis of borderline personality disorder, noting that the two disorders are sometimes difficult to distinguish. We find the notion of combining two diagnoses because they are difficult to differentiate questionable at best; we discuss problems involving borderline personality disorder comorbidity in Chapter 2 and in the section on differential diagnosis below.

It should be noted that the DSM-IV residual category of bipolar-NOS allows for the inclusion of many suspected

BOX 3-7. DSM-IV Definition of Cyclothymia

DSM-IV (p. 363) defines cyclothymia as follows:

Criterion A: *Cyclothymic disorder* is a chronic, fluctuating mood disturbance involving numerous periods of hypomanic symptoms and numerous periods of depressive symptoms.

Criterion B: The hypomanic symptoms are of insufficient number, severity, pervasiveness, or duration to meet full criteria for a manic episode, and the depressive symptoms are of insufficient number, severity, pervasiveness, or duration to meet full criteria for a major depressive episode. During the 2-year period (1 year for children or adolescents), any symptom-free intervals last no longer than 2 months.

Criterion C: The 2-year period of cyclothymic symptoms must be free of major depressive, manic, and mixed episodes.

Criterion D: After the initial 2 years of the cyclothymic disorder, manic or mixed episodes may be superimposed on the cyclothymic disorder, in which case both cyclothymic disorder and bipolar-I disorder are diagnosed. Similarly, after the initial 2 years of cyclothymic disorder, major depressive episodes may be superimposed on the cyclothymic disorder, in which case both cyclothymic disorder and bipolar-II disorder are diagnosed. The diagnosis is not made if the pattern of mood swings is better accounted for by schizoaffective disorder or is superimposed on a psychotic disorder, such as schizophrenia, schizophreniform disorder, delusional disorder, or psychotic disorder not otherwise specified.

Criterion E: The mood disturbance must also not be due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) nor a general medical condition (e.g., hyperthyroidism).

cases of bipolar disorder that are excluded by the manual's rather strict definitions of hypomania and mixed episodes. Thus, bipolar-NOS

includes disorders with bipolar features that do not meet criteria for any specific Bipolar Disorder. Examples include 1. Very rapid alternation (over days) between manic symptoms and depressive symptoms that do not meet minimal duration criteria for a Manic Episode or a Major Depressive Episode; 2. Recurrent Hypomanic Episodes without intercurrent depressive symptoms; 3. A Manic or Mixed Episode superimposed on Delusion Disorder, residual Schizophrenia, or Psychotic Disorder not otherwise specified; 4. Situations in which the clinician has concluded that a Bipolar Disorder is present but is unable to determine whether it is primary, due to a general medical condition, or substance induced. (p. 366)

In effect, most cases of bipolar spectrum illness that are more atypical than bipolar-II disorder or cyclothymia fall under the nonspecific rubric of bipolar-NOS. We should note here that, although DSM-IV does not address bipolar spectrum disorder (which is covered in Chapter 1), there is an emerging literature proposing criteria for its diagnosis.¹⁰

Schizoaffective Disorder

In DSM-I and -II, schizoaffective illness was included as a subtype of schizophrenia, reflecting the broad Bleulerian concept of schizophrenia as discussed later in this chapter. Subsequent research (reviewed in Chapter 2) documented the frequent occurrence of Schneiderian first-rank¹¹ and related schizophrenic symptoms (e.g., catatonic features, paranoia, bizarre behavior, formal thought disorder) in individuals whose family history, natural course, other symptoms, and treatment outcome clearly placed them in the manic spectrum. American psychiatry departed significantly from the Bleulerian tradition when, in DSM-III, the scope of affective illnesses was substantially broadened to include nonaffective psychotic symptoms. Schizoaffective illness was moved from schizophrenia to an intermediate category labeled "psychotic disorders not elsewhere classified." With DSM-III-R and ICD-9, schizoaffective disorder was given its own criteria. Those criteria essentially restated the acute symptoms required for a diagnosis of schizophrenia, but without continuous signs of illness for 6 months or more. The schizoaffective category was thus reserved for patients who met the acute symptomatic criteria for mania (or depression) and for schizophrenia and who had delusions or hallucinations in the absence of prominent mood symptoms for more than 2 weeks. (If the delusions or hallucinations were present for less than 2 weeks, the patient met criteria for a primary affective disorder.)

In DSM-IV, the main change is in criterion C. This criterion had previously been worded as follows: "Schizophrenia has been ruled out, [when] the duration of all episodes of a mood syndrome has not been brief relative to the total duration of the psychotic disturbance." In DSM-IV, this wording is somewhat clearer: "Symptoms that meet criteria for a mood episode are present for a substantial portion of the total duration of the active and residual periods of the illness." By still using the somewhat deliberately vague phrase "substantial portion," the DSM-IV definition seeks to increase the relevance of mood symptoms to the definition of schizoaffective disorder. In other words, one might diagnose DSM-IV schizoaffective disorder in a person with prominent mood syndromes and only a relative excess of psychotic symptoms (e.g., 2 weeks of psychosis outside of a mood syndrome). Yet one would not diagnose the disorder in a person with prominent chronic psychosis and only brief mood episodes (e.g., 2 weeks of a major depressive episode). Mood episodes must be relatively frequent and lengthy in the DSM-IV definition of schizoaffective disorder. Otherwise, the appropriate diagnosis would appear to be schizophrenia with comorbid major depressive episodes (in the case of depression). This tendency of the DSM-IV definition of schizoaffective disorder to be weighted toward the presence of mood symptoms is intended to focus this diagnosis on persons whose illness is closely related to mood disorders.

Some controversy persists over whether this newly delineated category is closer to affective illness or to schizophrenia, or whether it is a valid diagnosis in its own right. There are at least five major schools of thought on the matter, among them that schizoaffective illness represents

- A separate illness.
- An intermediate form on the continuum of psychosis.
- Comorbidity of schizophrenia and affective disorders.
- A more severe variant of bipolar disorder.
- A less severe variant of schizophrenia.

Some investigators believe that since patients with mood-incongruent symptoms are now included under mood disorders in DSM-IV, the remaining individuals with a mix of schizophrenic and affective symptoms (particularly depressive symptoms) are closer to the schizophrenic end of the schizoaffective spectrum (Kendler et al., 1986). As outlined in Chapter 13, family history studies support an association between DSM-III-R (or RDC) schizoaffective disorder and manic-depressive illness, as well as schizophrenia. Yet most studies have not found that schizoaffective disorder runs in families, as would be expected if it were a separate disease entity (Kendler et al., 1993). The genetic finding of co-occurrence of schizophrenia and bipolar disorder in at least some genealogies of schizoaffective

disorder supports most strongly two of the above five models—either the continuum (described below) or comorbidity perspective. The latter perspective, perhaps the newest, holds that schizoaffective disorder results when schizophrenia and bipolar disorder (two relatively common medical conditions) happen to occur in the same individual.

The position that schizoaffective illness will ultimately occupy on the spectrum of schizophrenia and affective illness may depend on whether one is referring to schizomanic or schizodepressive conditions. The schizomanic condition clearly appears to be associated more closely with affective illness, with a somewhat worse course than bipolar disorder (Gershon et al., 1982; Coryell et al., 1990). Schizoaffective depressed patients, by contrast, often demonstrate outcomes or neuropsychological profiles similar to those of the schizophrenic pole (Brockington et al., 1980; Tsuang and Coryell, 1993; Evans et al., 1999).¹²

An integrative perspective on these models and the associated data may be similar to that proposed by Tsuang and Simpson (1984). According to this perspective, in some individuals with predominantly manic symptoms and less pronounced psychosis, the diagnosable schizoaffective condition may represent a more severe variant of bipolar disorder. In individuals with predominantly psychotic symptoms and less pronounced mood symptoms (which are solely depressive), the diagnosable schizoaffective condition may represent a less severe variant of schizophrenia. And in others with a nearly equal mix of psychosis and mood symptoms (both mania and depression), the diagnosable schizoaffective disorder may represent a true comorbidity of schizophrenia and bipolar disorder, a condition not likely to be very common. Indeed, recent epidemiological studies have found the community prevalence of schizoaffective disorder to be a fraction of a percent, as might be expected if the comorbidity model is correct (Kendler et al., 1993, 1996). In contrast, clinical samples often show quite high diagnostic rates for schizoaffective disorder, perhaps reflecting the fact that those with more than one condition are more likely to come to clinical attention. In addition, higher rates of schizoaffective diagnosis could reflect the clinical tendency at times to overdiagnose schizoaffective disorder rather than engage in the arduous task of identifying psychotic and mood syndromes.

Problems in Applying the DSM-IV Criteria

We have discussed conceptual problems inherent in the DSM-IV system, including those engendered by the separation of bipolar disorder from depressive disorders. Here we note the practical problems that arise when applying this system in the clinical context.

As noted above, DSM-IV lists bipolar disorder first and then assigns depressive disorders to a totally separate category. This separation of categories at the outset is incompatible with the reality of clinical practice, where assessing patients with depressive symptoms is the most common diagnostic decision faced. The clinician's first task is to determine whether the patient meets criteria for major depressive disorder or dysthymia, and then to review the individual's history for evidence of bipolar or unipolar illness (if at all possible with the assistance of a family member). Compounding the problems caused by separating bipolar and depressive disorders "from the top," milder depressive states are listed only under the depressive disorders—that is, the nonbipolar disorders. A patient who is mildly or moderately depressed and also has a history of mania finds a niche in this system only by some awkward fitting. The system implies more homogeneity and separateness for the bipolar category than is justified by the data.

Clinical Summary

The nosological systems that evolved during the latter part of the 20th century are in many respects superior to those used earlier. They are, for the most part, etiologically neutral, allowing for independent assessment of the types and severity of symptoms, the presence of precipitating events, the extent of functional impairment, personality characteristics, and the presence of other psychiatric diagnoses. Problems remain in the classification of manic-depressive illness, however. For example, DSM-IV implies that bipolar disorder is a separate illness and fundamentally different from all forms of unipolar depression; this supposition goes beyond the data, especially with respect to the more recurrent forms of unipolar depression. Also troubling is the absence from all categories of affective illness of criteria concerning long-term course and family history and the failure to provide for a mild form of depression in bipolar illness. These and other features of the system are problematic for clinical as well as conceptual reasons.

THE PSYCHOSES: SEPARATE OR CONTINUOUS?

In the first edition of this volume, we emphasized the controversial and important topic of whether psychotic conditions should be classified as a few major conditions or as one continuous spectrum. The ensuing decade and a half has not resolved this debate, though overall, perhaps, the available evidence is accumulating more in support of than against the Kraepelinian dichotomy. Readers interested in the history of this topic may refer to Tables 3-1a and 3-1b.

TABLE 3–1a. The Two-Entities Tradition

Author	Schizophrenia	Manic-Depressive Illness
Kraepelin, 1896	Characterized by a steady downhill course into chronic dementia	Characterized by an episodic course with intermittent recovery.
Bleuler, 1911	Certain symptoms are specific and pathognomonic—namely, those symptoms that define splitting of thought from feeling and behavior.	Symptoms are nonspecific; diagnosis is made only after schizophrenia is excluded.
Kraepelin, 1919	Some patients appeared to recover.	Some patients followed a progressive chronic course.

TABLE 3–1b. A Schizophrenia–Affective Continuum

Study	Findings
Kasanin, 1933	Coined the term “schizoaffective psychosis” to describe a group of relatively young patients with good premorbid adjustment who in response to stress developed the rapid onset of a psychosis characterized by “marked emotional turmoil” and “false sense impressions,” but without “passivity.”
Langfeldt, 1937	Coined the term “schizophreniform” to describe patients who today would probably be referred to as schizoaffective.
Slater and Roth, 1969	Contended that the patient with a mix of affective and schizophrenic symptoms who is observed long enough can usually be confidently diagnosed as having either an affective illness or schizophrenia.
Brockington and Leff, 1979	Applied eight different published definitions of schizoaffective illness to a sample of patients, and found virtually no agreement among the various definitions.

The Two-Entities Tradition

Kraepelin's (1913) lucid discrimination of pattern in a mass of confusing clinical phenomena led him to propose a dichotomy of fundamentally different classes of psychotic illness. Lacking knowledge of etiology or pathophysiology, he based the distinction on family history, age at onset, course, and outcome. In his original formulation, dementia praecox was marked by a steady downhill course into chronic dementia, and manic-depressive illness followed an episodic course with intermittent recovery.

Kraepelin's original contribution was followed rapidly by the revision of Bleuler (1968), who changed the term “dementia praecox” to “schizophrenia,” extended the condi-

tion's boundaries, and focused on intrapsychic symptoms. The concept of manic-depressive illness, in contrast, grew increasingly narrow with time, especially in the United States, where it attracted little interest on the part of psychoanalytic groups. A U.S.–U.K. study (Copper et al., 1972) highlighted how far American clinicians had likely gone in overdiagnosing schizophrenia and underdiagnosing manic-depressive illness. With the introduction of DSM-III, this situation gradually began shifting back to one of greater balance, though there is some evidence that bipolar disorder is still misdiagnosed as schizophrenia, particularly, perhaps, in state hospitals in the United States or in developing nations (Vieta and Salva, 1997; Ghaemi et al., 1999).

A Schizophrenia–Affective Disorder Continuum

As noted previously, the complex concept of schizoaffective disorder could be seen as a rejection of the Kraepelinian dichotomy, as suggested by Crow (1998); on the other hand, the available evidence does not support the validity of schizoaffective disorder as a unique disease entity. This view was well expressed as early as 1969, in the revision of Mayer-Gross' *Clinical Psychiatry*, in which Slater and Roth contended that the patient with a mix of affective and schizophrenic symptoms who is observed long enough can usually be confidently diagnosed as having either affective illness or schizophrenia. This assertion implies that, by and large, the schizoaffective category has reflected incomplete or imperfect diagnoses rather than a meaningful diagnostic entity.

This observation is supported in part by epidemiologic studies of schizoaffective disorder conducted since the first edition of this book was published in 1990. In both the Roscommon study (2003) and the National Comorbidity Survey, schizoaffective disorder appeared to represent a small fraction of 1 percent of the population (Kendler et al., 1993, 1996). This finding contrasts with what one might expect from the unitary psychosis model, in which schizoaffective presentations, occurring in the middle of the psychotic continuum, would be presumed to be quite frequent. The Roscommon family study in particular also appeared to provide a new explanation for schizoaffective disorder—the idea of comorbidity. It could be that if families with propensities to develop schizophrenia and bipolar disorder were to merge, some offspring would develop both types of symptoms, presenting phenotypically as schizoaffective disorder. The genetic data from that study strongly support this interpretation.

Some support for a continuum model is provided by the observation that neurobiological studies have not clearly distinguished between affective disorders and schizophrenia (Crow, 1990). This observation, if accurate in the long run, does not necessarily entail the continuum model, however. Two diseases can be different phenomenologically, as well as in their etiologies, but share many pathophysiological mechanisms. In the case of the brain, the presence of many shared “final common pathways” is a well-known feature of brain function. In any case, the neurobiological or neuropsychological findings of some studies do suggest differences between patients with schizophrenia and those with affective disorders (Keri et al., 2001), although there are enough conflicting reports to leave this question open (see Chapters 9, 14, and 15). Ketter and colleagues (2004) have proposed a mixed dimensional–categorical model that they believe allows for a more flexible approach to considering pathophysiological findings and treatment options. It is their view that a dimensional

construct may be best when evaluating relationships between biological or other variables and symptoms such as psychosis in bipolar disorder or schizophrenia, while a categorical construct allows evaluation of diagnostic reliability.

Findings of a carefully conducted nosological study by Kendler and colleagues (1998) argue against the concept of a nosologic continuum. That study assessed diagnostic groupings based on family data, as well as symptom groupings. It found that most patients appeared to fall into different diagnostic categories rather than one (as suggested by Crow). Similarly, based on a factor analysis of a group of 191 psychotic patients whose diagnoses included schizophrenia and mood disorders with psychosis, Dikeos and colleagues (2006) concluded that diagnosis by itself explained the large majority of the clinical characteristics examined, although dimensional measures were more useful than diagnosis as predictors of clinical course. Others who have explored the predictive value of diagnostic versus dimensional measures in psychotic patients across both schizophrenic and affective disorder patients include van Os and colleagues (1996, 1998), Toomey and colleagues (1998), Ventura and colleagues (2000) and Serretti and colleagues (2001). Finally, another view, closer to that of Crow, is expressed by Craddock and Owen (2005, p. 364) who pointed to the emerging evidence for shared and overlapping susceptibility genes as “the beginning of the end for the Kraepelinian dichotomy,” a topic that is explored in Chapter 13.

DIFFERENTIAL DIAGNOSIS

Until the 1980s, the most commonly encountered problems in making differential diagnoses of bipolar illness involved its overlapping boundaries with schizophrenia and schizoaffective illness, as well as with personality disorders, especially borderline disorders. These two major differential diagnoses remain highly important, but to them must be added the most clinically significant problem—the differential diagnosis of bipolar disorder and unipolar depression. Bipolar illness also must be distinguished from schizophreniform disorder, brief reactive psychosis, cycloid psychosis, atypical psychosis, organic brain disorders, and epilepsy. The overlap between primary affective diagnoses and substance abuse is of such importance that we address it in a separate chapter (see Chapter 7).

Schizophrenia and Schizoaffective Disorder

As discussed previously, the clinician should be able to assign the great majority of patients a diagnosis of either affective illness or schizophrenia by carefully applying the diagnostic criteria shown in Box 3–8. Schizoaffective

BOX 3-8. DSM-IV Definition of Schizoaffective Disorder

DSM-IV (p. 309) defines schizoaffective disorder as follows:

Criterion A: The essential feature of schizoaffective disorder is an uninterrupted period of illness during which, at some time, there is a major depressive, manic, or mixed episode concurrent with symptoms that meet Criterion A for schizophrenia.

Criterion B: In addition, during the same period of illness, there have been delusions or hallucinations for at least 2 weeks in the absence of prominent mood symptoms.

Criterion C: Finally, the mood symptoms are present for a substantial portion of the total duration of the illness.

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (Copyright 2000). American Psychiatric Association.

disorder can sometimes be excluded by considering previous episodes; a history of either clear affective illness or clear schizophrenia cautions against diagnosing a present episode as schizoaffective.

Mania versus Schizophrenia or Schizoaffective Disorder

Differentiating mania from schizophrenia or schizoaffective illness is a diagnostic challenge often faced by clinicians. Viewed cross-sectionally, acute symptoms of irritability, anger, paranoia, thought disorder, and catatonic-like excitement cannot distinguish mania from schizophrenia. Because presenting symptoms can be similar in mania and schizophrenia, the clinician must give equal attention to the level of premorbid functioning, family history, natural course, and the character of any prior episodes. This differential diagnosis has been made more rational and straightforward by the previously discussed broadening of the criteria for mania to include a range of psychotic features.

A key DSM-IV criterion for diagnosing psychotic mania or depression in the presence of schizophrenic symptoms is the more or less continuous prominence of the affective symptoms. Thus, bizarre mood-congruent delusions or hallucinations (including Schneiderian first-rank symptoms) are not inconsistent with a diagnosis of mania as long as they have been accompanied substantially by affective symptoms most of the time (the DSM-IV criteria for mania allow for up to 2 weeks of delusions or hallucinations free of other prominent manic symptoms, whereas the RDC allow for 1 week).

If the period of quiet (i.e., affect-free) delusions or hallucinations is substantial (by criterion, exceeding 2 weeks), a diagnosis of either schizophrenia or schizoaffective

illness should be considered. Schizophrenia would be diagnosed if, in addition, the patient continuously manifested overt signs of a psychotic illness for at least 6 months, and the manic symptoms were brief relative to the duration of the schizophrenic symptoms. On the other hand, schizoaffective illness, manic type, would be diagnosed if the criterion of 6 months of continuous psychotic illness were not met, but there had been more than 2 weeks of quiet delusions or hallucinations.

It is now well recognized that strict application of the Bleulerian concept of thought disorder as pathognomonic of schizophrenia can result in misdiagnosis of manic-depressive patients (see Chapters 1 and 10). More than a quarter of patients with mania have "classic" Bleulerian symptoms of schizophrenia (Pope and Lipinski, 1978).¹³ See Chapter 2 for further discussion of psychosis and thought disorder in mania and schizophrenia.

Bipolar Depression versus Schizophrenia or Schizoaffective Disorder

As with mania, the DSM-IV criteria for differentiating bipolar depression from schizophrenia and schizoaffective disorder focus on the prominence of the affective symptoms, their temporal relationship to the psychotic or schizophrenic symptoms, and the length of time the patient has been continuously delusional or hallucinatory. (As for mania, the DSM-IV criteria for major depression allow for up to 2 weeks of "mood-free" delusions or hallucinations, whereas the RDC allow for 1 week.) These criteria reemphasize classic descriptions that include considerable psychosis among the affective disorders.

Studies emerging since the first edition of this book was published have emphasized other clues to psychosis in the depressive syndrome, which are especially relevant to many bipolar patients with psychotic depression (Schatzberg and Rothschild, 1992). Those clues include relatively intact insight, marked guilt, and marked psychomotor changes. Intact insight in particular can lead to an increased effort on the part of the patient to mask psychotic symptoms.

Mixed Bipolar States versus Schizophrenia or Schizoaffective Disorder

Mixed bipolar states can pose special problems of differential diagnosis because of their instability, the often confusing mix of manic and depressive symptoms, and the fact that these states occur most characteristically in association with the most severe stage of mania (stage III) (Carlson and Goodwin, 1973). Frequently associated with mixed states is the presence of alcohol or drug intoxication, which can further mask pure affective symptoms and confuse differential diagnosis.

Clinical Summary

The clinician can distinguish manic-depressive illness from schizophrenia or schizoaffective disorder in most cases by careful attention to the patient's personal and family history, premorbid functioning, age at onset, and sequence and patterning of symptoms. In manic-depressive illness, delusions or hallucinations generally follow a period of either manic or depressive symptoms, and affective symptoms are prominent almost continuously.

Unipolar Depression

As noted in Chapter 1, evidence has begun to accumulate over the last decade that the misdiagnosis of bipolar disorder as unipolar depression is a major clinical problem. There are likely five primary causes for this development: (1) patients' lack of insight with regard to manic as opposed to depressive symptoms; (2) clinicians' neglect of information available from family members or other third parties; (3) clinicians' relative focus on euphoric rather than dysphoric or irritable mood as a criterion for hypomania; (4) the structure of DSM-IV, which by separating out bipolar from all depressive disorders has obscured the close relationship between early-onset recurrent depression and bipolar disorder; and (5) widespread interest in and use of "second-generation" antidepressants.

In some clinical studies, between 40 and 60 percent of patients with bipolar disorder appear to have been misdiagnosed with unipolar depression in both inpatient and outpatient psychiatric settings (Benazzi, 1999; Ghaemi et al., 1999, 2000). Data that are not widely known because they were collected as part of a family history study (Tsuang et al., 1980) illustrate the extent of the problem. When patients who had previously been hospitalized for mania were evaluated by an extensive research diagnostic interview several years later (but without input from a family member), about 60 percent had forgotten or denied that they had ever been manic. These findings, reported in the United States, appear to hold true in other countries as well; similar results were found in Spain, for example, although the latter study also noted a high rate of misdiagnosis as schizophrenia and personality disorder (Vieta and Salva, 1997). In another study, careful evaluation of the history of 108 patients in primary care revealed that 48 (44 percent) had hypomanic symptoms, thus indicating an apparent misdiagnosis rate of about 40 percent in the primary care setting as well (Manning et al., 1997). Hence careful attention to the differential diagnosis of bipolar disorder and unipolar depression is essential.

As we note throughout this text, much of the problem of the misdiagnosis of bipolar disorder as unipolar depression has to do with the structure of DSM-IV itself (recall

Fig. 3-1). Since DSM-III, the diagnostic system used in the United States has separated bipolar disorder from all depressive disorders "from the top," as does ICD-10. Major depressive episodes are always identified initially as unipolar (not bipolar), and a diagnosis of bipolar disorder relies entirely on diagnosis of a spontaneous manic or hypomanic episode. By excluding antidepressant-related mania or hypomania and by providing a very strict definition of mixed episodes, DSM-IV makes it likely that unipolar depression will be diagnosed more and bipolar disorder less frequently.

Unfortunately, in the case of the depressed patient, a diagnosis of bipolar disorder becomes entirely dependent on obtaining a history of past spontaneous mania or hypomania. A number of factors—related to both patient and clinician—mitigate against a complete and accurate diagnosis in such circumstances (see Box 3-9).

Among patient factors, lack of insight is perhaps most important. Researchers have demonstrated that about half of patients with acute mania lack insight into their symptoms (Amador et al., 1994; Ghaemi et al., 1995). Thus among depressed patients, that proportion or more would be unable to provide an accurate history of mania simply because they had never recognized having its symptoms. For example, in one study, patients reported prodromal

BOX 3-9. Patient, Clinician, and Illness Factors Leading to Misdiagnosis of Bipolar Disorder as Unipolar Depression

Patient Factors

- Lack of insight with regard to mania
- Impaired memory during the depressive state and/or memory selective for past depressions (state-dependent memory)
- Experiencing of hypomania as normal "good times"
- Cultural positive feedback for manic/hypomanic symptoms

Clinician Factors

- Failure to include a family member in the diagnostic evaluation
- Structure of DSM-IV, which, "from the top," separates bipolar from all depressions
- Inadequate knowledge of manic criteria
- Intuitive "prototype" approach to diagnosis
- Practical desire to make a diagnosis (e.g., unipolar depression) for which many effective treatments exist
- Lack of awareness of the high population rate of bipolar illness

Illness Factors

- First episode of illness is often depression, not mania
- Dysphoric depression is not conceptualized as a mixed state
- Depressive episodes last longer than the often fleeting hypomanic states

behavioral symptoms of mania only half as frequently as did family members (Keitner et al., 1996). These data strongly support the need to obtain family or other third-party reports (e.g., teachers, halfway-house staff, social workers, psychotherapists, friends) in assessing the bipolar diagnosis. In fact, one might reasonably say that it is virtually impossible to rule out bipolar disorder with any degree of confidence in the absence of third-party reports.

Depressed patients' self-reports are also impaired by the depressive state. As is well known, depression not only impairs memory but also makes it more likely that memories will focus on past depressions—that is, memory can be state dependent. Thus, even if patients had previously possessed some insight into their manic symptoms, they might have difficulty recalling those symptoms clearly and accurately enough for the clinician to make a definitive diagnosis. Also, patients are often in such psychic pain during a depressive episode that they may be unmotivated to search their memory carefully for times when they may have felt better (albeit pathologically). Even then the mania may be remembered simply as "good periods."

Even more challenging is the ascertainment of prior hypomania, given the ill-defined boundary between hypomania and normal good mood (Gershon et al., 1982). Indeed, patients often cannot distinguish the hypomanic state, since they may not view it as behaviorally different from their usual personality—a phenomenon recognized by DSM-IV in requiring third-party reports for the diagnosis of hypomania. Cultural factors are also relevant: in the United States, hypomanic traits are often prized and socially promoted, making it difficult for some patients, as well as some observers, to recognize them as "abnormal."

Clinician-related factors are important as well. First and foremost, clinicians are often not aware of manic symptoms. In one study, clinicians could not describe accurately more than three of the seven manic criteria when asked to write them down, as compared with their ability to describe seven of the eight major depressive criteria (Srock, 1988). This apparent ignorance of the features of mania may be due in part to the "prototype" phenomenon (Cantor et al., 1980), which relates to diagnosis by clinical intuition alone. Clinicians often practice with prototypes of the common syndromes in mind—the "typical" patient with depression, schizophrenia, or mania. Experience over the years has taught, however, that such prototypes need to be augmented by careful attention to empirically based diagnostic criteria. Furthermore, prototypes usually represent cross-sectional symptomatic presentations (e.g., the manic patient is agitated and grandiose); we know that such observations need to be augmented with longitudinal data regarding age at onset and course, as well as family history and prior medication responses.

In the past, such intuitive diagnostic techniques tended to lead to overdiagnosis of schizophrenia and probably to underdiagnosis of major depression as well. In the last decade or so—in part as a result of major continuing medical education programs often underwritten by the pharmaceutical industry (with interests in the multitude of new antidepressants)—much greater attention has been paid to major depression, and clinicians now routinely apply DSM-IV diagnostic criteria to that disorder. The evidence suggests, in contrast, that many if not most clinicians fail to apply the diagnostic criteria for mania routinely, and instead rely on a largely intuitive approach to diagnosis of the condition. With this approach, it is likely that only patients with pure euphoric mania at the time of the evaluation will be diagnosed; mixed episodes, rapid-cycling episodes, and bipolar depressed patients will tend to be missed.

Clinicians are practitioners first and foremost. The recent tendency to diagnose bipolar disorder less frequently may relate to the relative paucity of mood-stabilizing options. The advent of new mood stabilizers appears to be generating increased interest in bipolar disorder. Unfortunately, a recent survey of the members of the National Depressive and Manic-Depressive Association (now renamed the Depression and Bipolar Support Alliance) in the United States failed to find improvement in diagnosis of bipolar disorder in 2000 (Lewis, 2001) relative to 1994 (Lish et al., 1994). About half of patients had initially been misdiagnosed with unipolar depression, and the accurate diagnosis of bipolar disorder had usually been delayed by about a decade after initial evaluations with mental health professionals. On average, more than three mental health professionals had been seen before the accurate diagnosis of bipolar disorder had been made.¹⁴ Relatively recent clinical studies have confirmed these findings. Thus, despite increasing attention to affective disorders in recent years, follow-up of treatment experience in a U.S. advocacy group population (which admittedly is probably not representative of bipolar illness generally) revealed little improvement during the last decade in the ability of U.S. practitioners to diagnose bipolar disorder (Hirschfeld et al., 2003). In one study, the mean time to a bipolar-I diagnosis from the first visit to a mental health professional (6 years) was twice that for unipolar depression (3.3 years), and the mean time to the correct diagnosis of bipolar-II disorder was even longer (nearly 12 years) (Ghaemi et al., 2000).

Of relevance to bipolar diagnosis is a self-report questionnaire, the Mood Disorder Questionnaire (MDQ), developed as a screening instrument for bipolar disorder (Hirschfeld et al., 2000).¹⁵ This questionnaire reflects DSM-IV criteria. Patients are asked to report whether they have experienced those symptoms, whether the symptoms

occurred simultaneously, and whether they led to significant social and occupational dysfunction. The sensitivity or true positive rate (the proportion of those actually ill thus identified) and specificity or true negative rate (the proportion of those not ill thus identified) of this self-report questionnaire depend on the population it is used to evaluate. Thus, as discussed more thoroughly in Chapter 11, relatively high sensitivity was achieved among patients from a university affective disorders clinic with a high proportion of bipolar-I patients who, moreover, were likely to have been educated about their illness. By contrast, in a community-based sample (where a screening instrument is presumably most useful), sensitivity was only 28 percent; that is, the MDQ missed more than 70 percent of those diagnosed as bipolar by a clinician using the Structured Clinical Interview for DSM (SCID) (Zimmerman et al., 2004). Similarly, in an independent validation study with a clinical sample, the MDQ was found to be more diagnostically sensitive for 26 patients with bipolar-I disorder (69 percent) than for 8 patients with bipolar-II disorder (30 percent) (Miller et al., 2002). Further, patients with impaired insight would be expected to deny their symptoms on the MDQ.¹⁶ These studies suggest that the MDQ may be more useful in a clinical than in a community setting (Hirschfeld et al., 2003). Modifications to the MDQ that might increase its utility as a screening tool in community samples have been discussed by Miller and colleagues (2004) (see Chapter 11).

Besides the issue of differential sensitivity in community versus clinical settings, the larger question is whether it is appropriate to use the MDQ as a diagnostic tool without further clinical assessment. Here the concept of predictive value is relevant (Phelps and Ghaemi, 2006). Sensitivity and specificity are characteristics of a scale; predictive values are characteristics of a sample to which the scale is applied. If the underlying prevalence of an illness is low, then even a highly sensitive scale can have a low positive predictive value, just as a highly specific scale can have a weak negative predictive value. For instance, if the MDQ, based on its two main validation studies, is applied in a community setting where the baseline rate of bipolar illness is 10 percent, a positive predictive value of less than 45–51 percent is obtained. In other words, only about half of the MDQ-positive subjects actually have bipolar disorder. In contrast, the negative predictive value of the MDQ in such settings would be quite high, over 92–97 percent. Thus in the community setting, the MDQ can help rule out but not rule in bipolar disorder. This limitation again highlights the importance of combining the MDQ or any self-report diagnostic scale with clinician-based interview evaluations. Further, this limitation should be taken into

account in some quite large research studies that assume that MDQ-positive scores are equivalent to a valid bipolar diagnosis.

In addition to clinician and patient factors, an important natural history factor can make it likely for bipolar disorder to be misdiagnosed as unipolar depression: the occurrence of depressive episodes before manic episodes in the onset of the illness (false unipolar depression). As noted in Chapters 1 and 4, this is a frequent presentation in bipolar illness, especially in females. Again, it is important to recognize that there is a relationship between false unipolar depression and age at onset. As detailed in Chapter 4, the risk of switching from false unipolar depression to bipolar disorder is highest in childhood and young adulthood, occurring at a rate of about 3 to 5 percent per year; it then decreases by the late 30s, at which point it flattens out to about 1 percent per year. Thus in any depressed child or young adult, the index of suspicion for bipolar disorder should be high, as opposed to depressed individuals in their 30s or older.

In addition to identifying past hypomanic or manic symptoms, clinicians should seek to assess clinical data in three areas that can better delineate the distinction between unipolar and bipolar depression: natural course (especially age at onset and episode frequency), family history, and treatment response.¹⁷ (For a more detailed analysis of the distinction between unipolar and bipolar depression, see Chapter 1.)

Attention-Deficit Hyperactivity Disorder (ADHD)

In children, a major differential for the diagnosis of bipolar disorder is ADHD, a topic discussed in more detail in Chapter 6. A principal overlap in symptomatology is distractibility, which is one of the criteria for mania. Child psychiatrists report that co-occurrence of marked irritability and aggression, often with major depressive episodes, should raise suspicion of bipolar disorder, at least comorbid with ADHD (Danielson et al., 2003; Fergus et al., 2003; Scheffer and Niskala Apps, 2004; Citrome and Goldberg, 2005). Retrospective data in adults suggest that in patients with bipolar disorder, symptoms of ADHD or anxiety disorder may predominate in childhood, and mood symptoms in adolescence and early adulthood (Sachs et al., 2000). Thus in some patients, ADHD may represent an early manifestation of an overall illness that later presents as a mood disorder. Another particularly informative feature is family history of bipolar disorder, which markedly increases the likelihood of bipolar disorder as opposed to ADHD. Also, if stimulant medications are ineffective or cause worsened aggression and irritability or even manic symptoms, the likelihood of bipolar disorder increases.

Finally, further research is required to establish the validity of adult ADHD. This is especially urgent now, given that adult ADHD is becoming an increasingly common diagnosis (some of this increase in diagnosis is, no doubt, in response to a new agent being marketed with this condition as an indication).

In the National Comorbidity Survey, adult ADHD was diagnosable in about 4.4 percent of the adult population (Kessler et al., 2006). However, 86 percent of these individuals were also diagnosable with mood or anxiety disorders. The authors, and many ADHD experts view these data as simply representing comorbidity; thus the importance of diagnosing and treating adult ADHD is emphasized. An equally possible if not more logical conclusion would be that since adult ADHD is hardly diagnosable without concomitant other mood or anxiety disorder diagnoses, those other diagnoses may account for most if not all of the cognitive symptoms that are labeled ADHD. This perspective flows from an appreciation of the concept of diagnostic hierarchy, whereby mood disorders in particular can cause other kinds of symptoms (whether psychotic, anxiety, or cognitive); thus those other diagnoses should not be made in the presence of an active mood disorder (Surtees and Kendell, 1979). In other words, if those mood or anxiety disorders are adequately treated, the cognitive symptoms will improve, suggesting that no separate ADHD diagnosis is necessary. Such extensive overlap between diagnoses should raise the possibility of a single diagnosis with multiple manifestations, not simply the concept of multiple diagnoses. Further, advocates for the diagnosis of adult ADHD often point to retrospective data in adults with bipolar disorder, in which 9.5 percent of such patients are retrospectively diagnosable with ADHD in childhood (Nierenberg et al., 2005). Yet such data do not necessarily support the common presence of ADHD in adulthood, but rather are compatible with the alternative view that many children with purported ADHD develop bipolar disorder in adulthood, raising the possibility that the ADHD-like presentation in childhood may have represented an early manifestation of the bipolar illness. In other words, instead of thinking that such persons had one illness in childhood and have another in adulthood, it may be more plausible that the same illness manifested itself differentially at different ages, with ADHD-like symptoms in childhood and more classic bipolar symptoms in adulthood.

In sum, given these possibilities, we would urge caution in the diagnosis and treatment of adult ADHD, always giving preference to initially diagnosing and treating mood disorders until euthymia is achieved before making the ADHD diagnosis or seeking to treat it with stimulants. Most experts would agree (given the abuse potential of

stimulants) that prescribing such agents for cognitive symptoms of distractibility without first trying to treat concurrent mood or anxiety conditions is not scientifically or clinically well informed.

Brief Psychotic Disorder

Brief psychotic disorder is a DSM-IV category (see Box 3-10) reserved for individuals who experience a psychotic episode lasting from a day to a month with “eventual full return to premorbid level of functioning.” The psychotic symptoms may or may not follow immediately after a major psychological or social stress, or they may occur postpartum. If the criteria for mania or major depressive episode are met, the affective diagnosis takes precedence. Often, individuals initially placed in the category of brief psychotic disorder eventually show symptoms that permit a diagnosis of either bipolar illness or schizophrenia. In particular, postpartum psychosis (often with depressive features) is highly associated with bipolar illness and may represent the first episode of the disorder (with manic episodes to follow) (Viguera and Cohen, 1998).

Cycloid Psychosis

The concept of cycloid psychosis, first described by Leonhard (1957), like that of schizoaffective disorder, a hybrid rooted in the overlapping symptoms of schizophrenia and recurrent (predominantly bipolar) affective illness, was discussed in more detail in the first edition of this volume. The condition occurs predominantly among females and

BOX 3-10. DSM-IV Definition of a Brief Psychotic Episode

DSM-IV (p. 139) defines a brief psychotic episode as follows:

Criterion A: The essential feature of brief psychotic disorder is a disturbance that involves the sudden onset of at least one of the following positive psychotic symptoms: delusions, hallucinations, disorganized speech (e.g., frequent derailment or incoherence), or grossly disorganized or catatonic behavior.

Criterion B: An episode of the disturbance lasts at least 1 day but less than 1 month, and the individual eventually has a full return to the premorbid level of functioning.

Criterion C: The disturbance is not better accounted for by a mood disorder with psychotic features, by schizoaffective disorder, or by schizophrenia and is not due to the direct physiological effects of a substance (e.g., a hallucinogen) or a general medical condition (e.g., subdural hematoma).

has a good prognosis. One study of 73 inpatients who met Perris's (1988) criteria for cycloid psychosis concluded that it is best regarded as an atypical variety of affective psychosis (Cutting, 1990). However, a more recent controlled family study of cycloid psychosis found a significantly lower morbidity risk for bipolar illness in first-degree relatives compared with relatives of patients with bipolar illness (Pfuhlmann et al., 2004). The authors concluded, therefore, that cycloid psychosis cannot be integrated into either the bipolar or the schizophrenic spectrum, but exists as an independent entity. Because of these conflicting results, further research is needed. Given the genetic vulnerability to psychosis that may cross the schizophrenia–affective boundary, it will be interesting to see what genetic studies of cycloid psychosis ultimately reveal.

Psychotic Disorder-Not Otherwise Specified

Classically, atypical psychosis was diagnosed in patients who had schizophrenic symptoms but showed rapid fluctuations in emotional states, an episodic course, and a generally favorable outcome. Mitsuda (1965) concluded from his study of monozygotic twins that atypical psychosis could be distinguished genetically from schizophrenia and, to a lesser extent, from manic-depressive illness. However, the relationship between this disorder and the cycloid psychosis delineated by Leonhard (1957) and Perris (1990) is not clear.

In DSM-IV, psychotic disorders-NOS is a residual category for patients with psychotic symptoms who do not meet criteria for any other DSM-IV disorder. For purposes of differential diagnosis, such patients would appear to fall in the schizoaffective spectrum.

Borderline Personality Disorder

The overlap between bipolar disorder and borderline personality disorder is quite controversial, and is discussed in more detail in Chapters 10 and 11. As a clinical rule of thumb, however, it may be good practice to use great caution in diagnosing borderline personality disorder in the midst of an active affective disorder (Parker et al., 2004). In other words, during a major depressive or hypomanic/manic episode, patients often may meet criteria for borderline personality disorder, whereas once the episode has ended, borderline features are no longer evident. Thus if possible, it is best to evaluate borderline personality disorder during periods of euthymia.

Making a differential diagnosis between bipolar depression and the depressive affect associated with borderline personality disorder involves attention to issues of lability, reactivity, and the overall symptom cluster. The depressive affect associated with borderline personality disorder is marked by considerable day-to-day or even hour-to-hour

variability, whereas the depressive mood associated with a bipolar episode is generally experienced as a discrete episode with a clear onset and termination and a relatively stable course during the episode. The mood of the borderline patient is more likely to remain reactive to the environment and, although intensely dysphoric, to change quickly with an appropriate stimulation or intervention. As noted earlier, the symptom cluster of bipolar depression generally involves pervasive changes in the regulation of sleep and appetite (usually hyperphagia and hypersomnia). These features are not associated as prominently with depressive mood in the borderline patient unless bipolar disorder also is present.

In evaluating elevated mood, duration is important as well. Given the extreme lability of mood in borderline personality disorder, mood elevation probably does not last long enough to meet the criteria for mania. On duration alone, the mood elevation in borderline personality disorder could overlap with that in hypomania or cyclothymia. The usual associated symptoms of hypomania, however, such as racing thoughts and decreased need for sleep, are generally not part of the mood lability of the borderline patient. The absence of events either precipitating or terminating the hypomanic mood would also suggest a true case of bipolar disorder, as would a positive family history of the disorder, although the latter would not be conclusive. In practical terms, emphasis on the linkage between borderline and bipolar diagnoses is important because all too often, the diagnosis of bipolar disorder is missed when borderline features are also present, especially in adolescents. As discussed in Chapter 6, bipolar disorder can be especially difficult to diagnose in this age group, since a wide range of apparently nonspecific symptoms is common. Not infrequently, moreover, individuals rediagnosed as bipolar on follow-up experienced their first manic or hypomanic episode after exposure to an antidepressant drug. The possibility of this outcome argues for considerable care in ruling out a bipolar diathesis before treating depressive syndromes in adolescents with presumed borderline features.

It is our impression that many patients who may have bipolar disorder, particularly the rapid-cycling type II variety, receive a diagnosis of borderline personality disorder because of an overreliance on the intuitive prototype approach described above. The clinical picture of the rapid-cycling bipolar patient can approximate that of borderline personality cross-sectionally. However, careful application of the criteria for mania or hypomania often distinguishes rather clearly between patients with bipolar disorder and characterological illness (Akiskal, 2005; Benazzi, 2000a).¹⁸ In some settings, moreover, patients with borderline personality disorder may be mistakenly diagnosed as bipolar

when the clinician relies overly on mood lability alone for a bipolar diagnosis, rather than assessing both the full criteria for a mood episode and the unique course features associated with bipolar disorder (Berns et al., 2003).

Organic Brain Disorders

Since manic-depressive illness has its own underlying biological foundation, differentiating it from secondary brain disorders can be semantically and diagnostically confusing. DSM-IV represents an advance over DSM-III-R in this regard. Whereas DSM-III-R applied the term "organic" to disorders in which psychological and behavioral abnormalities are "associated with transient or permanent dysfunction of the brain," DSM-IV refers to "secondary" psychiatric disorders, in which symptoms are secondary to a specific medical condition, a specific medication or other substance, or identifiable conditions such as delirium or dementia of the Alzheimer's type. With DSM-IV, the designations "functional" and "organic" were replaced by "primary," meaning no definitive established etiology, and "secondary," with reference to the specific established etiology. This terminology is more precise and accurate, and allows for the fact that many primary psychiatric disorders, such as manic-depressive illness, may have biological etiologies that are not yet identifiable. The catch-all DSM-III-R diagnoses of "organic mood syndrome" and "organic personality syndrome," which often overlapped with manic-depressive illness, do not appear in DSM-IV.

The absence of specific pathognomonic neuropsychiatric manifestations of secondary brain disorders means that differentiating these disorders from bipolar illness requires an understanding of the variety of potentially associated conditions. Some behavioral features—principally changes in cognitive function, including impairment of orientation, memory, general intellectual function, and judgment—are more prominent in most of these disorders than in bipolar illness (see Chapter 9). Of comparable importance in making a differential diagnosis is a history of bipolar illness. However, the absence of such a history does not rule out primary bipolar illness, especially when the patient is still within the age of risk for onset of the disorder; here a positive family history of bipolar disorder can be helpful.

A standard neurological examination usually does not aid in differential diagnosis, since in most organic psychiatric syndromes, the results of such an examination remain normal until the disease is far advanced. The so-called soft neurological signs often thought to mark secondary brain disease have not proven to be specific.

Neuropsychological testing can be helpful in quantifying the extent of impairment but is not particularly useful in the initial differential diagnosis. This is so because, as detailed in Chapter 9, both depression and mania can be

associated with substantial disturbances in responses on a wide variety of neuropsychological tests designed to measure cognitive changes. Procedures such as magnetic resonance imaging (MRI), computed tomography (CT) scans, and electroencephalograms (EEGs) may be helpful, but unless they can identify a localized lesion, they have not yet proven reliable in differentiating secondary brain disorder from bipolar illness. Newer methods, such as functional MRI (fMRI), positron emission tomography (PET), and single photon electromagnetic transmission (SPECT), provide enhanced functional assessments of anatomic function, which can be particularly useful in assessing changes during varying mood states. However, their utility remains limited primarily to research.

The Concept of Secondary Affective Episodes

Krauthammer and Klerman (1978) made an important conceptual contribution by reviewing the literature for reports of manic syndromes occurring shortly after medical, pharmacological, or other somatic dysfunctions. As described previously, DSM-IV places a great deal of emphasis on secondary causes of mania or hypomania. Box 3-11 lists conditions that have been associated with secondary manic or hypomanic symptoms.

Studies of secondary mania are uncommon. One study found that EEG abnormalities in patients with bipolar disorder predicted better valproate than lithium response (Stoll et al., 1994). Studies of secondary depression are more common. Its occurrence is frequently related to stroke or other neurological disorders (Whyte and Mulsant, 2002).

In general, while the primary–secondary distinction in psychiatry has not been carefully validated, it appears to have clinical utility and theoretical attraction.¹⁹ As discussed in Chapter 1, however, an alternative to dividing mania and depression into primary and secondary categories is a spectrum model reflecting varying levels of vulnerability. The greatest vulnerability would be expressed as a *primary* case, in which little or no external stress was required; lower levels of vulnerability might show up only as *secondary* cases, that is, requiring the operation of external factors for the episode to appear. (For a more complete discussion of secondary affective presentations, see Chapter 17.)

We now review three specific secondary conditions: two related but nonaffective states—delirium and dementia—and epilepsy.

Delirium

The DSM-IV diagnostic criteria for delirium are given in Box 3-12. Severe (stage III) mania (Carlson and Goodwin, 1973) can involve clouding of consciousness, occasionally rendering it difficult to differentiate from delirium

BOX 3-11. DSM-IV Features Associated with Secondary Mania or Hypomania

DSM-IV (p. 328) defines features associated with a manic episode as follows:

Individuals with a manic episode frequently do not recognize that they are ill and resist efforts to be treated. Ethical concerns may be disregarded even by those who are typically very conscientious. The person may be hostile and physically threatening to others. Some individuals, especially those with psychotic features, may become physically assaultive or suicidal. Adverse consequences of a manic episode (e.g., involuntary hospitalization, difficulties with the law, or serious financial difficulties) often result from poor judgment and hyperactivity. Some individuals describe having a much sharper sense of smell, hearing, or when catatonic symptoms (e.g., stupor, mutism, negativism, and posturing) are present, the specifier with catatonic features may be indicated (see p. 382). Mood may shift rapidly to anger or depression. Depressive symptoms may last moments, hours, or, more rarely, days. Not uncommonly, the depressive symptoms and manic symptoms occur simultaneously. No laboratory findings that are diagnostic of a manic episode have been identified. However, a variety of laboratory findings have been noted to be abnormal in groups of individuals with manic episodes compared with control subjects. Laboratory findings in manic episodes include polysomnographic abnormalities, increased cortisol secretion, and absence of dexamethasone nonsuppression. There may be abnormalities involving the norepinephrine, serotonin, acetylcholine, dopamine, or gamma-aminobutyric acid neurotransmitter systems, as demonstrated by studies of neurotransmitter metabolites, receptor functioning, pharmacological provocation, and neuroendocrine function.

DSM-IV (p. 335) defines features associated with a hypomanic episode as follows:

Associated features of a mixed episode are similar to those for manic episodes and major depressive episodes. Individuals may be disorganized in their thinking or behavior. Because individuals in mixed episodes experience more dysphoria than do those in manic episodes, they may be more likely to seek help. Laboratory findings for mixed episode are not well studied, although evidence to date suggests physiological and endocrine findings that are similar to those found in severe major depressive episodes.

(see Chapter 2) (Fink, 1999). Indeed, delirious mania was well described by Kraepelin (1921) and others. The absence of the preceding stages of mania or of a history of mania is sometimes helpful in making this differential diagnosis. Perceptual disturbances usually have a more sudden onset

BOX 3-12. DSM-IV Definition of Delirium

DSM-IV (p. 127) defines delirium as follows:

Criterion A: The essential feature of a delirium is a disturbance of consciousness that is accompanied by a change in cognition that cannot be better accounted for by a preexisting or evolving dementia. The disturbance develops over a short period of time, usually hours to days, and tends to fluctuate during the course of the day. The disturbance in consciousness is manifested by a reduced clarity of awareness of the environment. The ability to focus, sustain, or shift attention is impaired.

Criterion B: There is an accompanying change in cognition (which may include memory impairment, disorientation, or language disturbance) or development of a perceptual disturbance.

Criterion C: In mild delirium, disorientation to time may be the first symptom to appear. Disorientation to self is less common. Language disturbance may be evident as dysnomia (i.e., the impaired ability to name objects) or dysgraphia (i.e., the impaired ability to write). In some cases, speech is rambling and irrelevant, in others pressured and incoherent, with unpredictable switching from subject to subject. The disturbance develops over a short period of time and tends to fluctuate during the course of the day.

in delirium than in stage III mania. The sustained euphoria (or irritability) characteristic of mania, by contrast, is not likely in delirium.

As with all diagnoses of organic brain disorders, indications (from the patient's history, physical examination, or laboratory data) of a specific organic etiological factor are important to the diagnosis. As noted in Chapter 7, manic episodes are commonly associated with substance abuse, particularly in young patients, and here the challenge is to differentiate a pure organic delirium from a manic episode precipitated and colored by alcohol or drugs.

Dementia

The DSM-IV criteria for dementia, given in Box 3-13, overlap somewhat with those for delirium. The considerable attention that has been paid to differentiating between true dementia and depressive pseudodementia is often justified since the pseudodementia associated with depression is highly treatable. Recent data suggest, however, that depression in the elderly can often herald dementia, making the distinction less exclusive than may earlier have been assumed (Jorm, 2000). As discussed in Chapter 9, bipolar patients in particular often experience profound deficits in

BOX 3-13. DSM-IV Definition of Dementia

DSM-IV (p. 139) defines dementia as follows:

Criterion A1: The essential feature of a dementia is the development of multiple cognitive deficits that include memory impairment and at least one of the following cognitive disturbances: aphasia, apraxia, agnosia, or a disturbance in executive functioning. Memory impairment is required to make the diagnosis of a dementia and is a prominent early symptom.

Criterion A2a: Deterioration of language function (aphasia) may be manifested by difficulty producing the names of individuals and objects.

Criterion A2b: Individuals with dementia may exhibit apraxia (i.e., impaired ability to execute motor activities despite intact motor abilities, sensory function, and comprehension of the required task).

Criterion A2c: Individuals with dementia may exhibit agnosia (i.e., failure to recognize or identify objects despite intact sensory function).

Criterion A2d: Disturbances in executive functioning are a common manifestation of dementia and may be related especially to disorders of the frontal lobe or associated subcortical pathways.

Criterion B: The items in both Criterion A1 (memory impairment) and Criterion A2 (aphasia, apraxia, agnosia, or disturbance in executive functioning) must be severe enough to cause significant impairment in social or occupational functioning (e.g., going to school, working, shopping, dressing, bathing, handling finances, and other activities of daily living) and must represent a decline from a previous level of functioning. The nature and degree of impairment are variable and often depend on the particular social setting of the individual.

cognition and memory, and consequently are sometimes misdiagnosed as having primary dementia. This misdiagnosis occurs most frequently with elderly patients, in whom clinicians tend to neglect affective symptoms and focus instead on somatic and cognitive symptoms. Although a history of manic or depressive episodes is quite helpful in making this differential diagnosis, it cannot be used absolutely: on the one hand, a small percentage of bipolar patients do not have their first episode until they are in their 50s or 60s; on the other hand, bipolar patients may independently develop dementia later in life. Since a high proportion of late-onset bipolar patients have frequent cycles (see Chapter 4), the clinical picture may convey chronicity and therefore appear to be associated with an organic etiology.

Other aspects of the depressive syndrome, such as sleep and appetite dysregulation, are not especially helpful in differentiating bipolar illness from dementia. Neuropsychiatric testing can be useful, especially if a focal lesion is involved, but it cannot be relied upon to establish a clear differential because bipolar depression can also be associated with profound cognitive impairment. As with other differential diagnostic questions, it is important to look for atypical forms of mania in the patient's history, particularly episodic irritability or agitation in the absence of euphoria. The periods of secondary affective lability sometimes associated with primary dementing illnesses do not appear as discrete episodes. Obviously, a definitive diagnosis can be made if an organic cause for the dementia can be uncovered. Box 3-14 lists diseases or conditions that have been associated with dementia.

Because of its enormous public health importance, the issue of acquired immunodeficiency syndrome (AIDS) dementia deserves special attention (Melton et al., 1997). The human immunodeficiency virus (HIV) belongs to a class of retroviruses that are neurotrophic; that is, they have a special affinity for the nervous system. By the time AIDS has reached its peak, involvement of the central nervous system is almost universal. More important to the issue of

BOX 3-14. DSM-IV Definition of Diseases Associated with Dementia

DSM-IV (pp. 133–134) defines the physical examination findings and general medical conditions associated with dementia as follows:

The associated physical examination findings of dementia depend on the nature, location, and stage of progression of the underlying pathology. The most common cause of dementia is Alzheimer's disease, followed by vascular disease, and then by multiple etiologies. Other causes of dementia include Pick's disease, normal-pressure hydrocephalus, Parkinson's disease, Huntington's disease, traumatic brain injury, brain tumors, anoxia, infectious disorders (e.g., human immunodeficiency virus [HIV], syphilis), prion diseases (e.g., Creutzfeldt-Jakob disease), endocrine conditions (e.g., hypothyroidism, hypercalcemia, hypoglycemia), vitamin deficiencies (e.g., deficiencies of thiamine, niacin, vitamin B), immune disorders (e.g., polymyalgia rheumatica, systemic lupus erythematosus), hepatic conditions, metabolic conditions (e.g., Kufs' disease, adrenoleukodystrophy, metachromatic leukodystrophy, and other storage diseases of adulthood and childhood), and other neurological conditions (e.g., multiple sclerosis).

Source: Reprinted with permission from the *Diagnostic and Statistical Manual of Mental Disorders*, Fourth Edition, Text Revision (Copyright 2000). American Psychiatric Association.

differential diagnosis, however, is the finding that among 20–25 percent of AIDS patients, the presenting symptoms originate in the central nervous system. These early AIDS symptoms may be difficult to distinguish from depression (Price et al., 1986; Bridge et al., 1988). Mania has also been reported as an early symptom (Gabel et al., 1986; Lyketsos et al., 1997; Yang et al., 2005). As the condition progresses, memory, concentration, and rapid alternating movements are impaired. Other indications include pyramidal tract signs, ataxia, leg weakness, and tremor. AIDS dementia becomes the presumptive diagnosis when the antibody test is positive. In addition, neuropsychological tests and MRI scans may be helpful in making the differential diagnosis. Of course it must be remembered that bipolar patients may also have AIDS, perhaps at a higher rate than comparable populations, given the prominence of reckless sexual behavior during mania.

Epilepsy

Epilepsy comprises a group of disorders of the central nervous system that, like other organic disorders, must be differentiated from bipolar illness. The condition is commonly associated with psychiatric symptoms, which can be divided into those occurring during actual seizure activity and those manifested only during interictal periods.

Findings of epidemiologic surveys of large numbers of patients with epilepsy (see, e.g., Gibbs and Gibbs, 1952) indicate that psychotic symptoms are about 10 times more likely to occur in association with temporal lobe than with generalized epilepsy (reviewed by McKenna et al., 1985; Kanner, 2004). The psychoses associated with temporal lobe epilepsy were initially described at a time when the broad Bleulerian concept of schizophrenia was prevalent. It is thus not surprising that patients with these psychoses tended to be described as schizophrenic, and less frequently as affectively ill. Clinically, these psychoses are generally mixed syndromes with a prominence of visual and olfactory hallucinations, rapid fluctuations of mood, catatonic features, and dreamlike states—all of which occur in an episodic course.

In his studies of patients with temporal lobe epilepsy, Flor-Henry (1969) found that 40 percent had either manic-depressive or schizoaffective features, and 42 percent had predominantly schizophrenic symptoms. Further frustrating attempts to understand the association between psychosis and temporal lobe epilepsy is the fact that patients can at times manifest predominantly affective symptoms and at other times predominantly schizophrenic symptoms. Flor-Henry also found an association between ictal laterality and type of mood syndrome: left-side epileptic foci in temporal lobe epilepsy were associated with depressive syndromes, whereas right-side epileptic foci were associated

with manic syndromes. While intriguing, this observation has not been well replicated. Conversely, Post and Weiss (2004) at the NIMH observed a relatively high frequency of epileptic-like phenomena in bipolar patients, particularly those with rapid cycles.

The specific relationship between epilepsy per se and bipolar disorder is relatively understudied. The most recent study of the topic compared 13 patients with generalized epilepsy and interictal manic episodes and 13 patients with primary bipolar disorder (Kudo et al., 2001). In that study, patients with epilepsy and mania tended to experience somewhat less severe manic episodes than did patients with primary bipolar disorder. The epileptic patients also tended to have substance-induced episodes somewhat more frequently than the primary bipolar disorder group. The epileptic foci were frontal or temporal in location.

Clinical Summary

Given the possibility that the pathophysiology of manic-depressive illness may overlap with that of some identifiable brain disorders, differential diagnosis cannot easily be reduced to simple formulas. For practical purposes, however, a differential diagnosis is critical to making an accurate treatment selection and prognosis. Thus, the clinician's first task when presented with manic or depressive symptoms is to consider other (possibly correctable) factors that might explain the symptoms. The absence of a personal or family history of affective illness and poor response to traditional treatments for manic-depressive illness are important clues suggesting the possibility of an organic etiology (McElroy et al., 1992). Although no single medical screening test is definitive, certainly a neurological examination, formal neuropsychiatric testing, an MRI, an EEG, a CT scan, and a chemical screen for metabolic and toxic disturbances should supplement the careful taking of the patient's history. Where the evidence points to a possible commingling of manic-depressive illness and a seizure disorder diathesis, anticonvulsants with a primary effect on temporal lobe disorders (e.g., carbamazepine, valproate, or lamotrigine) should be the treatment of choice.

CONCLUSIONS

To make an accurate diagnosis of bipolar disorder, the patient's history should be reviewed carefully with the patient *and* a family member; this focus on history is at least as important as a full description of the presenting episode. Whenever possible, the onset, duration, and treatment response of all past episodes should be recorded on a life chart, along with important life events. Much of this information can be obtained before the initial appointment by having the patient and family members fill out a

life chart form. The most important differential diagnostic issue in evaluating depression is determining whether the patient has a unipolar or bipolar form of the illness. Obviously, this distinction must rest on knowledge of the patient's history, especially any prior episodes of mania or hypomania. Once again we must emphasize the importance of obtaining information from the family, especially given that impairment of insight is a major problem in about half of patients with bipolar disorder. Without family input, more than half of patients with a prior history of mania will deny or forget it, and the resulting overdiagnosis of unipolar depression is even more likely when the bipolar history involves hypomania only.

If the patient has had two or more previous depressions without evidence of mania or hypomania, an age at onset above 25 or 30, and a family history negative for bipolar disorder, it is reasonably safe to assume a unipolar diagnosis, even though about 10 percent of such patients will later develop a manic episode and be reclassified as bipolar. In children and adolescents presenting with depression, the likelihood of an eventual bipolar course is much higher. As noted above, a family history of mania can provide an important clue to a possible bipolar diathesis, and may be helpful in choosing a mood stabilizer over an antidepressant for the treatment of highly recurrent depression. When manic-like symptoms characterize the presenting picture, the clinician may face difficult questions of differential diagnosis. If a patient is in the hyperactive psychotic state described as stage III mania (see Chapter 2) and a complete patient or family history is not available, the clinician must rely on an analysis of the presenting symptoms. (If there is a history of manic or depressive episodes, especially with well intervals, bipolar illness is the presumptive diagnosis, despite the atypical presenting symptoms.)

The principal alternative diagnoses that should be ruled out in diagnosing the manic phase of bipolar illness are acute schizophrenia and psychoses secondary to substance abuse or a general medical condition, although the latter can, and often do, occur in an individual with bipolar illness. The presence of delusions (including paranoid delusions), hallucinations, and thought disorder does not support a diagnosis of schizophrenia over that of mania. Schizophrenia should be suspected, however, if the delusions are organized into a formal and stable system that has continued for a considerable time in the absence of prominent mood symptoms. As a practical matter, differentiating acute stage III mania from schizoaffective illness and schizophrenia is not absolutely critical, since the initial treatment—antipsychotic medication (especially an atypical agent)—often is essentially the same for all three. If an affective component is suspected, the addition of a mood

stabilizer, such as lithium or an anticonvulsant, should be considered. When the acute psychotic episode is under control, differential diagnosis often becomes clearer, even if information on the patient's personal or family history is still missing. If delusions or hallucinations persist in the absence of manic mood or hyperactivity (i.e., the patient is quietly delusional), schizophrenia or schizoaffective disorder is the more appropriate diagnosis. If the patient meets criteria for both schizophrenia and affective illness in the present episode or by history, schizoaffective illness is the appropriate diagnosis. Care should be taken to avoid overuse of the schizoaffective diagnosis simply because the patient's past history is unavailable. Distinguishing between bipolar disorder and schizophrenia can be particularly difficult in an adolescent because at that age, psychotic features are especially common in manic syndromes.

When vivid hallucinations (especially visual ones) or delusions dominate the clinical picture, particularly in a young person, a drug-induced state should be suspected, and a urine screen becomes especially important. Indeed, for most adolescent patients, it is sensible to employ a urine screen routinely. True mania may be present even if these suspicions are borne out, because it is not at all uncommon for initial manic episodes to be precipitated by drugs of abuse. In such cases, differential diagnosis can be difficult during the acute phase.

When presented with milder manic-like symptoms (or a history of such symptoms), the clinician must differentiate between clinical hypomania and normal elevated mood. Here it is important to recall the spectrum concepts outlined in Chapter 1. The threshold for a DSM-IV diagnosis of hypomanic episode is reached when (1) elation, excitement, and/or irritability cluster in discrete episodes lasting at least 4 days; (2) the symptomatic criteria outlined previously are met; (3) symptoms are out of proportion to any environmental precipitant; (4) symptoms represent a clear change in the individual's normal functioning; and/or (5) the episodes have a high potential to result in negative social, professional, and/or financial consequences. While the criteria for hypomania can be met without (4) or (5), the latter are prominent in the DSM-IV definition of a hypomanic episode. Again, we cannot overstate the importance of obtaining corroborating information from a spouse or other family member in evaluating the presence (or history) of hypomanic symptoms.

When presented with psychotic depressive symptoms, the clinician faces a somewhat different diagnostic challenge. Again, assuming that no history is available, one must rule out schizophrenia and schizoaffective illness, drug-induced states, and dementia. If delusions are present, they should be depressive in content to support an affective diagnosis. Among the depressive disorders, delusions are

more likely to be associated with the bipolar form. Differentiating the bipolar form of manic-depressive illness from personality disorders or post-traumatic stress disorder (PTSD) is complex. Frequently, the conditions can co-occur. If any acute episodes meet the criteria for mania or hypomania, bipolar disorder should be diagnosed, regardless of the extent of concomitant PTSD or personality disorder features. If the course is almost completely characterized by physical or sexual trauma, along with the typical features of borderline personality (interpersonal conflict and rage, repeated self-injury, manipulative relationships), then the occurrence of mood lability *by itself* likely will not justify the bipolar diagnosis. Again, attention should be paid to family history, and more emphasis placed on course of illness rather than acute presentation.

NOTES

1. Andreasen et al., 1981; Tsuang et al., 1981; Andreasen and Grove, 1982; Keller and Baker, 1991; Blacker and Tsuang, 1992; Dunner, 1992; DeBattista et al., 1998; Goodwin and Ghaemi, 1998.
 2. The RDC, together with the Schedule for Affective Disorders and Schizophrenia, proved to be reliable diagnostic instruments when used by interviewers from different centers around the country to rate past psychiatric symptoms and lifetime diagnoses in patients who were mentally ill at the time of assessment. However, the lifetime diagnoses of hypomania and recurrent unipolar depression were not as reliable as other categories (Keller et al., 1981).
 3. Angst, 1980; Marneros et al., 1988, 1989, 1991, 2000; Maj et al., 1989.
 4. Akiskal et al., 1995; Goldberg et al., 1995, 2001, Kessing, 2005.
 5. Outside the United States, most of the rest of the world is characterized by geographically stable populations, making it easier to recognize the recurrent nature of the affective disorders.
 6. Not all studies are consistent. For instance, one study found that bipolar-II disorder was much less stable (33 percent unchanged diagnostically 6 years later) than bipolar-I disorder (60 percent unchanged); it also found that decreased need for sleep was the best predictor among diagnostic criteria for bipolar-II disorder (Rice et al., 1992). Dunner also found that the reliability of the bipolar-II diagnosis was much greater when made by clinicians with expertise in mood disorders than when based solely on research diagnostic instruments such as the Structured Clinical Interview for DSM (SCID) (Dunner and Tay, 1993).
 7. Testing the DSM-IV definition, Benazzi (2001) reported that almost all patients who met the DSM-IV definition of bipolar-II disorder also experienced 2 to 3 days of hypomania.
 8. A recent excellent historical review demonstrated that Kraepelin's original conception of mixed states was derived largely from Weygandt, and that Kraepelin and Weygandt viewed mixed states not as uncommon, but as being the most common form of manic-depressive illness (Salvatore et al., 2002).
 9. Along with major depression and inner agitation, at least three of the following symptoms must be present: (1) racing or crowded thoughts, (2) irritability or unprovoked feelings of rage, (3) absence of signs of retardation, (4) talkativeness, (5) dramatic descriptions of suffering or frequent spells of weeping, (6) mood lability and marked emotional reactivity, and (7) early insomnia (which is often associated with racing or crowded thoughts).
 10. See Chapter 2; also, especially, Akiskal, 1996, 2002; Ghaemi et al., 2002.
 11. The Schneiderian first-rank symptoms that overlap most commonly between schizophrenia and manic-depressive illness include thought broadcasting, thought insertion, experiences of influence, delusional perceptions, and incomplete auditory hallucinations (Schneider, 1959). Descriptive data suggest that manic patients with first-rank and/or catatonic symptoms cannot be distinguished from those without such symptoms on the basis of family history or treatment response (Jampala et al., 1989). Jampala and colleagues (1985) reported that manic patients with so-called emotional blunting—"a constricted, inappropriate, unrelated affect of diminished intensity, with indifference or unconcern for loved ones, lack of emotional responsiveness, and a loss of social graces"—had family histories suggestive of schizophrenia, but with a pattern of treatment response related more closely to mania without emotional blunting.
 12. Schizoaffective depressed patients do not have a history of mania; that is, they are unipolar.
 13. The following case history reported by Pope (1983, pp. 326–327) illustrates the devastation that can follow the misdiagnosis of manic-depressive illness as schizophrenia:
- Ms. B, a 28-year-old woman, had been a psychiatric in-patient in a state hospital for the greater part of nine years. She had first been admitted at the age of 19 when she developed psychotic symptoms. . . . A history taken at that time by the admitting psychiatrist elaborately described her delusions and hallucinations but gave no information about whether Ms. B displayed mood change, activity change, an increase or decrease in energy level, or other affective symptomatology. No family history data were elicited. . . . Ms. B had been treated with virtually every antipsychotic drug available but had never been treated with lithium or ECT [electroconvulsive therapy]. . . . [Her] hospital records revealed that she had had periods of unusual irritability, coupled with increased activity and talkativeness . . . [and] had also displayed distractibility, grandiosity, and interpersonal intrusiveness. However, during most of her hospitalization, she was described as apathetic, with hypersomnia of 10 to 11 hours a night, lacking in energy and concentration, eating poorly, and displaying little interest in social contact. She was also markedly self-deprecating and was described as having long guilty ruminations on religious themes. She had made two suicide attempts during these periods.
- During Ms. B's ninth year in the hospital, her 21-year-old brother was admitted to a private psychiatric hospital. He was suffering from a relatively typical manic episode . . . [and] responded relatively well to lithium carbonate. When the brother's psychiatrist learned of Ms. B's illness, he elicited more information about the family and discovered that a maternal aunt and the

maternal grandmother had had major depressive episodes. This evidence seemed to support his theory that Ms. B was suffering from a chronic form of bipolar disorder. . . . [T]he brother's psychiatrist made further inquiries about the possibility of the sister's being given a trial of lithium carbonate. The doctors at the state hospital refused, saying that the patient was "clearly schizophrenic." . . . However, after a great deal of pressure from Ms. B's mother, [they] reluctantly agreed to start Ms. B on lithium.

Within about three weeks Ms. B became markedly less agitated, less irritable, and more cooperative with staff. Shortly thereafter she was discharged to the quarterway house. Within two months, she transferred to a halfway house setting and was able to engage in a productive job with only a modest degree of supervision. However, she then became somewhat more depressed, and shortly thereafter stopped both her lithium and her antipsychotic drugs. Within a week, she had become sleepless, hyperactive, irritable, distractible, and grandiose. She was readmitted to the state hospital where she was treated with antipsychotic drugs but not with lithium. In spite of the clear temporal association between use of lithium and clinical response, the doctors claimed that the patient's "schizophrenic" symptoms ruled out a diagnosis of manic-depressive illness, and were unwilling to resume lithium therapy. At last report Ms. B's mother was still battling with the state hospital to reinstitute lithium.

14. Although the association's samples are not likely to be representative of patients with bipolar disorder in general, the point is that in this sample, early ascertainment of bipolarity had not improved recently.
15. The MDQ is a five-part questionnaire. The first part comprises 13 brief yes-or-no statements related to manic symptoms, all of which begin with the precursor "Has there ever been a period of time when you were not your usual self

and . . ." These questions assess various bipolar symptoms, such as hypersexuality ("you were much more interested in sex than usual?") and racing thoughts ("thoughts raced through your head or you couldn't slow your mind down?"). The second part is one yes-or-no question, which asks whether those manic symptoms occurred simultaneously. The third part has the subject evaluate the problems caused by those manic behaviors along a four-point scale, ranging from "no problem" to "serious problem." The fourth and fifth parts assess bipolar disorder in the subject's relatives and previous bipolar diagnoses, respectively.

16. One study found that 93 percent of patients who joined a voluntary bipolar disorder case registry accurately reported having bipolar disorder in agreement with a research diagnostic interview (Cluss et al., 1999). However, 94 percent of these patients had previously been diagnosed by professionals with bipolar disorder. It would appear likely that they would be influenced by such professional interactions. What is of concern for a screening instrument is how well it accurately diagnoses individuals who have never been correctly diagnosed with bipolar disorder despite having the condition, and in those circumstances, impairment of insight would appear to predict low accuracy of self-report.
17. Mitchell et al., 1992; Akiskal et al., 1995; Akiskal, 1996; Benazzi, 2000b; Benazzi and Rihmer, 2000; Ghaemi et al., 2004; Akiskal and Benazzi, 2005.
18. It also has been suggested that personality inventories, such as Cloninger's Temperament Character Inventory, may be used to distinguish between bipolar disorder and borderline personality disorder (Atre-Vaidya and Hussain, 1999).
19. In their review of reported reserpine-induced depressions, Goodwin and Bunney (1971) found that the great majority of reserpine "depressions" were, in fact, pseudodepressions that did not mimic the full natural syndrome. Those with full endogenous or melancholic symptoms generally had a personal or family history of affective illness. These authors inferred that reserpine merely uncovered a vulnerability rather than inducing depression *de novo* (see Chapter 19).

4

Course and Outcome

The universal experience is striking, that the attacks of manic-depressive insanity . . . never lead to profound dementia, not even when they continue throughout life almost without interruption. . . . As a rule the disease runs its course in isolated attacks more or less sharply defined from each other or from health, which are either like or unlike, or even very frequently are [the] perfect antithesis.

—Emil Kraepelin (1921, p. 3)

Emil Kraepelin's central insight, one that continues as an organizing principle in modern descriptive psychiatry, was his division of the major psychoses into two groups based largely on course and outcome. He observed that whereas dementia praecox (schizophrenia) tends to be chronic and to follow a deteriorating course, manic-depressive illness is episodic and ultimately exacts a less devastating toll from those affected. Today we face a paradox: whereas the discovery of the prophylactic potential of lithium and, subsequently, some of the anticonvulsants and atypical antipsychotics has revived interest in the natural course of manic-depressive illness, widespread use of these prophylactic agents, as well as antidepressants, has substantially altered that course. Investigators must confront the fact that "natural" course now includes the largely unquantified effects of routine, acute, and prophylactic treatment.

In this chapter, after briefly reviewing salient methodological issues, we examine findings of the literature on the following aspects of the course and outcome of manic-depressive illness: premorbid functioning, age at onset, number of episodes, frequency of episodes (cycle length), onset and duration of episodes, polarity, pattern, precipitants of episodes, long-term outcome, mortality, the course of bipolar-II disorder, and mechanisms of recurrence. Studies assessing the impact of prophylactic treatment are reviewed in Chapter 20, and biological correlates of natural course are covered in Chapter 14.

METHODOLOGICAL ISSUES

As with most fields of inquiry, studies of the course and outcome of manic-depressive illness involve methodological complexities that should be kept in mind when interpreting the study results. Two issues are especially important.

The first relates to patient selection. The index hospitalization required in many older outcome studies can produce either underestimates or overestimates of recurrence. Underestimates can result when, during a single hospitalization, a patient has multiple rapid cycles that are counted as a single episode. On the other hand, overestimates can result from basing recurrence rates on hospital admission data, because those data exclude patients who experience a single episode, recover without hospitalization, and never have a recurrence. While some recent studies (virtually all of which focused on the bipolar subgroup) have avoided these problems by recruiting patients from the general community, other samples (e.g., those of the Stanley Foundation Bipolar Network) have been drawn from clinics in which sicker, treatment-resistant patients tend to be overrepresented. Indeed, clinical samples are, by definition, not representative, because a substantial portion of the bipolar population is not receiving treatment at any given time.

The second issue has to do with diagnosis. Many of the classic studies of natural course do not distinguish between the bipolar and recurrent unipolar subgroups. Numerous interpretive problems result, particularly in studies from the United States, where diagnostic criteria for unipolar illness (i.e., depressions that are not bipolar) allow for considerable heterogeneity (see the discussions of this issue in Chapters 1 and 3). For this reason, we emphasize the literature on bipolar patients, although some conclusions may be relevant to the more recurrent forms of unipolar illness as well. Furthermore, most classic studies of bipolar patients have involved patients hospitalized for mania and thus have not included the bipolar-II subgroup. The extent to which patients with schizoaffective features are included in the sample is another diagnostic issue (see the later discussion).

In addition to these issues, a traditional methodological problem is the lack of a generally accepted convention for collecting data on the course of manic-depressive illness or for defining recovery and relapse. Standardized methods for charting the course of the illness, proposed for both retrospectively derived data (Post et al., 1988; Honig et al., 2001) and prospectively derived data (Keller et al., 1987; Leverich et al., 2001), have improved this situation but are still far from universally applied. These methods have clinical as well as research uses. For example, detailed description of the prior course of the illness may reveal that medications, such as lithium, given to the patient in the past were mistakenly judged ineffective when they actually led to improvement. Conversely, charting may uncover instances in which certain drugs, such as antidepressants, exacerbated the course of the illness. In addition, previously unrecognized associations of episode onsets with anniversaries, life events, or other stressors may aid in psychotherapeutic understanding and behavioral management. These standardized charting methods are all the more important in industrialized countries, where population mobility is exacerbating a situation in which there are increasingly fewer opportunities for a single clinic or clinician to follow a cohort of patients over a lifetime.

A final methodological consideration in reviewing this literature is its largely retrospective nature, a troublesome aspect given the problems inherent in recalling the past, especially for depressed patients. Future studies need to be prospective and to focus on patients in naturalistic treatment settings.

PREMORBID FUNCTIONING

The distinction between “premorbid” functioning in children and childhood manifestations of full-blown manic-depressive illness can be somewhat arbitrary, because the disorder may present a different clinical picture in childhood than in adolescence or adulthood. We discuss clinical manifestations of possible childhood variants of the illness, as well as premorbid functioning in its early-onset forms, in Chapter 6, issues of premorbid/underlying personality in Chapter 10, and issues of neurocognitive development in Chapter 9. Here we focus on other measures of premorbid functioning (e.g., social, academic) in samples that do not include childhood-onset recurrent mood disorder.

In the original Kraepelinian definition, patients with manic-depressive illness were free of any morbid symptoms before the onset of their illness. Some modern data are consistent with this impression. In an elegant prospective study, Reichenberg and colleagues (2002) examined results from an extensive array of tests designed to measure level of functioning in persons who later developed schizoaffective,

schizophrenic, or nonpsychotic bipolar disorder. Patients were matched with normal controls on age and education level. The nonpsychotic bipolar group showed no significant impairment on intellectual tests, reading/writing, or various behavioral measures.¹ Schizophrenic patients displayed premorbid impairment across most measures of intellectual and behavioral functioning, whereas schizoaffective patients showed less consistent impairment, suggesting a psychotic continuum of premorbid impairment.²

Some studies of premorbid functioning in psychotic bipolar patients paint a picture slightly different from the Kraepelinian model. For example, in their retrospective analysis comparing a large sample of bipolar and unipolar patients, Stephens and McHugh (1991) found significantly greater premorbid impairment on descriptive measures of social and work functioning in the bipolar group, which also had significantly higher rates of mood-congruent psychosis; however, the unipolar group was not selected for the more recurrent form. In a retrospective study using maternal interviews, Cannon and colleagues (1997) compared hospitalized schizophrenic patients with hospitalized psychotic bipolar patients and healthy controls on measures of premorbid social functioning and school performance. The psychotic bipolar group scored significantly worse than healthy controls on premorbid social adjustment measures, but significantly better than schizophrenic patients. Other studies have corroborated the finding that patients with psychotic and/or severe forms of bipolar disorder displayed significantly less premorbid impairment than did schizophrenic patients, lending weight to the notion that degree of premorbid impairment is an important distinction between bipolar disorder and schizophrenia.³ Nevertheless, it appears that subtle premorbid dysfunction (especially cognitive dysfunction) may exist in some patients with bipolar disorder, particularly those with psychotic forms of the illness. More prospective data from epidemiologic samples, employing *Diagnostic and Statistical Manual* (DSM)-IV diagnoses and incorporating both psychotic and nonpsychotic forms of the disorder, are needed to further elucidate the premorbid phenomenology of bipolar disorder.

AGE AT ONSET

The age when manic-depressive illness most often begins (in both its bipolar and recurrent unipolar forms) is intrinsically important to genetically vulnerable individuals and their clinicians and may offer clues to future course. In this section, we examine the literature on this issue in general; Chapter 6 focuses on studies of early onset in prepuberty and adolescence, and Chapter 13 examines how differences in age at onset relate to estimates of the degree of genetic vulnerability.

We pooled data from 15 studies published after 1990 (i.e., since the first edition of this text appeared) reporting average age at onset in samples of patients with bipolar illness (summarized in Table 4-1) and derived a weighted mean of 22.2 years.⁴ When gender was specified, the difference for males and females was not significant (Fogarty et al., 1994; Hendrick et al., 2000; Suppes et al., 2001). Studies reporting separate figures for bipolar-I and -II disorder showed similar averages for the two groups (McMahon et al., 1994; Judd et al., 2003).

It is interesting that the post-1990 mean is 6 years younger than the weighted mean taken from the 22 pre-1990 studies examined in the first edition, which used the same basic inclusion criteria. Because the data are not normally distributed, however, these figures may be misleading. Averages can be raised by a relatively small number of patients with late onset, for example. When median age at onset is reported, it is usually in the early twenties. Here again, these medians are several years younger than those found in the literature before 1990.

As noted earlier, some of the variance across individual studies in Table 4-1 is related to differing criteria for onset. In general, the age when symptoms first appear is younger than the age when patients meet diagnostic criteria, and the age of first clinical contact is later still. (Studies of first hospitalization are not included in Table 4-1 because this measure says very little about age at onset.) Some studies have used age at first clinical contact on the assumption that dating of initial symptoms would be too imprecise. Egeland and colleagues (1987a), however, using information gleaned from patient charts and interview records to compare six clinical indices of onset for bipolar disorder, obtained high interrater reliability ($r=.89$) using the measure of first achievement of Research Diagnostic Criteria (RDC) for a major affective disorder.⁵ As might be expected, the ages obtained with this measure are significantly younger than those derived from first treatment or first hospitalization.

Indeed, the literature is consistent in finding a significant time gap between onset of the illness and first treatment. Meeks (1999) found that mean age at first symptoms in a bipolar and unipolar population was almost 6 years younger than age at first treatment. A demographic study of the first 261 patients in the Stanley Foundation Bipolar Network (which may represent patients on the more severe end of the spectrum) revealed an 8-year difference between age at first diagnosis and age at first medical treatment (22.9 and 30.4 years, respectively), whereas age at first symptoms was only 2 years before age at diagnostic onset (Suppes et al., 2001). In a Stanley Foundation recruitment survey administered by Kupfer and colleagues (2002), more than 50 percent of a large bipolar sample indicated that they had received no treatment for their first affective

episode. Thus it is to be expected that age at first treatment is a poor indicator of onset. Although retrospective self-reporting has its own pitfalls—which should be controlled for whenever possible with corroborating family reports and medical/academic records—using “first episode” as an onset measure with standardized (*International Classification of Diseases* [ICD]-10 or DSM-IV) criteria appears to be the most accurate indicator.

The lower age at onset in more recent studies reflects, in part, a cohort effect that is supported in the literature. For example, Chengappa and colleagues (2003) examined two separate cohorts of patients with bipolar disorder in a large patient sample and found that the more recent cohort had a mean age at onset 3 years younger than that of the older cohort. When the investigators examined a third, still more recent cohort in a post hoc analysis, they found that onset occurred at an even younger age, with a statistically significant different mean among the three cohorts. Kupfer and colleagues (2002) made similar findings in their examination of separate birth cohorts in a patient population from the Stanley Center’s Bipolar Disorder Registry: the earliest birth cohort (1900–1939) was 3.5 years older at onset than the later two cohorts.

Researchers have advanced several hypotheses to explain this reduction in age at onset. Changes in nosology and illness definition could be a partial explanation. With the exception of the retrospective studies, the data in Table 4-1 were taken largely from samples of patients diagnosed in the past three decades (Stephens and McHugh, 1991). Many of these patients might have been classified as “schizophrenic” 50 years ago. The diagnostic inclusion of more psychotically ill subgroups could lower the age at onset, particularly in light of the earlier impairment observed in these groups (as discussed earlier). Genetic anticipation could play a role in the heightened predisposition to development of the disorder with each subsequent generation (see Chapter 13). Some investigators have proposed that the increasing use of antidepressants and stimulants in adolescents and children may help induce the onset of bipolar disorder at an earlier age in those already susceptible (Goodwin and Ghaemi, 1998; Cicero et al., 2003; Rechardt, 2004).⁶ This phenomenon would be consistent with what we know about the effect of antidepressants on mania induction and cycle acceleration, but more research is necessary to draw a solid conclusion. Similar to the antidepressant association is the hypothesis that the increased use of recreational drugs and alcohol among young people contributes to earlier onset. Here again, sound evidence is lacking, and it is difficult to establish a unidirectional association between onset of affective symptoms and onset of drug use.⁷

To gauge more accurately the distribution of the published ages at onset in the bipolar patient population, we

TABLE 4–1. Average Age at Onset in Studies Since 1990

Study	Sample	Average Age at Onset (Years)	Purpose/Design	Other Findings
Stephens and McHugh, 1991	235 bipolar	26.7	Retrospective analysis of notes on patients treated and monitored at a large institution, 1913–1940	Average age at onset lower in bipolar than in unipolar patients by approximately 6 years; average of 6 years between average age at onset and age at first admission
Kessler et al., 1993; Weissman et al., 1996	116 bipolar	23.3	Data from national comorbidity survey	—
Fogarty et al., 1994	22 bipolar	20.3: 20.5 male, 20.0 female	Determined clinical characteristics of mania by survey of randomly selected households	Age at onset: 5th percentile, ~9.0; 50th percentile, ~18.5; 95th percentile, ~25.5
Benazzi, 1999	186: 45 bipolar-I, 141 bipolar-II	26.7: 28.5 bipolar-I, 26.0 bipolar-II	Determined first episode using retrospective Structured Clinical Interview for DSM (SCID)/patient interview	No significant difference in age at onset ($p=.53$) in bipolar-I vs. bipolar-II
Meeks, 1999	86 bipolar	24.9	Determined factors of functioning in late-life bipolar disorder through patient interviews conducted three times over 8 months	Early onset related to poor functioning, increase in episode number and severity
Hendrick et al., 2000	37 bipolar-II	20.5: 21.8 male, 19.6 female	Gender comparison for average age at onset and a number of other clinical variables; first episode determined by retrospective questionnaire	—
Johnson et al., 2000	190 bipolar	31.4 (range 14.0–78.0)	Examined relationship between average age at onset and family history, early life events; average age at onset = first episode as determined by retrospective questionnaire	—
Bellivier et al., 2001	211 bipolar-I	25.9 (standard deviation 4.5)	Used admixture analysis (a clustering method) to determine average age-at-onset distribution patterns/first diagnosis	Three subgroups of bipolar patients based on average age-at-onset distribution with distinct clinical profiles; findings support average age-at-onset subtypes

McElroy et al., 2001	288 bipolar (I or II)	22.3: 26.0 noncomorbid diagnosis, 20.3 comorbid diagnosis	Compared attributes of bipolar patients with comorbid Axis I diagnosis and purely bipolar patients through retrospective interviews	Comorbidity related to earlier average age at onset
Suppes et al., 2001	261: 211 bipolar-I, 42 bipolar-II, 5 bipolar-not otherwise specified (NOS), 3 schizoaffective-bipolar type	22.9: 23.4 (± 11.0) male, 22.5 (± 10.0) female	Descriptive analysis of demographic features and course for 261 recruits in Stanley Foundation Bipolar Network; average age at onset ascertained by first full syndrome development using SCID	Early average age at onset associated with increased mood switching, worsening course of illness, history of early abuse
Carlson et al., 2002	123 bipolar	25.66 (standard deviation 9.9)	Outcome as a function of early vs. late average age at onset, first-episode SCID history, records, third-party interviews	22% <19.0, 78% >19.0. Early average age at onset an independent influence on poor functioning
Dittmann et al., 2002	152 bipolar	24.4 (standard deviation 10.9)	Follow-up of 152 patients entered in Stanley registry clinical sample, mostly hospitalized	No associations with age at onset included in this report
Judd et al., 2002, 2003	232 bipolar	22.2	Combined data reported in two studies on bipolar-I and -II patients from National Institute of Mental Health's Collaborative Depression Study. Average age at onset based on Research Diagnostic Criteria for first episode	Average age at onset did not correspond with measures of chronicity in either bipolar-I or bipolar-II group. Median age: bipolar-I = 21.0; bipolar-II = 19.0 (nonsignificant)
Kupfer et al., 2002	2,308 bipolar	19.8	Analysis of clinical and demographic characteristics of respondents to a Stanley recruitment survey; average age at onset determined by self-report using DSM-IV criteria for first manic or depressive episode	Median age = 17.5; younger cohort (1950–1959) had higher median average age at onset (22.5) than two older cohorts (1940–1949 = 19.0; 1900–1939 = 19.0); more than 50% of participants received no treatment for first episode

Note: Weighted means; 15 studies since 1990 (N=4,494)=22.2; studies before 1990 (N=4,210)=28.1; studies 1907–present (N=8,704)=25.1.

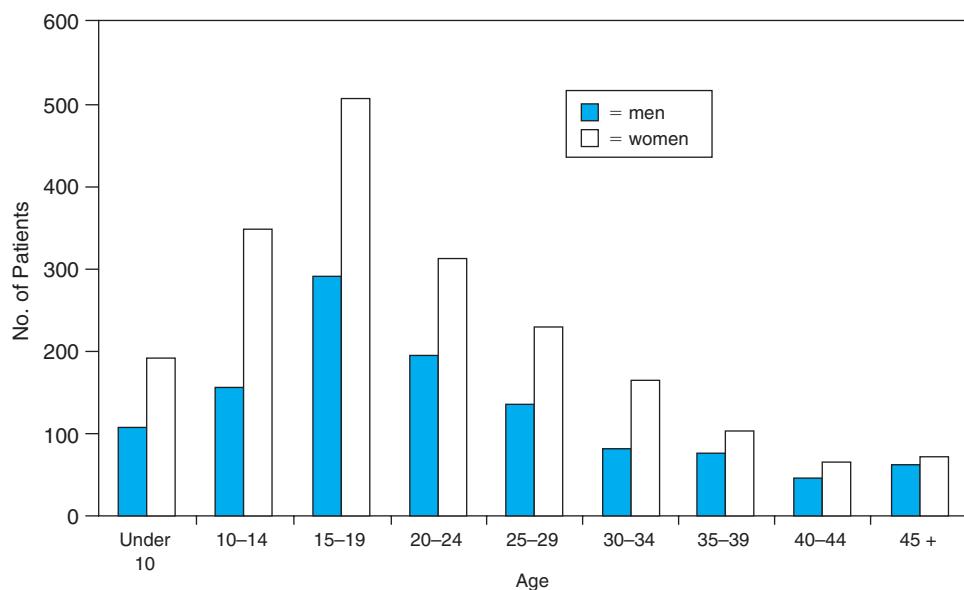

pooled data from seven studies specifying the number of patients with first episodes beginning in each decade of life (a total of 2,968 patients). This finer-grained analysis resulted in a peak in the age range of 15 to 19, followed closely by the 20–24 and 10–14 ranges, which were almost equal (Fig. 4–1). Note that the age-at-onset distribution is similar for men and women. Note also that this distribution provides only a rough picture and is heavily influenced by the large cohort of bipolar survey participants recruited by the Stanley Center Bipolar Registry, in which the largest subset (approximately 26 percent) of a sample of 2,308 participants were aged 15 to 19 (Kupfer et al., 2002).⁸ Still, the rising concentration of bipolar diagnosis before age 20 is a clear trend in the recent literature and is consistent with Epidemiological Catchment Area (ECA) data showing hazard rates for the development of mania to be at their highest in the 15–19 age range (Burke et al., 1990).

Some investigators have defined two primary groups by age at onset—early and late (Carlson et al., 2000; Schurhoff et al., 2000; Suppes et al., 2001; Patel et al., 2006), with bimodal cutoff points ranging from the late teens (Goldstein and Levitt, 2006) to the mid-twenties (Grigoriou-Serbanescu et al., 2001). Others have proposed three subgroups of onset—early (child or early adolescent), intermediate or typical (late adolescent, young adult), and later life (after age 35) (Sax et al., 1997; Bellivier et al., 2001; Mick et al., 2003; Lin et al., 2006). These hypotheses can be difficult to verify because “early,” “late,” and varying degrees of intermediate categories have tended to be defined inconsistently and arbitrarily.⁹ However, Bellivier’s group (2001)

used “admixture analyses” to determine the subgrouping model of best fit in a sample of 211 patients. Their findings correspond to an early–intermediate–late model (that is, a trimodal distribution), with mean onset at ages 16.9, 26.9, and 46.2, respectively. In a subsequent study (Bellivier et al., 2003), this group tested the fitness of this model on a different patient population ($N=368$). The model fit within the bounds of statistical sameness, further validating the trimodal distribution of onset age. Also, Bellivier and colleagues (2001) reported that bipolar siblings of a patient in a particular subgroup were statistically more likely to be part of the same age subset ($p=.0001$), a finding that supports a genetic etiological component to age-at-onset subgroups. A similar familial aggregation by age at onset was recently reported by Lin and colleagues (see Chapter 13).

Very late onset (i.e., after age 60) generally has been considered rare (Carlson et al., 1974; Loranger and Levine, 1978), although some data suggest that it may be more common than previously thought (Spicer et al., 1973; Shulman and Post, 1980; Stone, 1989; Wylie et al., 1999; Almeida and Fenner, 2002; Kessing, 2006). Angst and colleagues (1978) reported a secondary peak of late onset among women in the 40–50 age range (see Fig. 4–1). Patients with very late onset are less likely to have a family history of the disorder and more likely to be organically impaired. For example, Tohen and colleagues (1994) compared two groups of elderly patients, one with late-onset mania (first episode after age 65) and one with multiple manic episodes before age 65. The former group was significantly more likely to

Figure 4–1. Distribution of age at onset (years) in bipolar-I and -II patients across seven studies.

experience neurological abnormalities.¹⁰ These observations highlight the importance of differential diagnosis of primary mood disorders and mood disorders that occur secondary to specific neuropathology (see Chapter 3).

It is not yet clear to what extent grouping patients by age at onset really identifies distinct subgroups with differential phenomenology, pathophysiology, family history, outcome, and/or treatment response. Studies examining family history in early- versus late-onset groups have generally shown more genetic loading for recurrent mood disorder associated with early onset (see below).¹¹ But age at onset did not differ significantly in several studies comparing patients with mixed and pure mania (McElroy et al., 1995¹²; Akiskal et al., 1998; Brieger et al., 2003), and it does not appear to be a distinguishing feature of bipolar-I versus bipolar-II disorder (Benazzi, 1999). On the other hand, early onset has shown rather consistent correlations with certain clinical features, including rapid cycling, presence of comorbid anxiety disorder, suicidal behavior, psychotic features, and treatment resistance.

Carlson and colleagues (2002) reported that patients with an early onset (before age 19) had significantly worse outcomes on a variety of measures than those with later onset (after age 19).¹³ Likewise, a French study of 58 early-onset (before age 18) versus 39 late-onset (after age 40) bipolar patients found that the former group experienced more psychosis (in agreement with the data of McGlashan [1988] and Schulze et al. [2002]), mixed episodes, panic disorder comorbidity, and lithium resistance and were more likely to have first-degree relatives with bipolar disorder (Schurhoff et al., 2000).¹⁴ Among 320 bipolar-I and -II patients, those with onset younger than age 18 had more comorbid anxiety, rapid cycling, suicidality, and substance abuse compared with those with an onset above age 18 (Carter et al., 2003). An examination of a large cohort of Stanley Foundation Bipolar Network patients showed significant correlations between early onset (up to age 17) and greater incidence of learning disabilities, rapid-cycling course, and family history of bipolar disorder (Suppes et al., 2001),¹⁵ while Ernst and Goldberg (2004) found that onset below age 19 was associated with more rapid cycling and comorbid substance abuse.¹⁶ Engstrom and colleagues (2003) reported lower levels of treatment response and significantly greater numbers of suicide attempts in early-versus late-onset patients in a Swedish population.

Although the evidence for a connection between early onset and the complicating illness features described is compelling, one must exercise caution when using cross-sectional studies to distinguish damaging effects of the illness from so-called “clinical subtype” features. That is, worse outcomes in early-onset patients could be a factor of longer duration of illness rather than a phenotypic characteristic.

The issue of duration of illness is discussed later in this chapter.

The genetic literature is discussed in detail in Chapter 13, but it is worth noting here that newer linkage/mapping studies, coupled with older family studies, support the proposition that different age-at-onset subsets represent genetically heterogeneous groups of bipolar patients. Several studies cited in the first edition of this text reported that earlier onset was linked to higher familial bipolar morbidity and to early onset in bipolar relatives (Baron et al., 1981; Smeraldi et al., 1982–1983). Grigorioiu-Serbanescu and colleagues (2001), using segregation analysis of a large sample of 177 bipolar-I probands and 2,407 relatives, found that early-onset bipolar-I disorder was transmitted with a different pattern of heritability (non-mendelian major gene model) than late-onset bipolar-I. Recently, polymorphisms in serotonin transporter (5-HTTLPR) and a glycogen synthase kinase (GSK3-β) were associated with age at onset within bipolar populations (Bellivier et al., 2002; Benedetti et al., 2002). A recent chromosomal linkage study also confirmed the heritability of onset age, linking it to three chromosomal regions (Faraone et al., 2004). Taken as a whole, the evidence for age at onset as a possible marker for genetic subtypes of bipolar disorder is robust (see the review by Leboyer and colleagues [2005]).

The association between psychotic features and early onset among bipolar patients has considerable support in the literature. In an extensive review, Angst (1986c) cited 10 studies reporting this relationship, a conclusion supported by Blumenthal and colleagues (1987) in their study of the Amish and confirmed by subsequent research (Dell'Osso et al., 1993; Verdoux and Bourgeois, 1993; Schulze et al., 2002). Yet adolescent-onset mania is not always associated with psychotic features, as evidenced by cross-sectional comparison studies (Coryell and Norten, 1980; McElroy et al., 1997). A more recent cross-sectional study comparing early with non-early onset groups likewise failed to find a significantly higher presence of psychotic features in the former (Perlis et al., 2004). However, cross-sectional studies cannot determine subsequent development of psychosis and may easily miss prior psychotic features, especially if the investigators rely on patient recall. Taken as a whole, the evidence for a connection between psychotic features and younger age at onset is strong. Coupled with the association between premorbid impairment and level of psychosis discussed earlier, this evidence supports the hypothesis that pervasive psychotic features mark a more severe form of the disorder that sometimes entails earlier syndromal manifestation and is more often characterized by premorbid impairment. The relationship between age at onset and episode frequency is discussed later in this chapter.

NUMBER OF EPISODES

In his classic 1921 monograph, Kraepelin noted that of 459 manic-depressive patients he had studied (which included unipolar patients), only 55 percent had experienced more than one episode and only 28 percent more than three. A careful reading of Kraepelin's clinical descriptions suggests, however, that many of his ostensibly single-episode patients were in fact severely and chronically ill and had experienced multiple episodes, which at that time required continuous hospitalization (the single hospitalization being counted as single episode).

Considered together, findings of longitudinal studies of manic-depressive patients not taking prophylactic medication (Table 4-2), which included those with both bipolar and unipolar forms of the illness, indicate that most patients—particularly those studied in the past 35 years—had more than one episode.¹⁷ Table 4-2 also indicates that most patients with major affective disorder (i.e., Kraepelinian manic-depressive illness) have a recurrent course. Many textbooks, apparently relying on older data, fail to emphasize this point sufficiently.

The near-total likelihood of recurrence is supported by recent research. In a 4-year naturalistic follow-up study of 75 bipolar patients, only 28 percent remained in remission (Tohen et al., 1990). If relapse were to continue at this rate over the long term (18 percent per year), fewer than 1 percent of patients would remain in remission at about 10 years' follow-up. In the National Institute of Mental Health's (NIMH) Collaborative Program on the Psychobiology of Depression-Clinical Studies (CDS), relapse into a new episode within 5 years was observed in 81 to 91 percent of patients, the variability in percentage being related to the polarity of the index episode (i.e., depressive, mixed, or manic states) (Keller et al., 1993).

In contrast, relapse in unipolar depression is not as frequent and is more dependent on the number of previous episodes, with a much higher risk of relapse after the third major depressive episode. In a separate analysis of the data from the NIMH Collaborative Program on the Psychobiology of Depression-Clinical Studies, the 5-year recurrence rate was 64 percent among 380 patients with unipolar depression, rising to 80 percent at 10 years and 85 percent at 15 years (Mueller et al., 1999). In a Japanese collaborative study (Kanai et al., 2003), 95 previously untreated unipolar depressed subjects (70.5 percent first episode, 29.5 percent recurrent; mean age 44.3) were followed for 6 years. In this cohort, lower rates of relapse were seen, with only 45 percent experiencing a new episode at 6 years. This lower relapse rate may reflect the fact that, unlike the CDS cohort, most of these patients had not already experienced recurrent major depressive episodes. The lower rate of episode

recurrence in unipolar compared with bipolar disorder does not address the issue of subsyndromal chronicity, however (see later discussion).

Angst (1980) subdivided his patients into three categories according to their pattern of recurrence: MD, Md, and Dm. As described in Chapter 2, MD represents the core illness, with both major manic and major depressive episodes; Md patients have full manic episodes, but their depressive episodes do not require hospitalization; and Dm patients have been hospitalized for depression, but their manic episodes are not severe enough for hospitalization (i.e., they have a history of hypomania).¹⁸ Angst's MD patients showed a tendency toward having the most episodes. In the larger cohort described in the CDS, however, Dm (bipolar-II) patients had the most prior episodes, although this number was not significantly different from that for bipolar-I patients (Coryell et al., 1989).¹⁹

As noted earlier in our discussion of methodological issues, some differences among studies relate to varying definitions of what counts as an episode. Some studies underestimate recurrence because they rely solely on hospitalization as a marker of episodes.²⁰ Other studies may be prone to overestimate recurrence because of treatment factors, such as use of antidepressants and selection of lithium clinic patients for study.

On the question of the contribution of antidepressant drugs, it is important to note that the highest relapse rates generally are the most recent. Thus it is conceivable, as suggested in the first edition of this text and by Koukopoulos and colleagues (1980) and Wehr and Goodwin (1987), that the increased use of antidepressants may have influenced the results. Indeed, in his analysis of the incidence of manic switches in one hospital studied over six decades, Angst (1985) noted a four-fold increase when the pretreatment decades were compared with the decades after electroconvulsive therapy (ECT) and antidepressant drugs became widely used. Some more recent studies (Altshuler et al., 1995; Ghaemi et al., 1999, 2000), but not all (Altshuler et al., 2001), support the possible impact of anti-depressants. Although other explanations, such as better diagnostic detection of mania, are plausible, these explanations also are consistent with the hypothesis that effective antidepressant treatments altered the course in some manic-depressive patients (perhaps particularly those with the bipolar form) toward more frequent recurrences. The evidence for and against this hypothesis is reviewed extensively in Chapter 19.

Another possibility is that a bias toward higher relapse rates is likely when an outcome study draws all of its subjects from patients referred to a lithium maintenance clinic. The studies of Angst and of Grof cited elsewhere in this chapter, however, included all patients who came to

TABLE 4–2. Total Number of Episodes

Study	Sample Size	Years of Observation	TOTAL EPISODES (%)				Comments
			1	2–3	4–6	7+

the clinic for treatment of an episode without regard to previous episodes (i.e., not just those deemed eligible for maintenance treatment). Other studies appear to have focused primarily on those judged eligible for lithium maintenance (Baldessarini et al., 1999, 2000). As noted earlier, both underestimations and overestimations of true natural recurrence rates have occurred in the literature. It appears that some recent studies may be prone to overestimation of recurrence rates as a result of the uncontrolled effects of treatment and to potential selection bias, although underestimation also occurs.²¹

FREQUENCY OF EPISODES (CYCLE LENGTH)

Cycle length is defined as the time from the onset of one episode to the onset of the next. Variation in cycle length reflects primarily variation in the length of the symptom-free interval, because the duration of episodes tends to be relatively constant in a given individual. Onset is used to calculate cycle length because it is generally easier to pinpoint than termination of an episode. In addition, treatment can easily obscure an episode's natural length. Most investigators agree that cycle length tends to grow shorter with subsequent recurrences; that is, episodes become more frequent. What is not as clear is the proportion of bipolar patients whose illness accelerates. After three to five episodes, however, the extent of shortening slows considerably and approaches a leveling off, or maximum frequency of episodes.

In the first edition of this text, we speculated that episode frequency might represent a familial trait, as suggested by Gershon and colleagues (1982). Subsequently, Fisfalen and colleagues (2005), examining 86 families with at least three members with a major affective disorder, found that episode frequency (evenly distributed over a wide range) was correlated among relatives ($r = 0.56$, $p < .004$). They also noted that, compared with the lowest quartile of episode frequency, the highest quartile was significantly (and independently) associated with bipolar-II, early age at onset, psychotic features, alcoholism, and suicidal behavior.

Decrease in Well Intervals with Increasing Number of Episodes

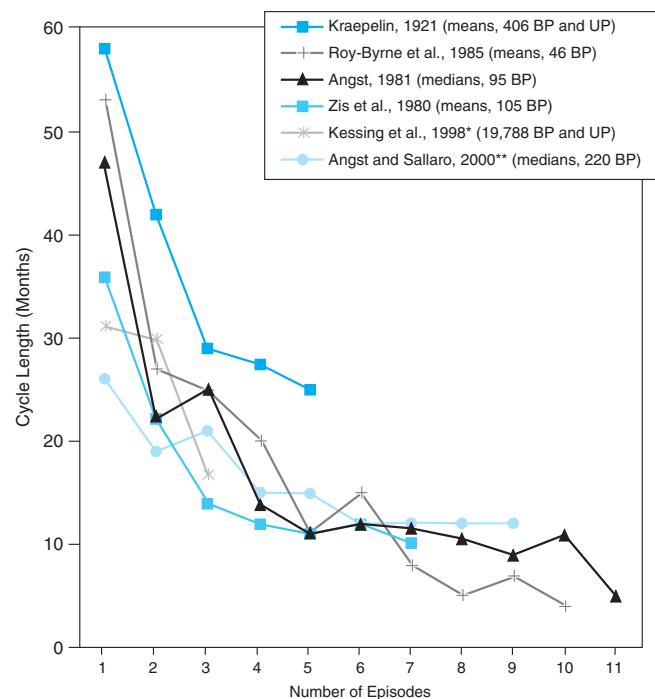

Kraepelin was the first to report that intervals of euthymia appear to decrease in duration in manic-depressive illness with increasing numbers of affective episodes. This observation later became a central impetus for the kindling model, with its prediction that episodes become more frequent over time, and that euthymic intervals between episodes become increasingly shorter. This observation was subsequently confirmed in a number of clinical studies. Recently, however, some methodological flaws underlying those

studies have been identified, and not all of the study findings have been consistent.

Figure 4-2 illustrates the relationship between average cycle length and episode number. This graph is based on six studies involving a total of 20,660 patients. Despite substantial individual variability, the averages show a remarkably consistent pattern across the studies. For example, note the pattern in the 105 bipolar patients of Zis and colleagues (1979): the average cycle length between the first and second episodes was 36 months, diminishing to about 24 months, then to 12 months. In 46 bipolar patients studied by Roy-Byrne and colleagues (1985a), the mean cycle lengths for the first seven episodes were 53, 28, 25, 20, 12, 15, and 9 months. In 95 bipolar patients from Angst's Zurich clinic, the median first cycle length was 48 months, compared with 22 months for the second cycle, 24 for the third, 14 for the fourth, and 12 for the fifth (Angst, 1981b). The longer average cycle length in the Kraepelin data reflects the inclusion of unipolar patients, whose cycles are longer than those of bipolar patients (Angst, 1981b; Fukuda et al., 1983).

The findings of the six studies illustrated in Figure 4-2 are consistent with the retrospective data of Taschev (1974), who found the average second cycle to be as long as the first, but the fourth cycle to be half as long as the second. A prospective study of patients in the 1980s (Keller et al., 1982) also documented the increasing probability of an

Figure 4-2. Episode number versus cycle length. BP=bipolar, UP=unipolar. (Source: Update of Goodwin and Jamison, 1984.)

earlier relapse with each episode, a finding suggesting that some fundamental characteristics of the illness course may persist despite treatment. The methodological consideration of “Slater’s fallacy”—the impact of the number of episodes on cycle length—needs to be taken into account when assessing these studies, however (see later discussion).

Recent studies have not been consistent with regard to the progressive shortening of cycle length. In a reanalysis of his Zurich cohort (identified 1959–1963, followed to 1997; N=220 bipolar patients), Angst and Selloro (2000) found shortening of cycle length in the first few but not in later episodes. In the studies of Winokur and colleagues (1993) and Turvey and colleagues (1999), who analyzed data from the same large NIMH cohort, bipolar patients did not appear to have more frequent and shorter episodes with time, nor was there a correlation between poor outcome and such a course. Rather, poor outcome was associated with “polyphasic” mood episodes; that is, immediate switching from mania to depression to mania without intervening euthymia.

Findings of other contemporary studies suggest that at least a subgroup of patients with bipolar disorder do experience a progressive shortening of cycle length. For instance, Goldberg and Harrow (1994) reported that 50 percent of 20 bipolar patients with two or more previous hospitalizations had experienced intervals between episodes of less than 1 year (defined as “kindlers”), whereas 19 other patients with fewer than two hospitalizations had experienced intervals between episodes of more than 1 year (“nonkindlers”). At 4.5-year follow-up, the kindlers were more likely to have had a recurrence than the nonkindlers. In a hospital-based case register study, Kessing and colleagues (1998a) found that 40 percent of a large sample (N=1,712) had shortening between first and second intervals, and 25 percent of this sample showed progressive shortening across two consecutive intervals.

The considerable individual variability in patterns of relapse was pointed out by Kraepelin (1921, p. 149):

If we give no more examples that is not because those already given represent adequately the multiplicity of the courses taken by manic-depressive insanity; it is absolutely inexhaustible.

The complexity of this topic increases when we pay attention to the above-noted methodological problem first raised by Eliot Slater in 1938 but ignored by most researchers until recently. Slater’s fallacy, as revived by Oepen and colleagues (2004), posits that patients with more episodes tend also to have shorter cycle lengths, and those with fewer episodes to have longer cycle lengths.²³ Thus if the two groups are pooled, as in Kraepelin’s original data, it will ap-

pear as if cycle length decreases with more episodes in the sample as a whole, whereas this apparent effect may be an artifact of pooling the two distinct subgroups of patients, those with few and those with many episodes. To truly demonstrate shortening of cycle length, then, one would need to correct for number of episodes.

Because this important methodological point went underrecognized for decades, we reanalyzed the studies described in the first edition of this text with regard to cycle length, as well as newer studies conducted since 1990. We found that the majority of studies either did not correct for number of episodes or did not address the subject. A number of investigators, however, without directly referring to Slater’s finding, appear to have been cognizant of this issue.²³ In two of these studies (Bratfoss and Haug, 1968; Angst et al., 1973), correction for number of episodes led to results similar to those reported by Slater; that is, no consistent evidence of progressive shortening of well intervals. In two other studies (Roy-Byrne et al., 1985a; Goldberg and Harrow, 1994), however, a “sensitization” or “kindling” pattern was identified in about half of patients with refractory bipolar disorder and not in the others (see Fig. 4–2). In a large Norwegian community-based study of hospitalized bipolar patients, half of those with three or fewer episodes also appeared to have progressive shortening of intervals of wellness, but a similar pattern was seen in only 25 percent of patients with four or more episodes (Kessing et al., 1998a). Slater’s fallacy was also avoided in a contemporary Italian study of 426 hospitalized research patients with mood disorders (182 unipolar, 244 bipolar) (Cusin et al., 2000). In that study, in which all patients had experienced periods of euthymic recovery (continuous and rapid-cycling courses were excluded), progressive shortening of cycle length was observed (based on retrospective evaluation) after correction for total number of episodes, up to a plateau of about one episode per year. In a recent 40-year follow-up of Angst’s Zurich cohort (N=406, 186 with recurrent unipolar depression, 220 with bipolar disorder), Kessing and colleagues (2004) specifically conducted their analysis to control for Slater’s fallacy by using a Cox regression model in which one of the variables was episode number, thus adjusting the overall hazard ratio for number of previous episodes. They found an increased likelihood (hazard ratio) of more episodes with increasing number of episodes (e.g., the hazard ratio for 1 episode was 1.0 as the reference point, while for 4 episodes it was 1.52 and for 10 episodes 2.19).

In these studies, then, correction for episode frequency revealed decreasing length of well intervals mainly in the first three episodes, with unchanging well intervals of about one per year for further episodes, which in fact was what the Goodwin group found earlier (Zis et al., 1980). These findings suggest that studies of well intervals that fail to capture

the first three episodes of illness are unlikely to observe any kindling-like effect. This point may be relevant to some studies that fail to find this effect, such as that of Turvey and colleagues (1999), in which the first episode was captured in only 15 percent of subjects recovered from the index episode. On the other hand, the recent data from the McLean-Harvard First-Episode Mania Study do not show evidence of shortened intervals of wellness, although the period of follow-up was brief (2 to 4 years) (Tohen et al., 2003).²⁴

As alluded to earlier, if the finding of shortening of well intervals cannot be applied to an entire sample of patients with manic-depressive illness, the question arises of whether it may be a subgroup effect. It is important to note that Post and colleagues (Post et al., 1986a; Post, 1990) proposed the kindling hypothesis as relevant to only a subset of patients with bipolar illness, particularly those who are unresponsive to lithium, more responsive to anticonvulsants, and with other "nonclassical" features of the illness. Granting Slater's critique, such a proposal would not be inconsistent with the available literature.

Clearly, the kindling model does not depend solely on the prediction of shortening of euthymic intervals of wellness. As discussed previously, the model makes other predictions as well, such as increasing frequency of episodes, increasing episode duration with time, decreasing importance of psychosocial triggers with time, and increasing treatment resistance with greater numbers of episodes (or differential efficacy in early versus later phases of illness). An important issue bearing on the generalizability of the kindling model is the proportion of patients with bipolar disorder whose course is consistent with these predictions.

Research on psychosocial triggers of episodes has revealed interesting data regarding this issue. Kendler and Karkowski-Shuman (1997) analyzed their sample of patients with recurrent unipolar depression so as to account for "within-person analyses." They reported on a sample of 2,395 female twin pairs followed for 9 years, in whom later mood episodes were associated less and less frequently with psychosocial triggers, as predicted by the kindling model.²⁵ They concluded (p. 542):

These results indicate the observed decline in the association between stressful life events and depressive onsets with increasing numbers of previous depressive episodes is a true within-individual phenomenon and cannot be explained by systematic differences between the kind of individuals who have a low versus high number of previous depressive episodes.

Is there any evidence that episodes increase in frequency over time? Kessing and Andersen (1999) reported that such was the case for both unipolar depression (15 percent increased risk of recurrence with each episode)

and bipolar disorder (9 percent) in a case register study of all hospitalized admissions in Denmark (7,925 unipolar, 2,011 bipolar; 1971–1993 time frame). A similar conclusion was reached by Bockting and colleagues (2006) on the basis of a study of 172 patients meeting DSM-IV criteria for recurrent unipolar depression.

Increasing treatment resistance with number of episodes has been reported in some studies (e.g., Koukopoulos et al., 2000) but not in others (e.g., Baldessarini et al., 1999). Kessing and colleagues (1998b) failed to find other evidence of worsened outcome, such as increased mortality, associated with a sensitization pattern of progressive shortening of cycle length, although there was an interesting association between that kindling-like pattern and an increased risk of dementia.²⁶

Recall that the kindling model predicts that outcome will be worse after more episodes. The outcome of both untreated and treated courses could be expected to reflect this pattern. This prediction is supported by some but not all studies. For instance, Gitlin and colleagues (1995) found that more previous episodes predicted earlier relapse at 4.3-year follow-up (2.2 versus 3.5 years; $p=.007$), a finding similar to that of Goldberg and Harrow (1994) noted earlier. On the other hand, in a 4.6-year study of outcome among 360 bipolar-I ($n=220$) and bipolar-II ($n=140$) patients on lithium maintenance therapy, Baldessarini and colleagues (1999) did not confirm the kindling-based prediction of worsening outcome with each successive episode. These investigators assessed delay in beginning lithium treatment after onset of bipolar illness and compared response to lithium treatment in subgroups of patients with few (0 to 4), some (4 to 9), or many (more than 10) mood episodes before treatment began. They reported no difference in lithium treatment response among these conditions; that is, lithium response was neither better nor worse if patients had experienced few or many previous mood episodes, or if they had begun lithium treatment soon after the onset of their illness as opposed to later. It is worth noting that lithium treatment had not been started until an average of 8 years after the onset of illness in this sample, which suggests that a significant delay occurred in most patients. Also, because this study was naturalistic, information about previous episodes and onset of illness was retrospective and subject to recall bias. It is notable that the average age at onset of bipolar illness in this sample (29.6 years)²⁷ was much older than the age in most other studies, a fact that may suggest the effects of recall bias or a difference in patient selection. It is also relevant that the kindling model may not be pertinent to the long-term outcome of lithium treatment. In the early work of Post and colleagues (Post and Weiss, 1989; Post, 1990), kindling was invoked to explain the treatment-refractory course of illness in those

patients who failed to respond to lithium and who appeared to respond to anticonvulsant agents.

Taken as a whole, the findings reviewed here, although not decisively confirming the validity or generalizability of the kindling model, appear to suggest its relevance to at least some patients with manic-depressive illness, including both bipolar and recurrent unipolar forms.²⁸

Other Cycle-Length Patterns

The relationship between frequency of episodes and age at onset remains somewhat unclear. Several older studies²⁹ found an increasing frequency of relapse with increased age at onset, but two studies failed to show this association (Dunner et al., 1980; Roy-Byrne et al., 1985a), and two found the opposite (Okuma and Shimoyama, 1972; Winokur and Kadrmas, 1989).³⁰ A multiple-regression analysis of the 105 bipolar patients studied by Grof and colleagues (1995) showed that the patient's age and age at onset each contributed independently to the prediction of relapse (Zis et al., 1979). Onset in the 20s was associated with a 20 percent probability of recurrence within 24 months, onset in the 30s with a 50 percent probability, and late onset (age 50 years or older) with a very high (80 percent) probability. Only the first cycle length (the time between the first and second episodes) was related to age at onset, however.³¹

A final question about the pattern of cycles in bipolar illness is whether burnout occurs. Kraepelin observed that the illness tends to decline after the fourth decade, although he did not elaborate on his observation. In a prospective follow-up study of 215 bipolar patients (150 bipolar-I, 65 bipolar-II) over a period of 17 to 21 years, Angst (1986d) found no age-related decrease in frequency of episodes; 26 percent of the bipolar patients (versus 42 percent of the unipolar patients) were free of relapses over 5 or more years, although most patients were still actively ill through their 60s, when the follow-up usually ended. Likewise, findings of recent studies do not generally support the concept of burnout (Goldberg and Harrow, 1999), although long-term follow-up from adulthood into the elderly years is rare.

Rapid Cycling

The inclusion of rapid cycling in DSM-IV was based to a large extent on a study by Bauer and colleagues (1994), who compared 120 patients with rapid-cycling bipolar disorder and 119 non-rapid-cycling patients. They found that 45 percent of the rapid cyclers had bipolar-II disorder, compared with 38 percent of the non-rapid cyclers, a difference that did not achieve statistical significance. Those with rapid cycling, not surprisingly, had more episodes in a 12-month prospective follow-up period; there were also more females in the rapid-cycling group. Based on these

differences in course and demographics, the investigators supported the differentiation of rapid-cycling bipolar disorder as a valid course specifier for inclusion in DSM-IV. They also supported the cutoff definition of four episodes per year, because of an increase in the number of patients who experienced four to eight episodes per year, versus two to three episodes, during the prospective follow-up (although this was observed only among the females). It is notable that this was an observational study, in which adjustments were not made for potential confounding variables or effect modifiers. Therefore, similarities or differences between the two groups in this study may or may not be related to rapid cycling per se. This limitation holds for most of the research on rapid cycling.

Rapid cycling is thought to be equally common in type I and type II bipolar illness, but there is no firm consensus on this point.³² Indeed, rapid-cycling unipolar depression (although uncommon) has been reported. It has generally been thought that rapid cycling develops later in the course of the illness and may reflect underlying pathophysiological mechanisms, such as the progressive kindling, or sensitization, discussed earlier (Fig. 4-3.). Late rapid cycling may also reflect the impact of certain treatments, especially antidepressants, in accelerating the natural course of the illness (see Chapter 19). The concept of rapid cycling as a later manifestation of bipolar illness has been proposed but is not supported by all investigators (see the later discussion) (Coryell et al., 1992). There may also be a predominance of rapid cycling in females (Koukopoulos et al., 1980; Coryell et al., 1992; Bauer et al., 1994), although Kupka and colleagues (2005) examined 539 outpatients in the Stanley Network and found that female preponderance was limited to those with eight or more episodes per year.

Box 4-1 highlights what is known about the relationship between rapid-cycling and non-rapid-cycling bipolar disorder. A study of the frequency distribution of cycle lengths could answer the question of whether rapid cycling represents a distinct subgroup or is simply one end of a continuum. Cycle-length data presented by Coryell and colleagues (1992) do not support a separate short-cycle-length group. The existing family history data also are more consistent with the continuum notion, in that the families of rapid-cycling patients have the same frequency of non-rapid-cycling affective disorders as families of non-rapid-cycling patients (Nurnberger et al., 1988b; Wehr et al., 1988; Coryell et al., 1992). The largest single prospective study of rapid cycling (Coryell et al., 1992) found that it is transient and not associated with the end stage of severe bipolar illness. The data in this study are based on the CDS, conducted in five tertiary-care academic health centers, in which 243 bipolar and 674 unipolar patients were

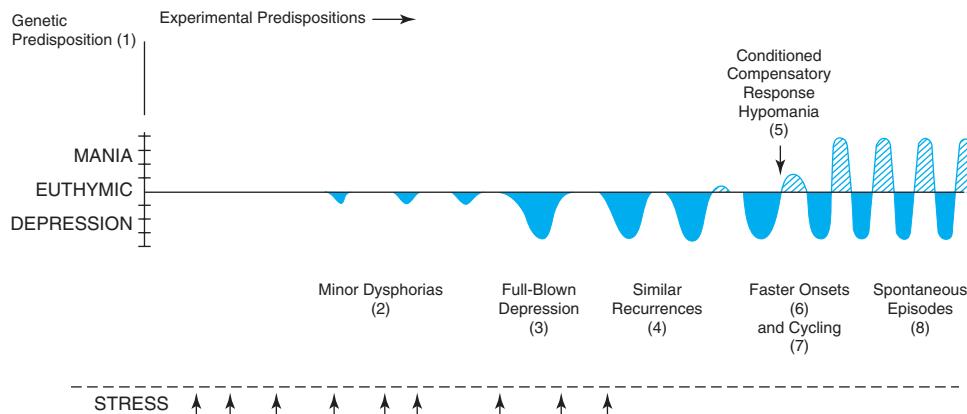

Figure 4-3. Behavioral sensitization paradigm of progressive course of illness leading to rapid cycles.
(Source: Post et al., 1986a.)

BOX 4-1. Relationship between Rapid-Cycling and Non-Rapid-Cycling Bipolar Disorder

- Data are insufficient to determine whether cycle length is distributed normally.
- In general, rapid-cycling patients appear to be related genetically and phenotypically to non-rapid-cycling patients (Nurnberger et al., 1988b; Wehr et al., 1988; Coryell et al., 1992).
- Illness in rapid-cycling patients can include a non-rapid-cycling course.
- Rapid cycling may be viewed as an extreme development of tendencies inherent in a non-rapid-cycling course:
 - Increasing frequency of episodes* (Grof et al., 1974)
 - Switches into new episodes with no normal interval between* (Winokur et al., 1969)
 - Circularity of episodes (Koukopoulos and Reginaldi, 1973)
- Rapid cycling may exhibit a somewhat different pharmacological response profile.
- Relative frequency in bipolar-I versus -II is unsettled.

*Potentiated by antidepressants, which are also capable of inducing rapid cycling (Wehr and Goodwin, 1979, 1987).

followed for 1 to 5 years, with interviews conducted every 6 months. The investigators found that 45 patients, all but one of them bipolar, developed a rapid-cycling course in the first year of follow-up; however, this group did not experience a lower rate of recovery at 5-year follow-up. Only 1 of the 39 rapid cyclers followed for the full 5 years continued to have four or more episodes in each year. In years 3 to 5, rapid cyclers did not differ from non-rapid cyclers in recovery from their index episode at the beginning of the study. However, there was a statistical trend for rapid cyclers to be less likely to experience a final follow-up year

with no affective symptoms (only 10 percent of rapid cyclers, versus 49.5 percent of non-rapid cyclers; $p=.09$).

Although the CDS has the major advantage of being the kind of careful prospective, naturalistic study needed by the field, it is limited by those same study methods. Patients who remained in the study after having been recruited into one of the five tertiary-care centers in which it was conducted may not have been representative of the larger population of patients with rapid-cycling bipolar disorder—individuals whose chaotic lives often do not allow for long-term prospective follow-up in a systematic research study. Nonetheless, one cannot ignore the findings of this study, especially given the fact that, in a separate cohort, Maj and colleagues (1994) also found that only 18.9 percent of 37 individuals with rapid cycling continued to experience four or more episodes per year during 5-year follow-up. Future prospective research on more community-based samples may clarify these questions that are so important to the estimation of prognosis in individual patients.

Rapid cycling appears to represent a generally treatment-refractory state compared with non-rapid cycling. Most of the studies on this issue have involved lithium, which has led to the common belief that rapid-cycling patients do not respond well to lithium and respond better to anticonvulsants. In fact, as discussed in Chapters 18, 19, and 20, it appears that most rapid-cycling patients do not respond particularly well to any medication—lithium or anticonvulsants. Alternatively, as suggested by a number of investigators (Koukopoulos et al., 1983; Wehr et al., 1988; Baldessarini et al., 2000), the responsiveness of rapid-cycling patients to mood stabilizers may be greatly enhanced when concomitant antidepressant use is avoided.

Recent genetic studies on rapid cycling have yielded instructive, if inconclusive, results. Associations have been

reported with the serotonin transporter gene polymorphism (Rousseva et al., 2003) and with a low-activity allele for the catechol-O-methyltransferase (COMT) gene (Kirov et al., 1998; Papolos et al., 1998), although the COMT allele association was not seen in a study of 52 children (mean age 10.9 years) (Geller and Cook, 2000). A family history study in 165 patients with rapid-cycling bipolar disorder did not identify major differences in familial mental illness compared with non-rapid-cycling bipolar disorder, with the exception of a suggestion of more substance abuse among relatives of rapid-cycling bipolar probands (Lish et al., 1993).

Taken together, the data tend to favor the concept that rapid cycling represents one extreme of a bipolar spectrum of cyclicity, but it is generally not a stable characteristic in an individual patient.

ONSET AND DURATION OF EPISODES

Often, the onset of manic episodes is abrupt, developing over a few days. Depressive episodes develop more gradually, over weeks, although bipolar depressive episodes are more abrupt in onset than unipolar depressive episodes (Winokur, 1976; Molnar et al., 1988; Keitner et al., 1996).

As we noted in the first edition, some patients experience a “hypomanic alert” (Jacobsen, 1965), a period of days or even weeks of hypomanic symptoms before the switch into mania. The most common prodrome is sleep disturbance, which had a prevalence of 77 percent in one study (Jackson et al., 2003). Family members are twice as likely as patients to observe early behavioral symptoms of mania (Keitner et al., 1996) (see Chapter 22).

Older estimates of the average duration of episodes in manic-depressive illness were derived from studies conducted before medications were available. In the CDS 5-year follow-up of a largely treated sample, the mean time to recovery was 6 weeks with pure mania, 11 weeks with pure depression, and 17 weeks with mixed states (Coryell et al., 1990). In a follow-up study conducted by Angst and Preisig (1995), the mean episode length was 4.3 months. Pure manic and pure depressive episodes lasted the same amount of time—approximately 3 months. Mixed episodes also lasted about 3 months, but “cyclic” episodes were longer (mean 4.2 months). The Baltimore site of the ECA community-based study of psychiatric disorders found that episodes lasted a median of 8 to 12 weeks (Eaton et al., 1997), with depressions lasting longer than manias. Maj and colleagues (2003) found longer duration of agitated depressive episodes compared with nonagitated depression in bipolar-I disorder (mean time to 50 percent recovery, 12 versus 9 weeks; N=120) (Maj et al., 2003).

POLARITY

Estimates of the proportion of bipolar patients who begin the illness with a manic episode range from 34 to 79 percent, averaging just over 50 percent. It is important to recognize that the other half of patients with the bipolar form of manic-depressive illness will go undiagnosed as bipolar at the onset of their condition, because they initially experience only major depressive episodes³³; this condition is sometimes called “false” unipolar depression. This dilemma arises from the current DSM nosology (see Chapters 1 and 3), which places primary emphasis on polarity at the expense of cyclicity or recurrence. This approach guarantees an initial misdiagnosis in many patients who have bipolar disorder but have not yet experienced their first manic episode. The problem was less acute with the classic construct of manic-depressive illness, which took into account other course factors, such as recurrence of episodes, as well as family history.

One study of false unipolar depression examined 17,447 patients with mood disorders who were hospitalized in Denmark over a 22-year period (1971–1993) (Kessing, 1999). Among those whose first episodes were depressive, if a manic episode was to develop, it usually did so within 5 years. Patients with false unipolar depression experienced more recurrent depressive episodes than did patients with true unipolar depression.³⁴

It is also important to recognize that there is a relationship between false unipolar depression and age at onset (see Chapter 1). An often-cited figure is that 1 to 2 percent of patients with depression may experience a hypomanic/manic episode in every year of follow-up. This figure is based on the CDS cohort (Coryell et al., 1995), in which 10.2 percent of a depressed subgroup (mean age 36.8 years) had a manic or hypomanic episode during 10 years of follow-up. A younger age at onset within this cohort was associated with increased risk of manic/hypomanic switch, however. Other younger cohorts have confirmed higher natural switch rates to mania (see Chapter 6). For example, in a group of 72 depressed children (mean age 10.3 years), Geller and colleagues (2001) found that 49 percent had experienced a manic or hypomanic episode at 10-year follow-up. In a group of 74 depressed young adults (mean age 23.0 years), Goldberg and colleagues (2001) observed that 46 percent had experienced a manic or hypomanic episode at 15-year follow-up. Thus the risk of switching from false unipolar depression to bipolar disorder is highest in childhood and young adulthood, occurring at a rate of about 3 to 5 percent per year; it then decreases by the late 30s, at which point it flattens out to about 1 percent per year.

Studies showing the highest estimates of manic onset utilize first hospitalization as the onset criterion. It is possible that these high estimates result from underestimation of depressive onsets, because many depressions do not require hospitalization. On the other hand, hypomanic onsets are probably underestimated compared with depressive onsets, because patients are more likely to experience (and report) depressive symptoms as illness. Angst (1978) reported manic onset of illness in the majority of his bipolar sample ($N=95$), where onset was defined as the first occurrence of symptoms requiring treatment. On the other hand, Roy-Byrne and colleagues (1985a), who defined onset as the first symptoms meeting the RDC for an affective episode, found that 60 percent of 71 bipolar patients had a depressive first episode.

Onset may influence the later pattern of illness. Perris and d'Elia (1966) reported that among patients with a manic first episode, 62 percent went on to have a predominantly manic course, and only 25 percent a predominantly depressive course. It is interesting that a predominantly manic course may herald a better outcome. In a hospital chart review study based on the premedication treatment era, Stephens and McHugh (1991) reported on outcomes in 297 bipolar and 945 unipolar patients admitted to the Johns Hopkins Hospital from 1913 to 1940. Only 2 percent of all patients with mood disorder experienced unipolar manic episodes, and their outcome was best (75 percent recovered or improved), followed by that of those with unipolar depression (69 percent) and bipolar disorder (57 percent) (Stephens and McHugh, 1991). This report is supported by another study of 320 patients with bipolar-I disorder (Perugi et al., 2000), in whom depressive episode onset was associated with higher levels of later rapid-cycling course, as well as suicide attempts. Later psychotic features were more likely to be associated with manic onset, however. In light of these findings of a relationship between polarity at onset and subsequent course, a recent report that the polarity of onset appears to be familial (Kassen et al., 2006) is especially interesting.

It has generally been observed that women tend to be more likely to have a predominantly depressive pattern to their bipolar illness, and men a predominantly manic pattern.³⁵ More recent data have not uniformly supported these findings, however. In one chart review of 131 patients (63 women and 68 men) (Hendrick et al., 2000), there were no statistically significant gender differences in age at onset, number of depressive or manic episodes, and number of hospitalizations for depression. However, women had been hospitalized for mania significantly more often than men, whereas substance abuse, although high in both groups, was more prevalent among men. Also, in a cross-sectional analysis of 500 subjects in the NIMH Systematic

Treatment Enhancement Program for Bipolar Disorder (STEP-BD) study cohort, there were no gender differences in number of past depressive versus manic episodes (87.4 percent of women and 86.8 percent of men had experienced three or more manic episodes; 92.1 percent of women and 92.3 percent of men had experienced three or more depressive episodes) (Baldassano et al., 2002).³⁶ As noted earlier in relation to age at onset of depression and false unipolar depression, polarity distinctions are not stable until approximately age 40.³⁷ Before that age, depressed individuals remain at a relatively elevated risk of eventual occurrence of manic or hypomanic episodes.

Some investigators have noted that polyphasic polarity patterns are associated with poor outcomes (Turvey et al., 1999; Maj et al., 2002). For instance, Maj and colleagues (2002) compared 10-year outcome in 97 patients with bipolar disorder whose index episode included switching from one mood phase to another and 97 patients whose index episode was monophasic. Overall, they found that a subgroup of those who switched had experienced multiple polarity switches ($n=23$) and had worse outcomes (ill 56 percent of the time during the follow-up period), compared with those who had one polarity switch (ill 26 percent of the time; $n=74$) or those with a monophasic index episode (ill 20 percent of the time; $n=97$).

A related question (discussed further in Chapter 19) is whether depression that occurs alone (preceded and followed by euthymia) is different in duration or risk of an antidepressant-related manic switch from depression that occurs immediately following mania. This pattern of differential risk was noted in a post hoc analysis of a small randomized clinical trial comparing the addition of paroxetine to a mood stabilizer (lithium or valproate) with a combination of the two mood stabilizers (Goldberg, 2001). Another study (Gitlin et al., 2003) examined 72 prospectively observed depressive episodes in 28 patients with bipolar-I disorder. It was found that 65 percent of depressive episodes were monophasic, and 35 percent were post-manic. Duration of episodes was somewhat longer in the monophasic group (82 ± 65 days) than in the postmanic group (62 ± 48 days). Antidepressant-induced manic switching was also higher in the postmanic group (36 percent, 4 of 11 patients) than in the monophasic group (26 percent, 9 of 34 patients). Although the authors interpreted these differences as unimportant because of a lack of statistical significance, there is a large risk of type II false-negative error due to the small sample size. Whether future research will confirm this suggestion of higher susceptibility to antidepressant-induced mania and perhaps an increased cycling rate in those with polyphasic as compared to monophasic depressive episodes remains an open question.

The features of a manic episode may also be related to the course of illness. In a retrospective assessment, Swann and colleagues (2001) found that mania with depressive features (mixed states) was associated with an earlier onset of illness and more prior episodes than mania with irritable features (but no concomitant depressive affect).

PATTERN

The topic of episode pattern is of historical importance. Early investigators demonstrated that three basic patterns were apparent: mania followed by depression and then a well interval (MDI), depression followed by mania and then a well interval (DMI), and continuous cycling (MDMD).³⁸ There is some evidence from these studies that the MDI pattern may have the best outcome (Koukopoulos et al., 1980) and the MDMD pattern the worst. As we suggested in the first edition, the DMI pattern appears to be associated with mania occurring after treatment of the depressive phase with antidepressants (Maj et al., 1989).

Contemporary studies of episode pattern are not entirely consistent with this older literature. In a study of all hospitalized cases of bipolar and unipolar disorders in Denmark over a 22-year period (1971–1993; N=17,447), the DMI and MDI courses were associated with a similar number of recurrences (Kessing, 1999). On the other hand, in a recent reanalysis of data from the CDS in which 165 bipolar-I patients were followed for 15 years, Turvey and colleagues (1999) reported that mood episodes beginning with depression (depression only or depression followed by mania) were associated with worse 15-year outcomes than those beginning with mania. Also, polarity sequences tended to remain stable over time: 75 to 80 percent of individuals whose first observed mood episode began with mania continued to have mood episodes beginning with mania, and 55 to 60 percent of those whose mood episodes began with depression also maintained that pattern. This study is the longest outcome study assessing polarity. Its findings suggest that patterns of mood episodes are sustained over time and that the poorer prognosis of depressive as opposed to manic episodes persists in the long run.

Finally, it should be noted that some confusion regarding the patterning of episodes has been introduced by recent treatment guidelines asserting that the polarity of the index episode predicts the polarity of a relapse following the episode. As discussed in detail in Chapters 17 and 20, this conclusion should apply only to those relapses that occur shortly after remission is achieved, and these generally occur as a result of an effective treatment's being withdrawn before the continuation phase of treatment is completed. In an analysis of the course of patients on placebo participating in an 18-month study of maintenance treat-

ment with lithium or lamotrigine when the time frame beyond the continuation phase of treatment was examined the next new episode was almost always (85 percent of the time) of opposite polarity confirming classic observations (F. Goodwin and Calebresi [in preparation]).

PRECIPITANTS OF EPISODES

Findings of most studies of diagnostically heterogeneous groups of depressed patients suggest that stressful life events, such as losing a loved one, changing jobs, or moving, are more frequent during the 3 to 12 months preceding the onset of a depressive episode. Although the literature on events precipitating depression is extensive, that pertaining specifically to bipolar patients is more modest. It comprises primarily interesting but ultimately inconclusive case reports (reviewed by Ellicott, 1988), an intriguing report on increased relapses among bipolar patients after a hurricane,³⁹ and 14 systematic studies, all but 3 of which were retrospective. These studies are outlined in Table 4-3; their conclusions are summarized in Box 4-2. Taken together, they provide considerable support for the importance of stressful events in the onset of episodes in bipolar patients.

Although some theories assign primary causal importance to psychosocial environmental forces, it is now generally accepted that environmental conditions—psychosocial or physical—contribute more to the timing of an episode than to underlying vulnerability, which is largely genetic (see Chapter 13). Thus modern biological theory reaffirms the classic position of Kraepelin (1921, pp. 180–181):

We must regard all alleged injuries as possibly sparks for the discharge of individual attacks, but that the real cause of the malady must be sought in permanent internal changes, which at least very often, perhaps always, are innate. . . . Unfortunately, the powerlessness of our efforts to cure must only too often convince us that the attacks of manic-depressive insanity may be to an astonishing degree independent of external influences.

Early precipitating events, rather than merely influencing the timing of an episode, may actually activate the preexisting vulnerability, thereby making the individual more vulnerable to subsequent episodes, as recently demonstrated by Dienes and colleagues (2006). The theoretical significance of this possibility, proposed by Post and colleagues (1986a), is elaborated in Chapters 14 and 17.

More recent evidence supports the conclusion that the influence of life events in triggering mood episodes is more prominent in earlier than in later phases of bipolar disorder. The studies summarized in Table 4-3 (total of 688 patients) generally support this observation.

TABLE 4–3. Life Events, Kindling, and Mood Episodes in Bipolar Disorder

Study	Sample Size	Life Event (LE) Method	Findings	Supports Kindling	Comments
Ambelas, 1979	67	Paykel LE scale	First-episode patients were overrepresented in LE-associated mania.	Yes	Retrospective only; hospitalized manic episodes assessed
Dunner et al., 1979b	79	Own LE questionnaire	52% reported LEs before first episode, compared with 15% before subsequent episodes.	Yes	Retrospective study of outpatients; not limited to hospitalized episodes
Glassner and Haldipur, 1983	53	Own interview with patients and families	23% of early-onset bipolar patients (age <20) had LEs before episodes, compared with 63% of late-onset bipolar patients (age >20). However, early-onset patients had the same percentage LEs before first and subsequent episodes (23%), as did late-onset patients (64% and 61%, respectively).	Indeterminate	Retrospective; included inpatients and outpatients
Perris et al., 1984	149	Own LE interview	More patients with later episodes than first episode of depression reported no preceding negative LEs (50% vs. 38%; $p < .02$) or conflict events (81% vs. 57%; $p < .001$).	Yes	Prospective; combined bipolar and recurrent unipolar disorders in sample
Bidzinska, 1984	36	Puzynski LE questionnaire	LEs preceded more of first three episodes (2.6) than fourth through sixth episodes (1.9; $p < .05$).	Yes	Retrospective; compared findings with those of studies of unipolar patients, in which results did not support kindling; criteria for episodes unclear

Swann et al., 1990	66	Two Schedule for Affective Disorders and Schizophrenia (SADS) scale items asking clinicians and patients to give impressions of stressful LEs and current episode	Perceived roles of stressful LEs (combined clinician and patient scores) were greater in patients with fewer previous episodes (3.7) than in those with more previous episodes (13.4; $p < 0.05$).	Yes	Retrospective; careful rating scale and diagnostic assessments; data for bipolar and unipolar patients not separate
Winokur et al., 1993	148	None	Patients with one or more previous episodes were more likely than first-episode patients to have a recurrence in 2-year follow-up (0.64 episodes vs. 0.46; $p = .18$), but not statistically significant.	Indeterminate	Prospective; episodes based on Research Diagnostic Criteria and not just hospitalization, up to 5-year follow-up
Palao et al., 1997	26	Scale of Assessment of LE and Social Support of the California Department of Mental Health	Fewer LEs were found before the first episode of bipolar disorder compared with the following two episodes ($p < .02$).	No	Outpatients; complete data not available, presented as abstract; method for assessing episodes not clear (apparently retrospective)
Hlastala et al., 2000	64	SADS-Lifetime (SADS-L) or Structured Clinical Interview for DSM (SCID)	Number of episodes experienced did not appear to have a significant effect on reactivity of bipolar-I patients to external stressors.	No	Prospective

Note: Total sample=688 (limited to patients identified as having bipolar disorder, with exception of Perris et al., 1984).

BOX 4-2. Precipitants of Episodes in Bipolar Illness: Conclusions

- All studies found significantly more stress prior to manic episodes, compared with various control groups.
- Only one study (Kennedy et al., 1983) involved a within-patient comparison (i.e., controlling for inherent stress vulnerability). It found significantly more stressful events preceding a manic episode.
- The onset of initial (or early) episodes is more likely to be associated with stress than is that of later episodes (five of six studies), which is consistent with the kindling hypothesis.
- Although bipolar–unipolar differences have been observed in some studies, there is no consistent pattern.
- Work-related events may be particularly important precipitating factors for manic or hypomanic relapses.
- Cyclothymia is associated with an increased response to stress, consistent with its being part of the bipolar spectrum (Depue et al., 1981).
- Manic patients frequently create stressful life events.
- Stressful events often lead to sleep loss, which in turn can precipitate mania.
- Stress can lead to increased alcohol and drug use, both of which can result in sleep loss and/or mania.

Recently, Kendler and colleagues (2000) conducted a large twin study involving 2,395 individuals with unipolar depression, interviewed four times over a period of 9 years, and found that stressful life events were increasingly less associated with triggering a major depressive episode over time. This pattern held for the first nine episodes, then tapered off. Although this study investigated unipolar disorder, its findings on precipitation of episodes appear to be highly relevant to mood disorders in general. A major strength of this study is that it employed a twin research paradigm and therefore could control for the effects of the environment, as opposed to genetics, in a way that clinical studies cannot. Employing this paradigm and mathematical models that can be used to predict genetic versus environmental causation, the investigators were able to suggest that the relationship between life events and major depressive episodes was causal and not simply correlational. Similar findings have reported from non-twin studies of recurrent unipolar depression (Brown et al., 1994; Hammen et al., 2000; Bockting et al., 2006.)

The older literature on an association between life events and relapse is supported by a study of 62 patients with bipolar disorder (Hunt et al., 1992), in which a more frequent rate of severe life events (19 percent) was found in the month before relapse, compared with the background monthly rate of such events (5 percent), during the 2-year

follow-up period. In another study, recovery from mood episodes in 67 hospitalized patients with bipolar-I disorder was delayed three-fold in the presence of a precipitating negative life event (Johnson and Miller, 1997).

Because external life events have been established as associated with mood episodes, recent research has focused on other aspects of the psychosocial circumstances of individuals with bipolar disorder. For instance, Staner and colleagues (1997) reported that, among 27 patients with bipolar disorder in remission for 1 year, social support, self-esteem, and attributional styles were not associated with increased risk of subsequent episodes of bipolar illness, but social maladjustment was.

Specific life events that deserve separate mention are pregnancy and childbirth. The earlier literature suggested a significant risk of postpartum (puerperal) depression or mania.⁴⁰ More recent data indicate a high risk of depression during pregnancy or the postpartum period in bipolar women (30 to 50 percent), as well as some risk of mood instability during pregnancy itself.^{41,42} The treatment implications of pregnancy and the postpartum period of treatment are discussed in Chapter 20.

Comorbidity of personality disorders may be another factor that interacts with psychosocial stressors in increasing the risk of relapse in bipolar disorder (see Chapter 10). In one study of 52 euthymic U.S. military veterans with bipolar disorder, 38 percent met DSM-III-R criteria for personality disorder, which, in an unadjusted analysis, was associated with lower employment status and increased substance abuse (Kay et al., 2002). In another study, 72 bipolar-I patients were assessed dimensionally for the presence of hyperthymic versus depressive temperaments. Adjusted for age, sex, and occupational level in a multiple-regression analysis, higher depressive temperament trait scores were associated with greater number of mood episodes, especially of depressive polarity, and more suicide attempts (Henry et al., 1999). The interaction between personality and psychosocial stressors is an important clinical and research topic for further evaluation.

Drugs and physical illness, unlike life events, are sometimes not recognized as significant precipitating factors for manic or depressive episodes, but they should be (Table 4-4). Both drugs and alcohol can, in their own right, precipitate manic episodes, and they also can impair both the quantity and quality of sleep, thereby increasing the probability of mania. The special situation of mania precipitated by antidepressant treatment is discussed in detail in Chapter 19; we review some of that literature here as it relates to precipitation of mood episodes.

In his cohort study, Angst (1981a) found no association between long-term administration of antidepressants and recurrence, although he did not report the raw data. Turvey

Note: This table is based on the definition of secondary mania provided by Krauthammer and Klerman (1978); the data have been updated by our own review and those of Lazare (1979), Yassa and colleagues (1988a), and Sultzer and Cummings (1989).

^aMania induced by antidepressants (tricyclic monoamine oxidase inhibitors [MAOIs] and selective serotonin reuptake inhibitors [SSRIs]) is thoroughly discussed in Chapter 20. Reports of antipsychotic-induced mania are discussed in Chapter 18.

^bThe impact of alcohol and illicit drug abuse on manic-depressive illness is detailed in Chapters 7 and 21.

^cUsed for treatment of acquired immunodeficiency syndrome (AIDS).

^dAntihypertensive medications.

^eA comprehensive review of secondary mania in association with central nervous system (CNS) pathology can be found in Chapter 17.

and colleagues (1999), analyzing the CDS data, reported that polyphasic as opposed to monophasic mood episodes were not associated with antidepressant use. Although polyphasic mood episodes were associated with poor outcome and initial depression was correlated with polyphasic mood episodes, antidepressant use could not be shown to be a factor in the poor outcome later observed. This study was a longer-term reanalysis of the same sample previously discussed (with similar findings) by Coryell and colleagues (1992). Because treatments were not randomized, one cannot know what influenced clinicians to use or not use antidepressants.

Other investigators, using other samples, have reported different results. As detailed earlier, Altshuler and colleagues (1995) found that about 25 percent of bipolar patients appeared to show an association between antidepressant use and rapid cycling. This figure was confirmed by Ghaemi and colleagues (2000), who reported that 24 percent of individuals treated in a university-affiliated health maintenance organization demonstrated such an association. Although

these latter reports are retrospective, rather than prospective like the CDS, the inability to replicate the findings of the CDS in other samples raises questions about the generalizability of the CDS sample.

Wehr and colleagues (1987a) proposed that sleep reduction may be the common denominator of several disparate events and stressors that reportedly precipitate mania. Indeed, this suggestion is well supported by our clinical experience. Sleep loss is common to reports of manic episodes following (1) various stressful events, such as bereavement (e.g., Krishnan et al., 1984); (2) the postpartum state; and (3) jet lag associated with flying across time zones. Selective serotonin reuptake inhibitor (SSRI) antidepressants are capable of destabilizing sleep patterns. Because of the importance of this issue, we outline in Chapter 19 specific approaches designed to minimize sleep loss in bipolar patients.

Another important potential trigger for mood episodes is the season of the year. Issues regarding light and seasonality were addressed extensively in the first edition and are

further discussed in Chapter 16 of this volume. In the context of course of illness, patients with bipolar and recurrent unipolar conditions often experience seasonal patterns. In one study published since the first edition of this text, 49 percent of 146 patients who met DSM-III-R criteria for seasonal affective disorder (Faedda et al., 1993) were diagnosable with bipolar disorder, mainly type I (30 percent of the total sample; 19 percent were type II), meaning that these patients tended to experience full manic episodes in spring or summer. While winter depression is often the focus in the diagnosis and treatment of seasonal affective disorder, the high likelihood of summer mania should also be noted.⁴³

LONG-TERM OUTCOME

The literature on long-term outcome in bipolar disorder can be quite confusing. We have already noted some problems that can contribute to this confusion, such as effects of treatment in studies done in the modern era, selection bias in studies from academic health centers, and lack of adjustment through appropriate statistical techniques (e.g., multivariate regression) for other potential predictors of outcome (such as socioeconomic status and antidepressant use). Another problem is multiple publications over time based on the same dataset, which can appear to readers to represent different datasets. For this reason, we have grouped studies of long-term outcome by their initial recruitment location, rather than by specific publications.

The literature from the 1970s and 1980s on long-term outcome in bipolar illness tended to find somewhat better outcomes than have more recent studies. For instance, in a report on a 35-year follow-up of the original 100 patients admitted for mania in the Iowa 500 study, Tsuang and colleagues (1979) found that when marital, residential, occupational, and psychiatric (symptomatic) status were combined, outcome was good in approximately 64 percent of patients, fair in 14 percent, and poor (i.e., chronic) in 22 percent. This study, while more than 25 years old, still encompasses the modern era in which pharmacological treatments were available.

Modern Prospective Cohort Studies

Since 1990, there have been reports on 11 prospective cohort studies of natural history in manic-depressive illness, all but one of which were limited to bipolar disorder (Table 4-5).⁴⁴ The two largest and most carefully examined are the CDS and McLean-Harvard first-episode cohorts, which are discussed at the end of this section. Two more recent cohorts are those of the Stanley Foundation Bipolar Network and STEP-BD. Longitudinal outcome data are beginning to become available from both of these studies.

The Zurich cohort consisted of 406 patients, 186 with unipolar depression and 220 with bipolar disorder, initially recruited on admission to a psychiatric hospital during 1959–1963 and then reinterviewed at 5-year intervals. In a follow-up period that lasted up to 20 years, Angst and colleagues (2005) reported that only 24 percent of the bipolar sample and only 30 percent of the unipolar sample had fully remitted (that is, had experienced no further episodes). Many patients, however, had experienced periods free of illness, comprising on average about 80 percent of the time; chronically ill outcomes were seen in only 16 percent of the bipolar and 13 percent of the unipolar sample. In a recent reanalysis involving a follow-up period of more than 40 years, only 16 percent of the total sample had fully recovered by age 68 (Global Assessment Scale score above 60, with no episodes in the past 5 years), and 52 percent still had recurrent episodes. A subgroup (16 percent) remained chronically ill, and 7.8 percent had committed suicide (Angst and Preisig, 1995).

The Chicago cohort consisted of 139 hospitalized patients, 73 with mania and 66 with unipolar depression, recruited from area hospitals in the late 1980s. Outcome was assessed with a scale that incorporated both symptomatic and functional assessments. In a follow-up period that lasted on average 1.7 years, 25 percent of unipolar and 19 percent of bipolar subjects had a good outcome, while 14 percent of unipolar versus 25 percent of bipolar subjects had a consistently poor outcome (Harrow et al., 1990). In a follow-up that extended up to 5 years (mean 4.5 years), outcomes looked somewhat better, with 41 percent of unipolar and bipolar subjects demonstrating a good outcome, versus 14 percent of unipolar and 22 percent of bipolar subjects having a consistently poor outcome (Goldberg et al., 1995).

The University of California-Los Angeles (UCLA) cohort consisted of 82 bipolar patients recruited to the university outpatient clinic from 1984 to 1990, followed for a minimum of 2 years (which led to the exclusion of 78 patients initially recruited) and then for up to 5 years (mean 4.3 years) (Gitlin et al., 1995). Among this sample, 37 percent had relapsed at 1-year follow-up and 73 percent at 5 years, with only 17 percent consistently euthymic. Most relapses (70 percent) involved multiple episodes.

The Cincinnati cohort consisted of two groups. The first comprised 134 hospitalized patients with DSM-III-R bipolar disorder recruited from their academic psychiatric units during 1992–1995. At 1-year follow-up (Keck et al., 1998), 48 percent had experienced syndromal recovery; 26 percent symptomatic recovery (full remission); and 24 percent functional recovery (defined as regaining premorbid occupational and residential status), which was associated with higher initial socioeconomic status and paralleled

TABLE 4–5. Prospective Cohort Natural-History Studies in Manic-Depressive Illness Since 1990

Study	Sample Size	Follow-up Period	Findings
Chicago cohort (Harrow et al., 1990; Goldberg et al., 1995)	139	Up to 4 years	22% poor overall outcome, 41% good overall outcome in bipolar subgroup
McLean/Harvard cohort I (Tohen et al., 1990)	75	Up to 4 years	Multiepisode cohort; 100% follow-up obtained. 28% poor functional outcome; only 28% episode-free
National Institute of Mental Health (NIMH) Collaborative Program on the Psychobiology of Depression-Clinical Studies cohort (Coryell et al., 1993, 1994, 1995; Akiskal et al., 1995, 1998; Judd et al., 1998; Turvey et al., 1999; Judd et al., 2002, 2003)	428	Up to 20 years	Mood symptoms presented in about one half of the follow-up period, primarily those associated with chronic subsyndromal depression
University of California-Los Angeles (UCLA) cohort (Gitlin et al., 1995)	82	Up to 5 years	Only 17% “consistently euthymic”
Cincinnati cohort I (Keck et al., 1998)	134	Up to 1 year	48% syndromal recovery; 28% symptomatic recovery; 24% functional recovery
Cincinnati cohort II (Strakowski et al., 1998)	50	Up to 1 year	First-episode mania cohort. 30% not improved; 30% with continued subsyndromal symptoms
McLean/Harvard cohort II (Tohen et al., 2000, 2003)	173	Up to 4 years	First-episode cohort; classic Kraepelinian features; almost complete syndromal recovery (98%), but less symptomatic (72%) and functional (43%) recovery
Stanley Foundation Bipolar Network cohort (Post et al., 2001, 2003; Suppes et al., 2001; Keck et al., 2003)	648	Up to 1 year	33% were substantially well, 67% mostly ill; 63% had a prospective rapid cycling course; cohort was depressed for 33% of the follow-up period and manic for 11%
Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) cohort (Kogan et al., 2004)	1000	Up to 5 years	Prospective data pending
Jorvi Bipolar Study cohort (Mantere et al., 2004)	191	N/A	A polyphasic episode was current in 51.3%, rapid cycling in 32.5%, and psychotic symptoms in 16.2%; mixed episodes occurred in 16.7% of bipolar-I and depressive mixed states in 25.7% of bipolar-II patients
Zurich cohort (Angst and Preisig, 1995)	406	Up to 40 years	Only 16% fully recovered; only 16% had chronic outcome

symptomatic recovery. Incidentally, only 47 percent of patients were fully adherent to treatment at follow-up, which is consistent with the literature reviewed in Chapter 21. A second Cincinnati cohort project, initiated in 1996, recruited bipolar patients hospitalized with their first manic

episode. The initial 50 subjects enrolled between 1996 and 1998 were characterized at about 6.8 months of follow-up (Strakowski et al., 2000). On average, the subjects remained in a full syndromal mood episode for about 30 percent of the follow-up period, spending an additional

30 percent of the time in subsyndromal mood states. Initial mood-incongruent psychosis predicted worse outcome than initial mood-congruent psychosis (after adjusting for some clinical factors with analysis of covariance).

The CDS and McLean-Harvard cohorts can be seen as complementary, because they represent different types of patients. Data on the CDS cohort were collected at five U.S. academic health centers. The cohort consisted of patients in their 30s and 40s initially, whose illness usually had begun a decade or more earlier with depression as its primary presenting feature (for which the patients had been treated primarily with antidepressants), and who tended to have comorbid diagnoses. This represents a “modern” manic-depressive illness cohort, with nonclassical features of illness. The McLean-Harvard cohort consisted completely of hospitalized bipolar patients, most of whom were psychotic and experiencing their first manic episode. Most were insured, of middle to high socioeconomic status, and with few psychiatric comorbidities. This cohort is close to a modern analogue of the classic patients of the pretreatment era, similar to those Kraepelin described from among psychotic patients hospitalized at the Munich asylum. As Grof and colleagues (1995) suggested, it could be that the natural history of the bipolar variant of classic Kraepelinian manic-depressive illness is quite different from that of the bipolar disorder identified in many cohorts today. At any rate, differences in findings among contemporary cohorts need to be assessed in light of the different samples they represent. Each cohort is discussed below in turn.⁴⁵

The CDS has produced the most published data in recent years on the course of manic-depressive illness. The sample in that study consisted of roughly one-third outpatients and two-thirds inpatients initially recruited during the years 1978–1981 at five U.S. academic health centers. This cohort has now been followed for up to 25 years, with a retention rate in follow-up of more than 80 percent. As of 2003, about 80 percent of this cohort was reportedly in continued treatment with pharmacotherapy (R. Keller, personal communication, 2003). At 5-year follow-up, more previous episodes predicted more relapses but also quicker recovery (recovery at 6 months was 55 percent for a first episode, 73 percent for one or two previous episodes, and 90 percent for more than three previous episodes). Psychosis predicted only 37 percent recovery at 6 months, versus 65 percent in nonpsychotic patients. At 5-year follow-up, all of the patients initially treated for pure mania had recovered, compared with 89 percent of those with pure depression and 83 percent of those with mixed states. Despite ongoing “high-intensity somatotherapy” in the majority of subjects (75 percent), early relapse rates were relatively high: at 6 months, 20 percent of patients with pure

mania had relapsed, compared with 33 percent of those with pure depression and 36 percent of those with mixed states. By 1 year, 48 percent of patients initially with pure mania had had a relapse, versus 57 percent of those with mixed states; at 5 years, these rates were up to 81 and 91 percent, respectively. Relapse rates among those initially treated for depression were similar to those among patients with mixed episodes (Keller and Boland, 1998). The question of antidepressant-induced worsening of the long-term course of bipolar illness also raises the possibility that these poor outcomes may have occurred in part because of (rather than despite) the high-intensity somatotherapy received by patients (although adherence to treatment was not reported).

Despite sustained syndromal recovery for 2 years, most of the sample of 148 bipolar and 240 unipolar patients experienced severe impairment of psychosocial functioning (Coryell et al., 1993). In the index episode, the co-occurrence of psychotic features with mixed states (depressive symptoms during acute mania) was associated with more long-term psychosis than was the co-occurrence of index psychotic features with pure mania (Coryell et al., 2001).

Other analyses of the CDS data were reviewed earlier in the discussion of kindling. More recent results from the CDS are presented later in the discussion of subsyndromal outcomes.

The McLean-Harvard First-Episode Mania Study consisted of two cohorts. The first (Tohen et al., 1990) included 75 bipolar patients who were recruited over a 1-year period (1983–1984) from the psychiatric units of McLean Hospital after admission for acute mania and followed for up to 4 years (100 percent of subjects were followed for the entire outcome period). This was primarily a multiple-episode cohort (68 percent). The second cohort (Tohen et al., 2000, 2003) started with bipolar patients in their first hospitalized episode; 173 such patients were recruited from 1989 to 1996 at the same hospital and followed for up to 4 years. The characteristics of this second cohort were as follows: 84.9 percent were Caucasian, with gender about equally distributed; 88.6 percent were psychotic; 75.3 percent were in a pure manic (not mixed) episode; only 18.7 percent had substance abuse comorbidity; and only 8.4 percent had another psychiatric comorbidity. As noted earlier, this second cohort can be viewed as representing close to the classic Kraepelinian description of what would now be referred to as the bipolar subgroup of manic-depressive illness.

In the first, multiple-episode cohort (Tohen et al., 1990), 28 percent were unable to work or study at 4-year follow-up, and 19 percent were unable to live independently. Only 28 percent were episode-free, and 28 percent had experienced three or more relapses, with a predominance of manic polarity. Poor occupational and residential status

was correlated with subsyndromal interepisode illness ($r=.42$ to $.46$). After Cox proportional hazard regression to predict time to relapse, adjusted for 13 risk factors, the statistically significant main predictors were, in order of magnitude, past alcoholism (hazard ratio [HR]= 3.9), index psychosis (HR= 2.2), and index depressive symptoms during the manic episode (HR= 2.0). A reanalysis assessing psychotic features found that mood-incongruent psychosis in particular predicted a quicker relapse (adjusted HR= 2.6) (Tohen et al., 1992).

In the second McLean-Harvard cohort (patients initially hospitalized for mania/mixed states), those with past substance abuse were less likely than nonabusers to be recovered at 2-year follow-up (86 versus 98.5 percent). Among patients with initial mixed episodes, only 33 percent were living independently at 2 years, compared with 82 percent of those who had been admitted for pure mania. Further, although almost all patients had recovered syndromally at 2 years (98 percent), fewer (72 percent) had achieved full remission, and only 43 percent had recovered functionally (defined as regaining premorbid occupational and residential status). New episodes had been experienced by 59 percent of patients—20 percent mania, 20 percent depression, and 19 percent polyphasic switches (Tohen et al., 2000, 2003). These data suggest that functional recovery lags behind episode recovery and, further, that complete symptomatic remission does not ensure functional recovery, even in a classic Kraepelinian group of patients with relatively good prognosis. Predictors of earlier syndromal recovery (using Cox regression to adjust for other clinical factors) were as follows: short initial hospitalization (HR= 1.99 ; 95 percent confidence interval [CI]= 1.36 to 2.93), female gender (HR= 1.72 ; 95 percent CI= 1.16 to 2.56), and fewer index depressive symptoms (HR= 1.65 ; 95 percent CI= 1.14 to 2.39). For functional recovery (using multiple logistic regression), predictors were older than age 30 at index episode (odds ratio [OR]= 3.28 ; 95 percent CI= 1.58 to 6.82) and shorter initial hospitalization (OR= 2.82 ; 95 percent CI= 1.36 to 5.88). Further analyses suggest that initial pure mania and mood-congruent psychosis predicted manic relapse, whereas initial mixed episode predicted depressive relapse. Further, there appeared to be more manic relapse among those with lower baseline occupational status and more depressive relapse among those with higher status.

In the Stanley Foundation Bipolar Network cohort ($N=258$) (Nolen et al., 2004), poor prognostic factors at 1 year of prospective follow-up (in an adjusted multivariate regression model) were comorbid substance abuse, more than 10 prior manic or depressive episodes, family history of substance abuse, past rapid-cycling course, and poor occupational functioning at study entry. In a German subgroup of

this cohort ($n=152$), predictors of poor outcome at 2.5 years of follow-up were bipolar-I disorder, comorbid Axis I disorders, and past rapid cycling (Dittmann et al., 2002).

In the first 1,000 subjects analyzed in the STEP-BD cohort, early age at onset (Perlis et al., 2004), past substance abuse (Weiss et al., 2005), and past comorbid attention-deficit disorder (Nierenberg et al., 2005) were associated with poor outcome (age-at-onset data only, based on an adjusted multivariate regression model).

Other Features of Long-Term Outcome

Another feature of long-term outcome that may be related to poor occupational functioning is cognitive impairment.⁴⁶ Findings of a number of studies indicate that cognitive impairment and neuroanatomical changes may be associated with the long-term effects of multiple mood episodes and/or duration of illness and/or treatment in both recurrent unipolar and bipolar patients (see Chapters 9 and 14). In one study using magnetic resonance imaging (MRI), lateral ventricles were larger in multiple-episode patients with bipolar disorder compared with 17 first-episode patients and 32 healthy subjects (Strakowski et al., 2002). In another study, duration of bipolar disorder ($N=43$) was associated with impaired performance on general memory tasks (Donaldson et al., 2003). In neither of these studies, however, was the potential impact of pharmacological treatment evaluated. Neuropsychological test abnormalities were confirmed in another study of 26 euthymic patients with recurrent unipolar or bipolar illness, with an association being found between degree of neuropsychological impairment and number of past hospitalized episodes (Tham et al., 1997). This finding was confirmed in another study of 25 euthymic patients with bipolar disorder compared with 22 age-matched normal controls (van Gorp et al., 1998).

It has been suggested that neuropsychological dysfunction may be a consequence of increased activity of the hypothalamic–pituitary–adrenal axis during mood episodes, which has been shown to lead to excitotoxic damage to sensitive brain regions, particularly the hippocampus (Lee et al., 2002). Hippocampal atrophy is more likely to occur in patients with greater numbers of mood episodes than in those with fewer mood episodes or in normal controls (Altshuler et al., 1991), and pilot data (detailed in Chapter 14) suggest that patients taking lithium, compared with similar patients not taking lithium, do not suffer such atrophy (Moore et al., 2000).

It should be noted that studies in this area focus primarily on symptomatic outcome, although some recent studies have begun to focus on functional outcome. As previously noted, these two kinds of outcome are correlated, but not completely. In other words, while episode recurrence and subsyndromal chronicity are, not surprisingly, both asso-

ciated with worse functional outcomes, about 40 percent of euthymic patients with minimal detectable symptoms still appear to be functionally impaired. Long-term state-independent cognitive impairment is one likely explanation for this asymptomatic functional impairment, but this link remains to be established.

Beyond functional recovery, moreover, the question of quality of life remains. Even if patients are working and living in normal circumstances, the quality of their work and level of satisfaction with life remain largely unexamined by standard functional outcome measures. In a study of 50 euthymic persons with bipolar disorder, Sierra and colleagues (2005) found that quality of life was lower than in normal controls, and Yatham and colleagues (2004) found that some aspects of quality of life may be worse in bipolar compared with unipolar depression. Findings of another study from Europe were more optimistic, noting some improvement in recent years in bipolar patients' reports of their quality of life as they learned more about the nature of their disorder and the need for treatment (Morselli et al., 2004). With regard to pharmacological treatment, our review of the quality-of-life literature revealed that, although mood-stabilizing treatments clearly improve symptomatic outcomes in the majority of patients with bipolar disorder, their effect on quality of life remains to be established (Revicki et al., 2005).

Finally, with regard to subsyndromal morbidity and interepisode symptoms, the most recent reanalysis of the CDS data (Judd et al., 2002) found chronic subsyndromal depression to be the main outcome of treated bipolar-I disorder. In a follow-up period ranging up to 20 years (mean 12.8 years; N=146), patients were symptomatic 47 percent of the time. During these symptomatic periods, patients were predominantly depressed (67 percent of symptomatic period, 32 percent of total follow-up period), rather than manic or hypomanic (19 and 9 percent, respectively) or in mixed states (13 and 6 percent, respectively). Depressive periods were almost three times more likely to be spent in subsyndromal states (25 percent of total period) than in major depressive states (9 percent of total follow-up period). In sum, these data reflect primarily subsyndromal or interepisode periods of chronicity. The fact that depressive rather than manic symptoms are responsible for the bulk of the morbidity and functional impairment associated with bipolar disorder has also been noted in a community survey using self-reports (Calabrese et al., 2004).

It should be noted that similar rates of subsyndromal chronicity were reported in the CDS cohort for patients with unipolar depression (N=431) (Judd, 1998). This cohort consisted of a first-episode group (28 percent; n=122), a recurrent-depression group (48 percent; n=205), and a "double-depression" group meeting criteria for recurrent

episodes and dysthymia (24 percent; n=104). In a follow-up of up to 20 years (mean 8.7 years), patients were symptomatic 59 percent of the time. During these symptomatic periods, depressive symptoms were again almost three times more likely to be associated with subsyndromal states (43 percent of total follow-up period) than with major depressive states (15 percent of total period).

As a result of these studies, Judd and colleagues (2002) and others (Kupka et al., 2005) have urged a shift in long-term studies to focus on chronicity and subsyndromal morbidity. One example of such work is a study that found subsyndromal depressive morbidity in bipolar disorder (N=25) to be associated with increased functional impairment (Altshuler et al., 2002).

It is also notable that subsyndromal manic morbidity was found to be most prominent in a 4-year follow up of children (N=86; mean age at baseline 10.8 years) (Geller et al., 2004). In this cohort, patients spent 57 percent of the follow-up time in manic or hypomanic states, versus 47 percent in depressive states and 37 percent in mixed states. (The total exceeds 100 percent because mixed states were included in all three categories.) These findings suggest that the chronic subsyndromal depressive course is a feature of adult bipolar disorder, whereas in children a more chronic manic/mixed course predominates (see Chapter 6).

A number of considerations arise in interpreting the results of outcome studies. The first is the extent to which these outcomes reflect natural history as opposed to being either attenuated or exacerbated by treatment effects. Most of the investigators cited earlier noted that their patients were treated primarily according to current standards, although information on specific treatments was not provided. When treatment effects were addressed, it was generally in the context of the assumption that continuing morbidity had to be occurring despite these effective treatments. Another possibility exists, however: that in some cases, treatment is only minimally beneficial or neutral, but capable of exacerbating the course of bipolar illness. As noted earlier and discussed in detail in Chapter 19, this possibility is especially salient for antidepressants, which may lead to subsyndromal cycling states that could in turn account for the outcomes described by Geller and colleagues (2004). The issue of how to treat subsyndromal chronic bipolar depression is a vexing problem for clinicians and an important unanswered question for researchers. If antidepressants are related to cycling, one option would be to decrease their use. On the other hand, if antidepressants were not being used, their possible benefits in some patients would be missed. The use of cognitive-behavioral and other psychotherapies would appear to be appropriate in this situation (see Chapter 22), although this approach has not been well studied. Other

behavioral interventions, such as enhancement of sleep hygiene, have also been suggested (Morris, 2002; see also Chapter 16).

MORTALITY

Suicide is a frequent outcome of manic-depressive illness; in bipolar patients, it occurs more frequently early in the course of the illness (see Chapter 8). Although suicide is the single most important factor contributing to increased mortality in manic-depressive patients,⁴⁷ other causes, such as the increased risk of cardiovascular disease, contribute as well. Indirect consequences of psychotic behavior during untreated episodes—including malnutrition, exposure, and exhaustion—all compromise general health and presumably contribute to a higher mortality rate. So, too, do smoking and alcohol and drug abuse. As reviewed in Chapters 14 and 15, some of the biological dysfunction noted in manic-depressive patients involves systems other than the brain. These dysfunctions could also contribute to higher-than-normal mortality rates.

Recent studies of mortality in bipolar disorder are listed in Table 4–6, along with the weighted mean standardized mortality ratio (SMR) from studies reviewed in the first edition of this text.⁴⁷ Early studies of mortality rates in manic-depressive illness, which did not separate bipolar from unipolar forms, claimed substantially increased mortality—up to six times the rate expected for the same age group in a normal population. More recent studies have found a less striking but still considerable increase in mortality, averaging approximately 2.3 times the expected rate in the general population. This difference in results probably reflects improvements in psychiatric care, particularly the availability of specific treatments for the depressive and manic phases. Thus in Derby's (1933) study, 22 percent of hospitalized manic patients died, and 40 percent of these deaths were from "exhaustion," whereas in the Iowa 500 follow-up, Tsuang and colleagues (1980) found a significant increase only in "circulatory" deaths and only among women. Corroborating the earlier Iowa findings in a follow-up of 1,593 affective patients, Black and colleagues (1987a) noted that non-suicide-related deaths were excessive only among those patients with a concurrent medical disorder.

The largest recent prospective study of mortality in bipolar disorder involved up to 38 years of follow-up of depressed hospitalized patients in Zurich. Angst and colleagues (1999) reported that, overall, these patients demonstrated increased mortality compared with the general population, with a 61 percent higher risk of death (SMR = 1.6). The greatest risk was associated with suicide (SMR = 18), but statistically significant risks were also associated

with cardiovascular disease (SMR = 1.6) and accidents (SMR = 1.9). Those with bipolar depression were somewhat less likely to commit suicide than those with unipolar depression (SMR = 12.3 versus 26.7) but somewhat more likely to die from cardiovascular disease (SMR = 1.8 versus 1.4). Treated patients had lower suicide risks than untreated persons with bipolar disorder (SMR = 6.4 versus 29.2), but confounding factors were not controlled statistically in this observational study. It is also noteworthy that since cardiovascular disease is much more common than suicide, the absolute amount of improvement in mortality associated with suicide was the result primarily of decreased cardiovascular-related mortality. In concluding this discussion of mortality it is important to note that, with adequate lithium treatment, the mortality associated with bipolar illness can be reduced to a level indistinguishable from that of the general population, an effect no doubt related, at least in part, to the antisuicide effect of lithium (Muller-Oerlinghausen et al., 1996; Tondo et al., 2001). This point is discussed in greater detail in Chapters 8 and 25.

BIPOLAR-II DISORDER

The course of bipolar-II disorder has not been as well studied as that of bipolar-I illness; moreover, one of the issues in research on bipolar-II disorder is the relative lack of reliability for this diagnosis (see Chapter 3). The CDS in particular, however, has begun to shed light on the course of this condition. In 5-year follow-up, while bipolar-II subjects were less likely than bipolar-I subjects to be hospitalized, no other clinical differences in outcome (cycle length, number of mood episodes, suicide attempts) were found (Coryell et al., 1989b). Depressive episodes and symptom severity did not differ between the two groups, nor did frequency or duration of hypomanic versus manic episodes (in the bipolar-I group). Differences in psychosocial outcome between the two groups also were not evident. Manic episodes, by definition, occurred exclusively in the bipolar-I group. In a follow-up period of up to 10 years, only 7.5 percent ($N=64$) of individuals with bipolar-II illness switched to type I. However, if one includes dropouts from follow-up in that study, which may reflect the disinclination of more severely ill patients to continue to participate in the biennial interviews, rates of switch from type II to type I approach 15 percent. In a follow-up of up to 20 years, the primary morbidity over time was chronic sub-syndromal depression, and the prominence of depression was even more pronounced than in the bipolar-I cohort (Judd et al., 2003). During the follow-up period (mean 13.4 years; $N=86$), patients were symptomatic 54 percent of the time. During these symptomatic periods, patients were predominantly depressed (93 percent of symptomatic period,

Study	Sample Size	Duration of Observation (Years)	Deceased (%)	Standard Mortality Ratio ^a	Suicide % of all Deaths	Cardiovascular Disease % of all Deaths	Comments
Angst et al., 2002	291 F 115 M	34–38	72.2 82.6	1.59 1.64	13.8 15.8	35.2 26.3	186 UP and 220 BP; BP patients had SMR for CVD = 1.84 vs. UP SMR for CVD = 1.36; treated BP patients had lower SMR for CVD than untreated (1.68 vs. 2.23)
Weighted mean pre-1990s ^b		2.28					

BP = bipolar; CVD = cardiovascular disease; Dx = diagnosis; UP = unipolar; SMR = standard mortality ratio; SZA = schizoaffective.

^aRatio of observed mortality to expected mortality based on a normal demographically matched comparison population.

^bBased on a total of 7,584 subjects from 11 pre-1990 studies in which excess mortality was determined.

50 percent of total follow-up period), and minimally hypomanic (2.4 and 1.3 percent, respectively) or mixed (4.3 and 2.3 percent, respectively). Depressive symptoms were almost three times more likely to be subsyndromal (37 percent of total follow-up period) compared with major depression (13 percent); again, then, these data reflect primarily subsyndromal or interepisode chronicity.

Vieta and colleagues (1997) reported that bipolar-II ($n=22$) compared with bipolar-I patients ($n=38$), had more past depressive episodes (5.6 versus 2.6), more hypomanic episodes (7.0 versus 3.2), and, of course, more total lifetime episodes (12.6 versus 6.3). Again, bipolar-I disorder was associated with more hospitalizations (3.0 versus 1.0).

The phenomenon of double-depression refers to the persistence of milder depressive states (dysthymia) following recovery from an episode of major depression (Keller et al., 1983). Klein and colleagues (1988) noted that, compared with other unipolar patients, those with double-depression had a higher incidence of hypomanic episodes during follow-up.

MECHANISMS OF RECURRENCE

Considering that recurrence is a major characteristic of manic-depressive illness, particularly in the bipolar form, it is surprising how little attention has been paid to its underlying mechanisms. None of the dominant neurotransmitter theories attempts to account for repeated episodes.

As noted earlier, the most widely cited explanation of the recurrent course of bipolar disorder is kindling, proposed by Post (1990) on the basis of experimental work on rodents (Weiss et al., 1990). The neurobiology of kindling is discussed extensively in Chapter 14, and earlier in this chapter we reviewed those aspects of the course of the illness that are relevant to evaluating this model. Those points bear repeating here.

Epileptic seizures are known to be generated by repeated subthreshold stimulation. The kindling model assumes that repeated stress and trauma can induce a similar progressive process in bipolar patients. Numerous studies have found fewer precipitants with increasing number of episodes in bipolar illness. Kindling may also be applicable in some cases to atypical DSM-IV bipolar disorder, with patients often reporting childhood traumas in retrospect. Unfortunately, none of the other predictions suggested by the kindling model appears to apply to classic bipolar disorder. For example, the kindling model would predict that patients treated later, after "a latency" and after more episodes, would have worse outcomes, but this hypothesis is not supported by the data (Baldessarini et al., 1999; Baethge et al., 2005). The kindling model would also predict that cycle length would shorten with more episodes,

but this is not a characteristic feature of later episodes of bipolar illness. Although regression analysis of cycles would create such an impression (Angst et al., 1970), progressive shortening is demonstrable only in a subgroup of patients, the MD type—patients who experience both major depressions and full manias (Angst, 1986c). Furthermore, 7 to 8 percent of patients actually show a gradual lengthening of cycle (Lat, 1973). Similarly, the kindling model might predict that patients fully stabilized after long-term lithium treatment would experience fewer episodes after gradual discontinuation than before the treatment, and this certainly is not the case.

Other proposed explanations of recurrence include those derived from biological rhythm models (see Chapter 16), especially catastrophe theory, based on a nonphysiological intersection of several endogenous rhythms. Other investigators have concluded that, in some cases, recurrent patterns of deterministic chaos may underlie the course of bipolar disorder (Bauer and Whybrow, 1988; Post et al., 1995).

CONCLUSIONS

The natural course and outcome of manic-depressive illness contribute to its definition and its differentiation from schizophrenia. For the clinician, understanding natural course can help answer a patient's questions about the most important estimate of all, the prognosis: Will it return, and when? Here we summarize the key points of this chapter that can help answer these questions.

Despite substantial methodological problems of both earlier and recent studies and limited data from prospective follow-up studies, the literature on the course and outcome of manic-depressive illness supports the following conclusions:

- The bipolar subtype has the earliest age at onset, followed by the more recurrent forms of unipolar depression, followed by the less recurrent forms. For the bipolar subgroup, the representative value varies with the definition of onset, ranging from the appearance of first symptoms (such as mood lability) before age 20 to the first hospitalization (in the 25–30 age range).
- Almost all bipolar patients experience relapse, given adequate observation time. Results of contemporary studies indicate higher relapse rates than those found in earlier studies; extended use of antidepressants may have contributed to this increase. Highly recurrent unipolar depression is a risk factor for developing bipolar illness.
- Cycle length does not change predictably with time, although it may shorten progressively in the initial stages of illness in a subgroup of individuals.

- An appreciable proportion of bipolar patients develop rapid cycling. Rapid cycling may represent one extreme of the bipolar spectrum rather than a completely autonomous group. The nosological status of rapid cycling remains unclear, however.
- The literature shows rather consistently that manic episodes are briefer than depressive or mixed episodes. The average episode duration remains stable throughout the illness.
- About 1–2% per year of unipolar patients experience a first manic or hypomanic episode, suggesting that over a long period of follow-up, a large minority of previously diagnosed unipolar patients will switch to diagnosable bipolar disorder. The pattern of initial depression followed later by mania is associated with poor long-term outcome. Antidepressants may have a role in hastening poor long-term outcome.
- Psychosocial and physical stresses continue to appear to be robust predictors of the timing of relapse, although these severe life events most likely interact with a patient's underlying vulnerability in a complex manner. Life events appear to be associated with relapse more in earlier than in later phases of bipolar illness.
- Long-term data suggest that up to one third of bipolar patients achieve complete remission, and a similar number achieve complete functional recovery. Although syndromal recovery is two or more times more frequent, fewer patients go on to recover premorbid levels of function. Chronic persistence of symptoms can be expected in about 20% of cases, and social incapacity in about 30%. Poor outcome in recent studies may be influenced by selection bias toward the inclusion of more severely ill patients in tertiary care centers. In the community setting, outcomes could be better than those cited here. Early age at onset, depression, mixed episodes, psychosis, substance abuse, medication noncompliance, and probably the long-term use of antidepressants are all associated with poor outcome. Mortality and suicide rates are increased in bipolar illness but can be substantially reduced by adequate lithium treatment.
- There are several interesting theories of the mechanisms of recurrence, including chronobiological explanations and kindling theory. Kindling may represent a subgroup effect, being relevant to a more severe or atypical subgroup of individuals with bipolar disorder.

NOTES

1. Behavioral, intellectual, and language tests were part of the standard examination battery administered by the Israeli Draft Board Registry. Anyone previously diagnosed with the aforementioned disorders by the time of the draft examinations or

- directly thereafter was excluded from the study. The experimental group was culled from those who developed the disorders at least 1 year after examination. To control for instability of diagnosis, the authors included only patients whose diagnosis after a 4-year follow-up was the same as the entry diagnosis.
2. Psychotic bipolar patients were excluded from this study because part of the cohort had been assessed using *International Classification of Diseases* (ICD)-9 criteria, before the bipolar definition had been broadened to include more psychotic features.
 3. van Os et al., 1995; Bromet et al., 1996; Vocisano et al., 1996; McClellan et al., 2003.
 4. While some of these data were taken from subanalyses of large epidemiological samples, most were gathered from clinical populations. We discuss age-at-onset results from epidemiological samples in Chapter 6. Although it is impossible to eliminate selection bias completely, we took care here to select only those patient samples that appeared to represent the general bipolar population.
 5. Reliability measures were based on age-at-onset assessments made by two independent physician raters. Reliability coefficients for first treatment and first hospitalization were 0.94 and 0.97, respectively.
 6. One must also consider the possible contributions of changes in maternal behavior (smoking and drinking during pregnancy), as well as changes in dietary factors, such as decreased intake of omega-3 fatty acids (since World War II) due to changes in infant formulas (see Chapter 5).
 7. It is likely that the lower age at onset seen in more recent birth cohorts results from a confluence of these multiple factors.
 8. Additional information about this survey was obtained from the study authors for the present review. Although subject to recall bias and not administered by a trained clinician, the survey used to determine age at onset did adhere to DSM-IV episodic criteria. Furthermore, to control for underreporting of later ages at onset, the authors did not include the youngest cohort of participants (born after 1959) in their analyses.
 9. For example, Mick and colleagues (2003) compared measures of cognitive and global functioning, comorbidity, and clinical features across three groups arbitrarily designated as childhood, adolescent, and adult onset. They found significantly more comorbid anxiety disorders in the child and adolescent groups compared with the adult group, but no difference among groups in cognitive or global functioning. However, there was a trend for more rapid cycling and mixed episodes in the earlier-onset group, although the sample size lacked the power to permit evaluation of statistical significance for some of these measures.
 10. Neurological abnormalities were descriptive and based on medical records. Among 14 patients in the elderly-onset mania group, 10 had neurological problems such as seizures, gait disturbance, recurrent cerebral contusions, and cerebral infarcts.
 11. Winokur and colleagues (1993) found no association between a family history of bipolar disorder and age at onset. Lish (1994) and colleagues, however, found a significant correlation between childhood/adolescent onset and a family history of the disorder. This finding was replicated by Engstrom and colleagues (2003). Johnson and colleagues (2000) reported that patients with a family history of bipolar disorder had a significantly lower age at onset than those with no such family history.

12. However, a recent study from this group did find that mixed episodes were more common in a bipolar group with an early age at first hospitalization (younger than 18) compared with those first hospitalized in their twenties (Patel et al., 2006).
13. Although this study included patients with adolescent onset (minimum age = 15), the authors confirmed the diagnosis at intake and at follow-up with clinician-administered Structured Clinical Interview for DSM (SCID) results and corroborating evidence from family reports, as well as school and medical records.
14. Here again, both early- and late-onset groups were adults at the time of assessment (mean age 33.6 and 60.2, respectively). Diagnosis was verified with DSM-IV criteria and corroborating medical records, as well as family interviews.
15. At the time of assessment, the sample included all adults (mean age 43.1) diagnosed with DSM-IV bipolar disorder. Age at onset was determined by clinician-administered questionnaire, medical records, and family interviews in some cases. Confirming other reports, Suppes and colleagues (2001) also found a highly significant relationship between incidence of childhood sexual abuse and early onset ($p \leq .001$), a possible triggering phenomenon discussed in Chapter 7.
16. As in most studies of this kind, Ernst and Goldberg ascertained age at onset retrospectively, in this instance using life charts.
17. Perris (1968) found 83 percent with four or more episodes and 43 percent with seven or more. In a 1978 paper, Angst (1978) updated a careful longitudinal study of 95 bipolar patients who at that time had been followed for an average of 26 years (standard deviation ± 11.9). The study included both retrospective and prospective phases, the latter involving direct patient and family contact at least every 5 years. Patients by and large did not receive prophylactic treatment, although most had individual episodes treated with medications. The number of episodes ranged from 2 to 54, with a median of 9; 84 percent had 5 or more episodes, 69 percent had 7 or more, and 42 percent had 11 or more. A naturalistic study of 51 bipolar patients who received unsystematic acute and prophylactic treatment showed that all but 2 of the patients had experienced 3 or more episodes, with a median of 15 (Roy-Byrne et al., 1985a). Although this finding is consistent with earlier data, it is important to remember that the patient groups are not comparable, because the research setting of the Roy-Byrne study tended to select treatment-resistant patients. In a chart review study of 236 bipolar patients from the prepharmacotherapy era (between 1920 and 1950), Winokur and Kadrmas (1989) found that, during a follow-up period averaging 2.4 years, 28 percent had 1 episode, 22 percent had 2, 14 percent had 3, 11 percent had 4, 4 percent had 5, 2 percent had 6, 0.8 percent had 7, 0.4 percent had 8, and 11 percent had 9 or more.
18. Angst's Dm group is roughly analogous to the bipolar-II subgroup in DSM-III-R, although hospitalization is not necessary for the diagnosis of either major depression or mania in DSM-III-R.
19. Today, given modern treatment, relatively few patients would actually meet this criterion (i.e., hospitalization).
20. In their 1979 review of the literature on the natural course of manic-depressive illness (both unipolar and bipolar, with the index episode usually a hospitalization), Zis and Goodwin (1979) divided studies that showed low rates of relapse from those that showed high rates. They found that those with low relapse rates were marred by methodological limitations, including short duration of observation, focus on episodes involving hospitalization, exclusion of episodes preceding index admission, inclusion of nonrecovered patients, combined episodes treated as single episodes, and high unipolar/bipolar patient ratio. For example, studies with low relapse rates tended to include only episodes requiring hospitalization, introducing a bias toward patients with longer and more severe episodes. Thus in Perris's 1968 study, only 40 percent of patients had had four or more episodes involving hospitalization, but when all episodes were included, more than 80 percent had had four or more. Obviously, excluding episodes preceding the index hospital admission also leads to underestimation. When, for instance, Bratfoss and Haug (1968) included preadmission episodes, the proportion of patients with single episodes dropped to 13 percent.
- As noted previously, early studies often found a high proportion of single-episode patients because they included in that single-episode count the many chronic patients who in fact had had multiple (but uncounted) episodes while hospitalized. Cutler and Post (1982a) traced the long-term course of illness in a group of bipolar patients who were chronically hospitalized in a state institution. Their detailed analysis indicated that each of these patients displayed a pattern similar to what Kraepelin had observed more than half a century earlier: multiple, discrete episodes embedded in a single long-term hospitalization. Estimates of relapse rates probably were lower than justified in the older studies, even when based on patients who were not chronically hospitalized. In those cases, combined episodes (e.g., a mania followed by a depression, perhaps interspersed with a brief well interval) may have been counted as a single episode. The presence of a continuously circular course (Koukopoulos et al., 1980) or rapid cycles (Dunner et al., 1976b) makes it more likely that multiple episodes will be counted as one.
21. It may also be that recurrence is related to other features of bipolar illness, such as age at onset and genetic risk. This interesting possibility has not been adequately explored since the time of a chart review conducted during the prepharmacology era (Winokur and Kadrmas, 1989), which suggested that certain clinical features may be associated with the illness's natural tendency to recur. Winokur and Kadrmas found that, compared with patients who had only one or two episodes during a follow-up period averaging 2.4 years, patients with a polyepisodic course (more than three episodes) were more likely to have had an early age at onset, a finding that replicates an earlier report by Okuma and Shimoyama (1972). Winokur and Kadrmas also found that a polyepisodic course was associated with a more insidious onset of the index episode and a greater frequency of bipolar illness in first-degree relatives. They speculated that this last finding could indicate that cyclicity more than polarity is genetically transmitted: the more total episodes, the greater the likelihood of manic episodes.
22. In 1938, Eliot Slater of the Maudsley Hospital in London published a paper ("On the Periodicity of Manic Depressive Insanity") (Slater, 1938a) in which he reexamined cases of patients who had been the source for Kraepelin's data regarding the shortening of cycle length. Unfortunately perhaps for later generations, Slater's paper, published in a German psychiatric

journal that was prominent before World War II, lapsed into obscurity in succeeding decades, especially in the non-German-speaking world. (This lack of attention in the Anglo-American setting is particularly ironic given that Slater was an Englishman.) In our review, we found the initial peer review and the most extensive discussion of "Slater's fallacy" in English in a 1996 paper by Haghigiat (1996), who also noted earlier citations in book chapters by Angst (1988). In 2000, Angst and Sellaro (2000) again referred to Slater's report in English, and we recently obtained an English translation of the original paper.

In that study, Slater reviewed 116 charts of patients diagnosed by Kraepelin in Munich with manic-depressive illness. Among the features he assessed, Slater highlighted his reexamination of Kraepelin's report of decreasing intervals of wellness with an increase in the number of episodes, which became a central feature of what would later be called the kindling model. Slater confirmed that the duration of mood episodes appeared to increase to a small degree over time. However, his key finding was that the apparent decrease in euthymic intervals between episodes was a statistical artifact. Slater pointed out that "people who have longer intervals between episodes will not fall ill as often as those in whom the intervals are shorter." In other words, if all patients are included in the analysis, some will experience only two episodes and others six, for example. It may be that those with six episodes have short periods of wellness between episodes, whereas those with two episodes experience long periods of wellness. If those two types of patients are added together, as was done by Kraepelin, there will appear to be a progressive decrease in euthymic intervals. The actual state of affairs will not necessarily be so. One would have to demonstrate that intervals of wellness shortened over time *in the same patients*, whether they had two episodes or six. In sum, interepisode intervals of wellness need to be corrected for the number of episodes. When Slater made this correction, Kraepelin's finding vanished (except to a small degree for earlier episodes). In a recent outcome study of first-episode manic patients at McLean Hospital, Baldessarini and colleagues (2000) found the same effect. Taken as a group, the sample appeared to demonstrate progressive shortening of intervals of wellness, but when the data were corrected for number of episodes, there was no apparent shortening of well intervals.

We would like to acknowledge and thank Dr. Ross Baldessarini for bringing this long-neglected paper to our attention. We would also like to acknowledge and thank our colleague, Dr. Godehard Oepen, for assistance in translating and interpreting Slater's study.

23. Bratfos, 1968; Bratfos and Haug, 1968; Angst et al., 1973; Roy-Byrne et al., 1985a; Goldberg, 1993; Goldberg and Harrow, 1994; Kessing, 1998; Kessing et al., 1998a; Cusin et al., 2000.
24. Another study found that number of episodes did not predict recurrence at 1-year prospective follow-up (Staner et al., 1997). Such short-term studies are less useful in refuting kindling hypotheses, however, because the kindling model is a long-term model. The studies of the groups led by Coryell and colleagues (2001) and Baldessarini and colleagues (1999) were longer-term (up to 10 years).
25. Kendler and Karkowski-Shuman (1997) also assessed this finding within individuals by stratifying their dataset by individual and assuming a separate hazard function for their Cox proportional hazards model for each person in the study.
26. In a study with the methodological limitation of including only hospitalized patients, there was no evidence of a difference in episode severity in individuals experiencing their first manic episode as opposed to one of multiple episodes (Keck et al., 1995). However, because all patients were hospitalized, differential severity may have been difficult to detect.
27. The sample was from the Mediterranean island of Sardinia.
28. Independent confirmation or refutation of the kindling model based on other lines of evidence may gradually develop. For instance, Huber and colleagues (2001) presented a mathematical nonlinear model of sensitization. This model has two components: a positive feedback loop (more episodes lead to more episodes) and a long time interval. The authors showed that this mathematical model can support autonomous disease progression as well as irregular rapid cycling as an end stage of disease, as predicted by the kindling hypothesis.
29. Swift, 1907; MacDonald, 1918; Pollock, 1931; Angst and Weis, 1967; Zis et al., 1979.
30. The 1989 study of Winokur and Kadrmas (1989), although limited by its chart review methodology, is nevertheless of interest because it is based on the prepharmacology era. The authors reported that patients with a polyepisodic course (more than three episodes per average follow-up of 2.4 years) were significantly more likely to have an early age at onset (before age 20) than those with one or two episodes.
31. Another question is whether episodes come in bursts or clusters, as originally described by Kraepelin in his studies of predominantly chronic patients with frequent relapses. As discussed in Chapter 20, this issue is important in assessing prophylactic treatment, and indeed in making treatment decisions. If episodes of manic-depressive illness characteristically occur in clusters, it may be difficult to interpret prophylactic trials in individual patients. The evidence on this issue is somewhat conflicting. Saran (1970) compared episode frequencies in six untreated bipolar patients for 2 years before and 3 years after an arbitrary point in time. Even in such a small number of patients, there was some suggestion of episode clustering. In a 2- to 20-year follow-up (mean 5.6 years) of patients admitted for manic episodes, Winokur (1975) found that 91 percent of first-episode patients had experienced another episode during follow-up, compared with only 53 percent of those with a history of previous episodes—a result interpreted as evidence of episode clustering. Angst and colleagues (1970) did not find different relapse rates before and after lithium treatment. It is also worth noting that there may be some methodological issues with extrapolating from such group findings to clustering in individual patients.
32. For example, Kupka and colleagues (2005) found more bipolar-I than bipolar-II patients among 539 outpatients in the Stanley Network.
33. In a study of 320 hospitalized patients with bipolar-I disorder, the polarity of the first episode was determined to be major depressive in 52 percent, mixed in 26 percent, and pure manic in 22 percent. Patients whose illness began with depression were more likely to develop a rapid-cycling course and experienced more suicide attempts but less psychosis than the other groups. The mixed group tended to be more

- chronic and made frequent suicide attempts but generally did not experience a rapid-cycling course (Perugi et al., 2000).
34. In this study, the incidence of false unipolar (pseudounipolar) depression was strikingly low (4.4 percent) and out of line with the rest of the psychiatric literature. This observation may suggest that studies based on hospitalization will overreport the incidence of manic as opposed to depressive episodes, because the latter lead less frequently to hospitalization than the former.
 35. Taschev, 1974; Angst, 1978; Koukopoulos et al., 1980; Roy-Byrne, 1985a; Coryell et al., 1989b.
 36. The literature is inconsistent in the relationships reported between predominantly manic or predominantly depressive episodes and age at onset or family history of affective disorder. Three studies (Mendlewicz et al., 1972a; Taylor and Abrams, 1973a; Stone, 1989) found a positive family history of affective disorder to be associated with an earlier age at onset, but this finding was not replicated by Winokur (1975). An association between earlier age at onset and a higher proportion of manic episodes in the course of illness was reported by Mendlewicz and colleagues (1972a) and by Angst (1978), but not by others (Taylor and Abrams, 1973a; Carlson et al., 1977; Roy-Byrne et al., 1985a).
 37. Other studies have tended to confirm the general observation of stability of polarity in the course of illness, but most have not addressed or corrected for age (Cassidy, Cassidy, Perugi, Woods). The one study (Perugi et al., 2000) with data on age at onset in the 20s found consistent polarity for manic and mixed episodes in the course of illness. Among those patients whose illness began with a depressive episode, however, future episodes were equally likely to be manic/mixed versus depressed.
 38. Winokur et al., 1969; Angst, 1978; Koukopoulos et al., 1980; Roy-Byrne and colleagues, 1985a.
 39. Sleep deprivation would appear to be a likely explanation for hurricane-induced manias; this recalls the earlier suggestion of Wehr and colleagues (1987a) that sleep loss is the final common pathway by which various stressors can trigger mania (Aronson and Shukla, 1987).
 40. Bratfoss and Haug, 1968; Reich and Winokur, 1970; Kendell et al., 1976, 1987; Kadrmaz, 1979.
 41. Viguera and Cohen, 1998; Viguera et al., 2002; Akdeniz et al., 2003.
 42. The occurrence of sexual abuse as a precipitant or predictor of mood episodes has also been studied. In one study, the rate of self-reported childhood sexual abuse was high in 142 persons with DSM-III-R bipolar disorder (18 percent of women and 4 percent of men) and was similar to the rates found in a unipolar comparison group of 191 persons (16 percent in women, 3 percent in men) (Hyun, 2000).
 43. An interesting suggestion has been made that part of the mechanism for seasonal instability in psychiatric conditions may be attributable not only to increased sunlight, but also to increased ambient light due to the cycles of the moon (Raison, 1998; also see Chapter 16).
 44. Here we are excluding lithium prophylaxis studies (O'Connell et al., 1991; Maj et al., 1995), which are discussed in Chapter 22. We are also excluding retrospective cohort studies, of which there have been a number, including a Cologne cohort (Marneros et al., 1990; Deister and Marneros, 1993), a Johns

Hopkins cohort (Stephens and McHugh, 1991), an Indian cohort (Khanna et al., 1992), a Danish cohort (Kessing, 1998, 1999), an Italian cohort (Cusin, 2000), and a Taiwanese cohort (Tsai, 2001).

The Cologne cohort consisted of 106 patients with DSM-III mood disorders, a subgroup of a total cohort of 402 patients (the rest with psychotic disorders). With a mean of 27.9 years of outcome data, 64 percent of the mood disorder sample was fully remitted (Marneros et al., 1990). Subclassification of bipolar and unipolar conditions was not performed. In multivariate analysis, male gender was a major predictor of poor functional outcome (Diester et al., 1993). Other apparent predictors were an "asthenic low self-confident" premorbid personality and a higher number of mood episodes.

The Johns Hopkins cohort, also mentioned in this chapter in the discussion of polarity, consisted of patients hospitalized between 1913 and 1940, and therefore represents a true pretreatment natural-history sample. The study group consisted of 914 patients with at least 5 years of medical record follow-up data. With a mean follow-up of 13.5 years, only 11 percent of the bipolar group ($n=297$) and 22 percent of the unipolar group ($n=945$) did not experience future mood episodes. About one third of the total sample had a chronic outcome, somewhat worse in the bipolar subgroup (43 percent), and 13 percent committed suicide.

The Indian cohort consisted of 95 patients with bipolar disorder hospitalized in an academic psychiatric hospital over a period of 3 months in 1989. Medical records were assessed for course of illness. The main findings were more manic than depressive episodes and worse outcomes in those with initial manic episodes (unadjusted for other clinical factors statistically). The sample was predominantly male (84 percent) and predominantly manic (83 percent of first episodes reported). Interestingly, not a single case of a rapid-cycling course or of polyphasic episodes was documented, a finding that one might speculate is related to lack of antidepressant exposure in a setting in which many patients remain untreated.

The Denmark cohort is described further in this chapter in the discussion of kindling.

The Italian cohort consisted of 244 patients with bipolar disorder with 14-year outcome data. The main finding was that an initial manic as opposed to depressive episode predicted a higher frequency of episodes in the outcome period.

- In the Taiwanese cohort, 101 patients with bipolar disorder were identified by hospital records and agreed to follow-up after 15 years. The main predictor of poor psychosocial outcome was medication nonadherence, which was observed in 33 percent of the sample.
45. Although the second McLean-Harvard cohort is a proxy for a first-episode study, it is notable that 24.7 percent had experienced previous nonhospitalized major depressive episodes. Therefore, this subgroup did not really consist of first-episode bipolar subjects.
 46. In Chapter 9, we review the evidence that some neurocognitive impairment may exist even prior to the onset of the illness.
 47. In a postmortem study of 122 bipolar patients, for example, Taschev (1974) found that 27 percent had died by suicide. Among manic patients from the Iowa 500 series, Winokur and Tsuang (1975b) found that 8.5 percent of the deaths were

suicides. Perris and d'Elia (1966) found that 11 percent of the deaths in their patients had resulted from suicide, exactly the same proportion as in Tsuang's (1978) 40-year follow-up. Reviewing the literature, Guze and Robins (1970) noted that about 15 percent of all deaths among patients with major affective disorders can be traced to suicide. See Chapter 9 for a more comprehensive review.

48. The large epidemiologic study on the association between depression and its treatment and cardiovascular disease (known as the SAD HEARTS study) was not included. While it provides an invaluable amount of information on the relationship between depression and heart disease, the study focused exclusively on unipolar patients, and the majority were nonrecurrent, having fewer than two episodes.

Seek the points of contact which may reveal the underlying law. Some things can be learned only by statistical comparison.

—Sir William Osler (in Thayer, 1920, p. 52)

Epidemiology, which has been called the basic science of public health, is the study of the distribution of disorders in human populations, the variation in rates that may provide clues to their cause, and the risk factors associated with their onset and course. Epidemiology focuses on populations rather than individuals. An observation that a disorder is considerably higher in one group than another can be used to identify an epidemic or determine protective factors. Studying the variation in rates by specific characteristics (risk factors) yields clues as to how altering those characteristics may interrupt the process that leads to a disorder. This information also provides a scientific basis for assessing the overall health status of a population and identifying who is or is not receiving treatment.

Epidemiologic methods are common to studies of all chronic noninfectious diseases, including psychiatric disorders. These methods fall into three categories (see the review by Rothman and Greenland, 1998): *descriptive* methods, used to study the rates of disorder in a population; *analytic* methods, used to explore variations among different groups in order to identify risk factors; and *experimental* methods, used to test the association between a risk factor and a disorder by controlling the risk factor to see whether a reduction in onset or reoccurrence results. In this chapter, we focus primarily on results of descriptive studies. We begin by reviewing the application of epidemiologic methods in studies of psychiatric disorders, and then examine the key methodological issues that arise in such studies. Next we summarize the methods and results of epidemiologic studies of manic-depressive illness, with an emphasis on the bipolar subgroup. (The term *manic-depressive illness* in the pre-*Diagnostic and Statistical Manual* [DSM]-III literature sometimes referred to patients

that would be called bipolar in today's nosology, while in other contexts, the term referred to all recurrent mood disorders.) The studies we review are of the bipolar subgroup and involve community surveys of adults and of children and adolescents, as well as studies conducted by the World Health Organization (WHO). Finally, we review what is known about correlates, or features associated with bipolar disorder.

APPLICATION OF EPIDEMIOLOGIC METHODS IN STUDIES OF PSYCHIATRIC DISORDERS

Population samples are utilized to understand the full magnitude of a disorder, as well as its spectrum, including mild and untreated forms. WHO's international projections of the disability associated with mood disorders in both developing and developed countries (discussed later in this chapter) have garnered the attention of mental health planners and have made international epidemiologic data on mood disorders the focus of considerable interest.¹ Yet epidemiologic methods utilizing large-scale studies of populations have been applied to psychiatric disorders relatively recently. The first large-scale epidemiologic studies of psychiatric disorders were reported in the 1980s. Since then, there has been a rapid increase in the number of such studies. Moreover, their quality has improved significantly.

Over the past decade, much more reliable data on the rates of psychiatric disorders have become available as concern regarding biases, inconsistencies, and inadequacies in the psychiatric epidemiology literature has led investigators to become increasingly more systematic and sophisticated in their methodologies. Yet although the newer epidemiologic data on bipolar disorder are the

product of considerable advances in methodology, they are not without difficulties:

- The findings almost always are based on structured interviews conducted by nonclinicians; studies comparing such data with diagnoses by experienced clinicians tend to show only modest correspondence.
- The relatively low prevalence of bipolar disorder requires large population samples for accurate estimates.
- There is an absence of community-based data on highly recurrent major depression, which falls within the spectrum of bipolar disorder (see Chapter 1).
- The boundary between normal mood and mild hypomania that may also be part of the spectrum, or an early sign of the illness, is ambiguous.
- Controversy exists about the nature of the disorder's clinical presentation in children and adolescents, which may complicate the ascertainment of true age at onset.
- One of the most important risk factors for bipolar disorder, family history, has not been included in epidemiologic surveys.

These problems do not in general apply to the same extent for major depression, which has a considerably higher prevalence than bipolar disorder and for which there is a more extensive body of research on first presentation in children and adolescents, although, as noted above, there is virtually no information on the more recurrent forms of depression in these age groups.

In the late 1970s, the National Institute of Mental Health (NIMH) sponsored the development of a diagnostic instrument, the Diagnostic Interview Schedule (DIS), suitable for use in large-scale epidemiologic studies of psychiatric disorders (Robins et al., 1981). In 1980, the Epidemiologic Catchment Area (ECA) study was initiated (Robins and Regier, 1991). This study included more than 18,000 adults aged 18 and older living in five U.S. communities (New Haven, Connecticut; Baltimore, Maryland; Piedmont County, North Carolina; St. Louis, Missouri; and Los Angeles, California). Using the DIS as the diagnostic instrument, lay interviewers generated DSM-III diagnoses (American Psychiatric Association [APA], 1980). The study was longitudinal, with a 1-year follow-up to determine incidence (i.e., first onset). Oversampling of African Americans, the elderly, Hispanic Americans, and the rural poor ensured that accurate rates of disorders and treatment needs among these groups could be ascertained.

The ECA demonstrated that the use of comparable and reliable methods allows rates of psychiatric illness to be compared across geographic regions. Over the course of the 1980s, comparable epidemiologic studies were undertaken in Edmonton, Canada (Orn et al., 1988); Puerto Rico (Canino et al., 1987); the former Republic of West Germany

(Wittchen et al., 1992); Florence, Italy (Faravelli et al., 1990); Paris, France (Lépine et al., 1989); Beirut, Lebanon (Karam, 1992); Christchurch, New Zealand (Wells et al., 1989); Taiwan (Hwu et al., 1989); and Korea (Lee et al., 1990a,b). A collaboration among the lead investigators—called the Cross-National Collaborative Group—was undertaken to conduct joint analyses (Weissman et al., 1996).

In the 1990s, the National Comorbidity Study (NCS) was initiated in the United States (Kessler et al., 1994). This study was unique in that it was a national probability sample, and it used a new diagnostic method, the Composite International Diagnostic Interview (CIDI) (WHO, 1990), which had the capacity to generate both *International Classification of Diseases* (ICD) (WHO, 1991) and DSM-III diagnoses (see Chapter 11). Thus, it was possible to use variable diagnostic criteria to make direct comparisons with cross-national studies.

The ECA, the Cross-National Collaborative Group, and the NCS, as well as other epidemiologic surveys in different parts of the world, demonstrated that the majority of psychiatric illnesses had their onset in childhood and adolescence.² The pressing need for a direct epidemiologic study of children became apparent, but such studies of children present even more methodological problems than those of adults. Many questions arise: Should the diagnostic criteria used with adults also be used with children (a question discussed below under methodological issues)? Who is the best informant? Should parents, children, or both be interviewed? What risk factors should be included? What is the youngest age at which psychiatric disorders can be meaningfully assessed? These questions have not yet been fully resolved. Nonetheless, the National Institute of Mental Health's (NIMH) Methods for the Epidemiology of Child and Adolescent Mental Disorder (MECA) study was initiated in the 1990s in New Haven, Connecticut; Westchester County, New York; Atlanta, Georgia; and Puerto Rico. Its purpose is to develop and test methods for a large national epidemiologic study (Lahey et al., 1996). Other studies of children are also under way, as described later.

Because of the relative lack of information on the epidemiology of childhood psychiatric disorders, NIMH has begun to capitalize on ongoing national physical health surveys of children by adding questions about mental health. These surveys include the National Health and Nutrition Examination Survey (U.S. Department of Health and Human Services [US DHHS], 1998) for children aged 8 to 18, the National Health Interview Survey (US DHHS, 1996) for those aged 4 to 17, and the National Household Survey on Drug Abuse (US DHHS, 1999) for those aged 12 to 17. The first two surveys are investigating the comorbidity of psychiatric with physical problems, and the third is examining comorbidity with drug abuse. The inclusion of

questions on mental health in ongoing national surveys of physical health among young people in the United States provides much-needed monitoring data on both psychiatric disorders in children and the relationship of these disorders to physical health. It is not clear whether bipolar disorder will be examined separately from other mood disorders.

By 1995, the availability of epidemiologic information from community surveys had made possible the first textbook on psychiatric epidemiology (Tsuang et al., 1995). At the close of the twentieth century, WHO, in collaboration with The World Bank and Harvard University (Murray et al., 1994), turned to developing methods for assessing the global burden of disease. Given changing disease patterns, including a decrease in communicable diseases, as well as increasing longevity, investigators sought measures other than the traditional mortality used in international projections. They found that four psychiatric disorders, including bipolar disorder, appeared among the top 10 disabling illnesses in both developed and developing countries. This information drew worldwide attention and laid the groundwork for the future generation of epidemiologic studies, which are global in scope.

METHODOLOGICAL ISSUES

The chapter on epidemiology in the first edition of this text focused on methodological problems because at the time there were more problems than data. Although these problems cannot be ignored in interpreting the growing body of data now emerging, we need not dwell on them because they have been addressed in many of the more recent studies. Therefore, this section reviews only those methodological issues that are particularly relevant to current understanding of the epidemiology of bipolar disorder.

Variable Diagnostic Criteria

During the past decade, methods for obtaining diagnostic data have improved significantly. Reliability across interviewers has improved, and many new approaches to diagnostic interviews are available. Yet despite these improvements, different diagnostic interview formats yield different rates of psychiatric disorders. Even when the same methods are used, comparing published rates across studies can be difficult because of differences in data presentation. Some investigators confine the data to cases that show an episodic pattern of mania and major depression (bipolar-I), whereas others include cases with a pattern of hypomania and major depression (bipolar-II). Still others combine bipolar-I and -II rates or include cyclothymia. For major depression, most investigators do not separate out the more recurrent forms (which are part of the manic-depressive spectrum) from the less recurrent forms, and some older studies reporting rates of manic-depressive illness do not separate the bipolar from the recurrent unipolar groups. The Cross-National Collaborative Group, mentioned earlier, was formed to address these differences in the reported data by standardizing methods for analysis and data presentation. The results of the group's efforts are presented in Table 5-1.

As detailed in Chapter 3, DSM-III, DSM-III-R, and DSM-IV improved specification of the diagnostic criteria for bipolar disorder; however, slight changes in the criteria over time have made comparisons of studies conducted even less than a decade apart problematic. In DSM-III, hypomania was classified as a disturbance similar to but not as severe as a manic episode, but no specific criteria were given (APA, 1980, p. 209) (see Chapter 3). Hypomania first appeared as a specific diagnostic entity in DSM-III-R, where it was defined as a distinct period of elevated mood but not severe enough to warrant the diagnosis of mania (APA, 1986, p. 218). In the 1990s, DSM-IV operationalized the criteria for hypomania,

TABLE 5-1. One-Year Disorder Prevalence (Percent Standard Error), Before and After Applying Clinical Significance Criteria

Disorder	Survey	Before CS	After CS
Unipolar major depression	Epidemiologic Catchment Area	4.9 (0.3)	4.0 (0.3)
	National Comorbidity Study	8.9 (0.6)	5.4 (0.5)
Bipolar-I disorder	Epidemiologic Catchment Area	0.9 (0.1)	0.5 (0.1)
	National Comorbidity Study	1.3 (0.2)	1.3 (0.2)

Note: Encompasses ages 18–54 years.

CS = clinical significance.

Source: Narrow et al., 2002.

requiring a persistently elevated, expansive, or irritable mood for at least 4 days (APA, 1994, p. 338); these criteria are consistent with those of ICD-10.

Even when diagnostic criteria are clear, mild forms of mania (such as hypomania) can fail to be detected. Most hypomanic episodes go undiagnosed even by psychiatrists, who when asking about episodes of depression may not elicit information about periods of unusual activity before and after an episode. As we emphasized in the first edition of this book, unless the patient and a family member are both carefully questioned about past hypomania, the bipolar nature of a depression may be missed (Simpson et al., 1993; Angst and Gamma, 2002). Indeed, hypomania is not well defined in research instruments. In community surveys, as the data presented later in this chapter suggest, it is exceedingly difficult to distinguish mild states of euphoria due to positive changes in a subject's life from the abnormal highs of hypomania; many patients initially diagnosed as having agitated depressions subsequently turn out to have had dysphoric hypomanias. In short, misdiagnosing and overlooking hypomanic states often leads to an underestimate of the true rate of bipolar disorder.³ (See Chapters 1 and 3 for a detailed discussion of these issues.) Higher incidence rates are obtained when a broader range of cases belonging to the presumed spectrum of bipolar disorder, such as cyclothymia or atypical bipolar illness, are included in the survey.

In the absence of a clear understanding of the pathophysiology involved, the distinctions among bipolar disorders, highly recurrent unipolar disorder, other mood disorders, and psychotic disorders remain unclear (see Chapters 1 and 3). These distinctions are especially difficult to make in community studies that include greater numbers of mild and untreated cases. At the psychotic end of the spectrum, a large number of patients have illnesses with features of both schizophrenia and bipolar disorder, termed schizoaffective disorder. The line between hypomania and mania is also difficult to draw, and DSM-IV offers differential diagnoses depending on the severity of symptoms and impairment. Patients with bipolar-II disorder are unlikely to present for treatment for hypomania, and even more unlikely to report it as pathology in community surveys (Akiskal, 1995, 1996; Coryell et al., 1995). Therefore, as shown later, the rates of bipolar-II are low in community surveys and are likely to be underestimated. (The reliability of diagnosis of bipolar-I and bipolar-II in community surveys is discussed further in the presentation of results of U.S. surveys.) Thus the distinction between bipolar-I and bipolar-II disorder is usually based on retrospective accounts, limiting reliability (Dunner and Tay, 1993). Moreover, applying criteria related to the clinical significance of a disorder based on impairment and the need for treatment

can markedly alter rates (Narrow et al., 2002) (see the later discussion).

Age-Specific Issues

The criteria for diagnosing bipolar disorder in children are even less clear than those used for adults (for example, see the discussion of problems in defining age at onset in children and adolescents later in this chapter and in Chapter 6). Indeed, since 1980 (DSM-III, DSM-III-R, and DSM-IV), adult criteria have been applied to diagnose mania and depression in children without taking into account differences in age and developmental stage (Sanchez et al., 1999). Bipolar disorder in young people may therefore be misdiagnosed or underdiagnosed. Moreover, although mania in youth can be a severe illness frequently associated with mixed features, psychosis, rapid cycling, and comorbid disruptive disorders, there is often a clinical bias against making a diagnosis of mania in children. And the relationship between bipolar disorder and other, more prevalent childhood psychiatric illnesses, such as attention-deficit hyperactivity disorder (ADHD), is problematic (see the later discussion of surveys of children and adolescents). Estimates of the age at onset of bipolar disorder must take into account this lack of clarity regarding first presentation of the disorder in youth. Eventually, longitudinal studies of children from families with a high risk of bipolar disorder may clarify issues of first presentation (see Chapter 6).

The effects of duration and severity on prevalence must also be considered when reviewing the literature on prevalence of childhood bipolar disorder (Sanchez et al., 1999). DSM-III-R removed the 7-day minimum duration criterion for mania required by DSM-III. Consequently, reports based on DSM-III-R criteria may overdiagnose mania, especially in childhood. In DSM-IV, the duration criterion was reinstated, and the severity requirement was added.

In April 2000, NIMH convened a group of experts for a Bipolar Child Roundtable to discuss possible approaches for addressing outstanding issues related to research on prepubertal bipolar disorder. The major issues of relevance to epidemiology addressed at the roundtable were the earliest age at which bipolar disorder can be diagnosed and the predictive value of the early manifestations of bipolar illness in children and adolescents. The experts generally agreed that a diagnosis of bipolar disorder using DSM criteria is possible in prepubertal children.

Discussion among the expert group resulted in agreement on two basic definitions: (1) a narrow phenotype that adheres strictly to bipolar-I and bipolar-II criteria, and (2) a broader phenotype that encompasses more heterogeneity—basically bipolar-not otherwise specified (NOS)—and includes children who do not quite meet the criteria (especially

the durational criterion) for an episode but still are severely impaired by symptoms of mood instability. Consensus on the former phenotype was that it can be diagnosed with available psychiatric assessment instruments, such as the semistructured Kiddie Schedule for Affective Disorders and Schizophrenia (KSADS) (Chambers et al., 1985). For clear communication, however, the importance of establishing thresholds for the boundaries between bipolar disorder subtypes (bipolar-I, bipolar-II, and cyclothymia) was emphasized because homogeneity is essential for biological, genetic, and epidemiologic research.

Currently, children with severely impairing mood disturbance who do not meet full DSM-IV criteria for bipolar-I or -II are not included in research studies and are difficult to assess in epidemiologic studies because of the perceived uncertainty of diagnosis. The expert group agreed that bipolar-NOS could be used as a working diagnosis to advance research on this broader phenotype, as long as the children were well described (with particular attention to symptoms of ADHD). Because available diagnostic instruments may not generate a reliable and replicable diagnosis of bipolar-NOS, it was recommended that careful assessment include all of the behaviors that are impairing, giving consideration when relevant to the frequency with which they occur, as well as their severity. Examples of the behaviors to be included are aggressiveness, agitation, explosiveness, irritability, mood lability (fluctuation independent of input), thought disorder (paranoia, misinterpretation of social cues), communication disorder (pragmatic language disorder that can look like flight of ideas, receptive and expressive language disorder that can interfere with the accurate performance and interpretation of structured interviews), and cognitive ability/cognitive impairment (significantly low intelligence quotient [IQ], reading disabilities).

Once agreement has been reached on exclusion criteria (certain comorbidities, such as pervasive developmental disorder and/or physical disease) as well as inclusion criteria for the broader phenotype, it should be possible to address questions about relationships among the disorders—for example, whether bipolar-NOS or its subtypes are precursors of bipolar-I and/or bipolar-II or have a different course. The expert group noted, for instance, that whereas the course of classic bipolar illness includes well periods, these children tend not to have such periods. Moreover, it should be possible to identify and fully characterize children who have bipolar symptoms and are severely impaired and to follow them prospectively, with attention to developmental stages and transitions, in order to resolve whether they have a childhood-onset variant of bipolar disorder (see Chapter 6 for a more complete discussion).

Validation studies also need to take developmental manifestations into account. The expert group suggested that studies could encompass children as young as 4 years of age. Reconstruction of the history of adults with early-onset bipolar illness may be useful as well. For example, in studies of the offspring of bipolar parents, which should include all of their children, parents should be asked about their own age at onset. The group deemed it important also that children with possible bipolar disorder, as well as their parents, be interviewed with developmentally appropriate measures.

Information about instruments currently employed in NIMH-funded studies of childhood-onset bipolar disorder was assembled for use at the roundtable. The most commonly used diagnostic instrument is KSADS—in most cases, the Washington University (St. Louis) version (WASH-U-KSADS) or KSADS with the WASH-U-KSADS sections on mood disorders and rapid cycling added. Ancillary instruments being used include the Child Behavior Checklist (CBCL) (Achenbach, 1991a,b).

Efforts that might be undertaken to resolve the diagnostic issues raised above include the following: describing the course of bipolar-I, bipolar-II, cyclothymia, and bipolar-NOS, with attention to the impact of development on changing patterns of symptoms; establishing the predictive validity of bipolar disorder in prepubertal children; defining thresholds for and boundaries between bipolar-I, bipolar-II, and cyclothymia in prepubertal children; and identifying occasions on which combining versus separating bipolar-I and -II would be appropriate (in treatment studies of mania, for example, where severity is an issue, combining manic with hypomanic patients may be inappropriate). Although future epidemiologic studies will need to incorporate the clinical findings of studies conducted to date, the unresolved issues of diagnosis in children described here make the accuracy of estimates of rates of childhood bipolar disorder and determinants of age at onset uncertain. See Chapter 6 for a comprehensive discussion of these issues.

Epidemiologic findings for the elderly are also ambiguous. In geriatric inpatient units, the prevalence of treated bipolar disorder has been described as reaching 10 percent (Yassa et al., 1988). Yet there is a disparity between the prevalence of bipolar disorder among elderly patients in hospitals and elderly individuals living in the community. Moreover, the rates of bipolar disorder are dramatically lower among community-dwelling elderly people than among younger persons (Shulman and Hermann, 1999). One reason for this is the increased early mortality from medical causes, such as cardiovascular disease and suicide among those with the disorder (Snowdon, 1991).

Diagnostic Methods

Over the years, we have seen the development of a number of structured interview instruments that have improved the precision with which psychiatric disorders can be identified and their rates estimated (see Chapters 3 and 11). Yet different diagnostic criteria or revised versions of the same criteria can affect rates and their comparisons. Thus differences among diagnostic instruments used in community studies may explain some of the variation in the rates obtained.

The DIS (Robins et al., 1981a), mentioned earlier, is a highly structured interview designed for large-scale epidemiologic studies. It generates DSM-IV diagnoses in computer algorithm form for the major psychiatric disorders. The CIDI (WHO, 1990; Wittchen et al., 1998a), also noted previously, consists of state-of-the-art structured diagnostic interviews based on the DIS and generates DSM-IV and ICD diagnoses. Trained lay interviewers administer both the DIS and the CIDI. The two instruments differ in that the DIS includes impairment criteria when generating diagnoses, whereas the CIDI does not. Moreover, after an initial round of questions about symptoms, the CIDI returns to reassess those symptoms, while the DIS asks about symptoms only once. A modification of the CIDI made by the University of Michigan Institute for Social Research (UM-CIDI) (Kessler, 1995) simplified that instrument's complex questions. Qualifiers such as "a lot" (as in the question, "Did the symptom interfere with your life and activities a lot?") were clarified (as in the question, "How much did the symptom interfere with your life or activities—a lot, some, a little, not at all?").

Another semistructured interview instrument is the Schedule for Affective Disorders and Schizophrenia (SADS) (Endicott and Spitzer, 1978), which is tied to the Research Diagnostic Criteria (RDC) (Spitzer et al., 1978) and the DSM. This instrument has been used less often than the DIS or the CIDI in community surveys because it must be administered by trained mental health professionals.

The Structured Psychopathological Interview and Rating of the Social Consequences of Psychiatric Disturbances for Epidemiology (SPIKE for the original German) (Angst et al., 1984) is yet another semistructured clinical interview. It allows the assessment of 29 separate syndromes, including hypomania, in terms of symptoms, their length, their frequency of occurrence, subjective suffering, social consequences, treatment, and family history, and generates DSM-III diagnoses.

The Structured Clinical Interview for DSM (SCID) is a semistructured clinical interview used for making a major Axis I DSM-III-R or DSM-IV diagnosis. Through a decision-tree approach, the SCID guides the clinician in

testing diagnostic hypotheses as the interview is conducted (see Chapter 11 for a discussion of issues involved in using decision trees). The output of the SCID is a record of the presence or absence of each of the disorders being considered for current episodes (past month) and for lifetime occurrence.

The Diagnostic Interview for Genetic Studies (DIGS) (Nurnberger et al., 1994) yields DSM-IV and RDC diagnoses and requires trained clinical interviewers. Questions on mania/hypomania in the mood disorder module are designed to assess current and most severe disorder, presence of psychotic features, impairment, organic factors, and treatment seeking. Mixed affective states and cycling are also assessed. The DIGS was designed for large-scale genetic studies and has not been used in community-based epidemiologic studies (see Chapter 13).

Finally, with few exceptions (Italy, Israel, Switzerland), the larger epidemiologic community surveys use trained nonclinical interviewers because it is costly and usually infeasible to send doctoral-level clinicians to conduct in-home interviews with thousands of subjects. Results of testing the congruence between findings obtained by non-clinical and clinical interviewers are described later in the presentation of the ECA findings.

Nonresponse or Refusal to Participate in the Survey

Another bias in community surveys that may affect the rates of bipolar disorder obtained is the failure of some subjects to participate, which may occur in the early phase of sample designation and again at measurement and interviewing. Because one cannot assume that nonresponse is randomly distributed across the intended sample, it can be a major source of bias. Nonresponse bias that occurs during the process of selecting and contacting the sample includes sample mortality, sample loss, and missing data (Badawi et al., 1999); also significant is refusal to respond in the middle stages of data collection.

The predictors of nonresponse bias were investigated in a 15-year follow-up of individuals in a probability sample from the household population of the Baltimore, Maryland, ECA. Mania was found to be associated with increased mortality, some of which may be related to the high rates of suicide, alcohol and drug abuse, and cardiovascular disease among this population (Badawi et al., 1999).

In the NCS, a special effort was made to estimate the rate of disorders among people who initially refused to participate in the survey. The results indicated that these individuals had higher rates of mental disorders, including bipolar disorder, than those who agreed to participate. Such data might be used to adjust prevalence estimates.

Other Issues

Sample Size

The relatively short duration of many manic and depressive episodes and the presence of mixed states cause difficulties in assessment. Short episodes are counted in some studies but overlooked in others that use diagnostic instruments with long-duration criteria. Short episodes also are responsible for large differences in rates of point and annual prevalence. Gagrat and Spiro (1980) explained this difficulty and underscored the problems created by studying a phenomenon with a low baseline rate. As they noted, point prevalence studies for a short-duration disorder with a yearly prevalence of 0.7 percent would require the screening of very large numbers of people. Even allowing for a mean duration of manic episodes of 2 months (a mean duration of 2 months assumes that many of the manic episodes in the community are shortened by treatment), the point prevalence rate would be on the order of 0.2 percent if the annual prevalence in the population at large were 1.0 percent. This means it would be necessary to screen 1,000 people to find 2 active cases. Epidemiologic studies of several hundred thousand people at a time would be required to determine the point prevalence in the population at large. Moreover, it is questionable whether current epidemiologic research instruments would be reliable in such studies.

Except for demographic characteristics such as age and gender, the relatively low prevalence of bipolar disorder makes estimates of variations in rates by risk factor difficult even in reasonably sized epidemiologic surveys. For example, in a sample of 5,000, which would be considered a reasonably sized community survey, a lifetime prevalence of 2 percent for a disorder would yield at most 100 cases. Few epidemiologic studies have 5,000 subjects. When the population is segmented by age, gender, and race, moreover, the sample size in each group dwindles rapidly. Finally, as discussed later, time constraints prevent any one study from including all the relevant risk factors, and multiple instruments are required.

Incidence and Prevalence Rates

Population measures of disease frequency include incidence and prevalence rates, the latter divided by different points in time (period prevalence). *Incidence* is defined as the number of new cases of disease in a *population at risk* for that disease per unit time. Incidence rates are used to determine differences in risk factors and are always difficult to obtain because they require a longitudinal study to identify new cases. Determining the incidence of bipolar disorder is yet more difficult because of the problems of determining subtle changes in mood and of knowing

when a case of major depression converts to bipolar. The lack of clarity of presentation in children and the need for large samples, as discussed previously, can further compound the problem. Indeed, few of the epidemiologic studies published since the first edition of this text have provided incidence data. The 13-year follow-up of the Baltimore ECA (described later) excluded incidence data for bipolar disorder because of an insufficient sample size (Badawi et al., 1999). Likewise, a 40-year follow-up of the Stirling County study in Nova Scotia assessing the incidence of depression did not include bipolar disorder (Murphy et al., 2000).

Prevalence is defined as the number of existing cases of disease in a *total population* per period of time. Prevalence rates can help identify unmet need. The studies reviewed in this chapter provide data on period prevalence, usually annual and lifetime. The lifetime prevalence is the proportion of the population that has had a disease at some point during a lifetime (Kramer et al., 1980). It is the rate obtained in response to the question, "Have you ever had . . . ?" Lifetime prevalence as a measure has been criticized for numerous reasons, including problems of recall. However, it is still applied widely as one of the imperfect but useful tools available for counting cases.

Functional Impairment

The assessments used in recent epidemiologic studies require some evidence of functional impairment to determine the clinical significance of the case. Questions about impairment of major roles or treatment seeking are designed to elicit this information. Variations in these questions can seriously alter rates among studies, as revealed by the comparison of the rates in the ECA and the NCS, described later.

Age at Onset

Different methods may be used for computing the age at onset of bipolar disorder. One method is to use two measures of central tendency: the mean or average age at onset and the median, or the age that corresponds to the 50th percentile of the distribution. An advantage of using this method is that age at onset can be summarized as one estimate. The disadvantage is that both the mean and the median can be biased by extreme values at either the lower or higher end of the distribution of ages.

Another method for analyzing age at onset is to compute the incidence (or hazard) rate of bipolar disorder for each age of life. This is done by taking the number of new cases that appear at each age and dividing it by the population at risk for that age. The major advantage of this method is that trends in incidence rates can be compared across all ages, although the population at risk becomes

smaller as age increases, inflating the incidence rate for older ages.

COMMUNITY SURVEYS AMONG ADULTS

In this section we review the methods and results of two surveys conducted among adults in the United States in the late 1970s, the two major epidemiologic studies conducted during the 1980s and 1990s, and comparable cross-national studies conducted throughout the world since the 1980s. Recent epidemiologic studies conducted among children and adolescents are discussed in the next section. Studies were included if they used standardized diagnostic assessments and defined sampling methods. When raw data were available, we undertook data analysis. In some cases, we used published results, so there is no standard presentation across sites; for example, bipolar-I and -II were sometimes combined in published results, and sometimes only annual, not lifetime, prevalence rates were given. The data presented are primarily annual and lifetime prevalence rates and incidence rates, where available.

New Haven Survey

The first community survey to use standardized diagnostic assessments and criteria was the New Haven survey, which was conducted in 1975 using the SADS-Lifetime (SADS-L) diagnostic instrument, based on the RDC (Weissman and Myers, 1978). This survey, considered a pilot study because it was a follow-up of a cohort identified 10 years earlier, included only 511 adults. A lifetime rate of 0.6 percent for bipolar-I was reported. The addition of bipolar-II raised the rate to 1.2 percent. Bipolar disorder was represented equally in males and females. These findings are comparable to those of subsequent large-scale community surveys.

The Amish Study

The Amish study of Egeland and colleagues (1983) is unusual in its assessment of the prevalence of affective disorders in a population that is culturally and genetically homogeneous. This subculture, a highly conservative Protestant religious sect in Pennsylvania, offered an “unheralded opportunity to study multigenerational pedigrees with large sibships” (Egeland and Hostetter, 1983, p. 70). Variables that confounded past research are not present in this population; for example, alcohol and drug abuse are virtually nonexistent, and criminal acts and violence are rare. Other obstacles had to be overcome, however. In applying specific diagnostic criteria to this group, the RDC definitions for mania and depression needed to be considered within the context of Amish culture. For example, manic behaviors to the Amish include racing one's horse

and carriage too fast, buying or using machinery or worldly items, using the public telephone excessively, and planning vacations during the wrong season (Egeland et al., 1983).

The Old Order Amish, 12,500 people who live primarily in Lancaster County, Pennsylvania, keep extensive genealogical and medical records of ancestors going back 30 generations (Egeland and Hostetter, 1983). The Amish study, which spanned the 5-year period from 1976 to 1980, attempted to identify all individuals who were actively ill, thus yielding incidence and period prevalence rates. As the authors noted, the close interactions among the Amish prevented even mild cases of emotional disturbance from being overlooked. Once an active case had been identified, medical records were abstracted and sent to a psychiatric board, which made a consensus diagnosis based on the RDC. If medical records did not exist, patients were interviewed directly using the SADS-L.

Reliability estimates were made based on the agreement between board consensus and a separate psychiatrist's diagnosis (Hostetter et al., 1983). Kappa statistics for reliability generally were high and consistent for any major affective disorder, for unipolar depression, and for bipolar-I disorder (0.87, 0.95, and 0.86, respectively). Only with bipolar-II disorder was the kappa coefficient much lower (0.68), suggesting a possible misrepresentation of this diagnosis among the Amish and less reliability in the diagnostic category. Indeed, the problem of unreliability in estimates of bipolar-II in community samples was found in subsequent studies described later.

During the survey period, 112 cases of mental illness were reported, 80 percent of which were affective disorders (71 percent major affective disorders), involving 1 percent of the Amish population (Egeland and Hostetter, 1983). A further breakdown of these rates revealed that 34 percent of the psychiatric cases were either bipolar-I or bipolar-II disorder, and 37 percent were unipolar depression. The remaining 9 percent comprised minor depression and hypomania (8 and 1 percent, respectively). As the authors pointed out, both the rate of major affective disorders and the rate of mental illness in general appeared to be below the general population average.

The most interesting finding is the apparent equivalence in rates of bipolar and unipolar illness. Other studies have shown a lopsided ratio. Weissman and Klerman (1978) and many subsequent investigators have found an almost 4:1 unipolar:bipolar diagnosis ratio across the United States, and some studies have shown a 10:1 ratio. In an attempt to explain these discrepant findings, Egeland and Hostetter (1983) noted that their sample of bipolar patients would have been greatly reduced had not community reports of behaviors suggestive of a “high” led to early SADS-L interviewing. In fact, the Amish data may more

accurately reflect the actual bipolar:unipolar ratio. Recent clinical research indicates that many cases diagnosed as unipolar illness may be variants of bipolar disorder (see Chapters 1, 2, 13, and 19). Another explanation for the discrepancy is the finding of Egeland and colleagues (1983) that 79 percent of their bipolar-I patients had previously been diagnosed as schizophrenic. Cultural factors may be partly responsible for this incidence of misdiagnosis: earlier clinicians, unfamiliar with the customs of the Amish, may have viewed thought disorder, paranoia, and grandiosity as symptoms of schizophrenia rather than mania (Egeland and Hostetter, 1983; Egeland et al., 1983). Of particular note are grandiose symptoms with marked religious overtones, because religion is central to the Amish. If other manic symptoms are not noted or are overlooked (as is apparent in early medical records), these symptoms may easily be seen as schizophrenic. Likewise, it is probable that Amish individuals who are the most ill stay within the community, whereas the less ill may emigrate.

Among both bipolar and unipolar patients in the Amish study, gender was equally distributed. Although this finding is consistent with others for bipolar illness, the majority of subsequent studies have found a 2:1 female:male ratio for unipolar depression. The most obvious explanation for this discrepancy, according to Egeland and Hostetter (1983), is that alcoholism and sociopathy do not mask depression in Amish males as they do in males in the general population.

Although the findings of this study have been debated, they provide a view of major affective disorders relatively untainted by violence, alcohol and drug abuse, and other variables that might otherwise mask such a disorder's presence.

Epidemiologic Catchment Area Study

The ECA study, conducted during 1980–1984, was the first comprehensive epidemiologic study of mental illness in the United States. It was designed to obtain accurate and uniform epidemiologic data on mental disorders in the United States that would be comparable across sites, as well as to assess the adequacy of services to the mentally ill (Regier et al., 1984). The design required representative sampling of populations from both community and institutional settings at two different time points 1 year apart (waves 1 and 2). In wave 1, prevalence data were gathered for lifetime, annual, 6-month, 1-month, and 2-week periods. Wave 2 was a follow-up to ascertain rates of relapse and remission, as well as to determine incidence rates (Eaton et al., 1989).

More than 18,000 people were interviewed by lay interviewers, who used the DIS, together with criteria from the DSM-III, RDC, and Feighner diagnostic systems. (The

latter two sets of diagnostic criteria are now used infrequently.) Subjects were first asked whether they had ever experienced a symptom at any time during their lives and whether they had experienced impairment in life activities from that symptom. For each symptom, the interviewer ascertained whether alcohol, drugs, medication, or physical illness was the underlying cause. Subjects were then asked whether they had experienced the symptom during the last 2 weeks, the last month, the last 6 months, and the last year, and this information was used to generate a diagnosis for period prevalence. The DIS determined the severity of a disorder in addition to its presence and duration.

The DIS appears to have relatively high reliability for diagnosing major depression but considerably less reliability for manic episodes. In comparing the agreement between the DIS administered to the same subjects by a lay interviewer and a physician, the kappa statistic for major depression was found to be 0.50 and for mania 0.21 (Helzer et al., 1985). Some questions remain about the continued use of the DIS and interpretation of the data it yields (see, e.g., Anthony et al., 1985). The accuracy of lifetime recall has been questioned, as has the lack of comparability of diagnoses made by lay interviewers and by experienced clinicians, whose pattern recognition and access to family history are likely to produce a more accurate diagnosis. Robbins and colleagues (1982) compared 1-month prevalence rates of depression and mania at two ECA sites (St. Louis and Baltimore) based on diagnoses by lay interviewers and psychiatrists using the DIS. Although the rates were not significantly different in Baltimore, both disorders were diagnosed three times more often by psychiatrists than by lay interviewers in St. Louis. A recent study of 41,838 individuals in the Swedish Twin Registry underscores the considerable problem in interpreting findings obtained by lay interviewers (Soldani et al., 2005). Telephone screening for mania, when compared with actual hospitalization and other medical records, resulted in spuriously high false-positive rates for mania in particular and for bipolar disorder in general. The investigators concluded that instead of the reported rate of 1.6 percent, a more accurate estimate would be 0.9 percent. These discrepancies suggest that some caution should be applied in interpreting ECA data, although the study is methodologically superior overall to past attempts at estimating the prevalence and incidence of bipolar illness.

The lifetime and annual prevalence and annual incidence for bipolar-I disorder for the total noninstitutionalized ECA sample and each of the five sites are presented in Table 5–2. The total sample size was 18,571 respondents aged 18 and older, 59 percent of whom were female. The overall response rate was 76 percent. The lifetime

Note: Encompasses ages 18 years and older.

prevalence of bipolar-I disorder was 0.8/100, ranging from 0.3/100 at Durham to 1.2/100 at New Haven. In general, the lifetime prevalence was the same for males and females, with slightly higher rates for males at Baltimore (M/F ratio = 1.4) and higher rates for females at Durham (M/F ratio = 0.2). The overall annual prevalence was 0.6/100, and the incidence was 0.4 per 100 cases per year. There was a tendency for females to have a higher incidence rate of bipolar-I than males, but this varied by site. The mean age at onset of bipolar-I disorder ranged from 14.6 years at St. Louis to 22.3 years at Baltimore (overall at the five sites, 18.6 years; overall median age, 18 years). (See the later discussion of the Cross-National

Collaborative Group for results and a discussion of rates for bipolar-II.)

The ECA also examined the use of mental health services by patients with bipolar disorder (Narrow et al., 1993; Regier et al., 1993). Overall, 61 percent of all individuals with bipolar disorder had been treated in the service sector within the past year—46 percent by specialty mental health providers and 29 percent by general medical providers. This was the highest rate of use of mental health services in the affective disorder group. It translates, on a population level, to approximately 1.1 million people with bipolar disorder making 16 million visits to outpatient mental health care facilities in the year before their wave 1 interview (Narrow et al., 1993).

One-third (33.4 percent) of bipolar patients receiving inpatient care did so at a general hospital facility, 19.5 percent at a private mental hospital, and 34.4 percent at a Veterans Affairs (VA) psychiatric hospital unit. The rest were treated at state and county facilities, community mental health centers, alcohol/drug units, or nursing home facilities.

National Comorbidity Survey

The NCS, administered by the staff of the Survey Research Center at the University of Michigan in Ann Arbor, was conducted between 1990 and 1992, or 10 years after the ECA. It was based on a probability sample of 8,098 individuals aged 15 to 54 from the noninstitutionalized populations of the 48 conterminous states; the response rate was 84 percent. Subjects were interviewed using the UM-CIDI, which made DSM-III-R diagnoses (Kessler et al., 1994). Unlike the ECA, which was based on five geographic sites, the NCS included a representative national sample from across the United States. Diagnoses known to have a low prevalence in population-based surveys (e.g., somatization disorder) or poor interrater reliability in the ECA (e.g., obsessive-compulsive disorder) were excluded. Respondents as young as age 15 were included because there was an interest in the comorbidity of substance abuse and other psychiatric disorders, and because the ECA had shown that the rates of psychiatric disorders were higher in younger than in older persons. Ten years after the NCS was completed, Kessler and colleagues (2005) conducted a replication (the NCS-R) of their initial study. Face-to-face diagnostic interviews were carried out on 9,282 English-speaking subjects by professional interviewers from the Institute for Social Research at the University of Michigan. DSM-IV diagnoses were generated based on the World Mental Health Survey initiative version of the CIDI (WMH-CIDI).

Table 5-3 shows the rates obtained for bipolar-I disorder in the NCS and NCS-R. Data on rates for bipolar-II were not reported in the NCS because of the unreliability of diagnosis of this disorder (see the later discussion); these rates were, however, ascertained in the replication study. The NCS and NCS-R rates shown in the table were adjusted for nonresponse and weighted to the sociodemographic characteristics of the target population from the 1989 U.S. National Interview Survey (US DHHS, 1992) and from the 2000 U.S. Census, respectively. In the NCS, the lifetime prevalence of bipolar-I disorder was 1.7 percent, with equal rates in males and females. The annual prevalence was 1.3 percent, also with equal rates by gender. The rates of bipolar-I were about twice as high in the NCS as in the ECA. The mean age at onset for bipolar-I disorder was 23.3 years (median 21 years). This onset age is about 3 years later than that found in the ECA.

The lifetime prevalence of bipolar-I disorder in the NCS-R was slightly lower, 1.0, than that reported in the NCS. The NCS-R found a lifetime prevalence of 1.1 in females and 0.8 in males. The annual prevalence for the total sample was 0.6. The mean age at onset for bipolar-I was 21.4 (median 19 years). For bipolar-II in the NCS-R, the lifetime prevalence was 1.1 (males, 0.9; females, 1.3); the annual prevalence was 0.8 (males, 0.7; females, 0.9); and the mean age at onset was 25.2 years (median 20 years).

There has been some debate about the reasons for the discrepancies in findings between the ECA and the NCS, and several attempts have been made to understand how differences between the two instruments (Table 5-4) might explain these discrepancies (Kessler et al., 1997; Regier et al., 1998; Narrow et al., 2002). The most obvious difference is the sampling frame. The ECA encompassed five selected sites, compared with a probability sample of all 48 conterminous states in the NCS. The ECA included persons living in institutions (prisons, boarding houses, nursing homes, and hospitals), while the NCS did not. The age structure of the two samples was also different, as mentioned earlier. Even when comparable age groups (18 to 54 years) are considered, however, the lifetime rate of bipolar disorder in the NCS remains at 1.7.

The controversy over which results are closer to the actual prevalence has not been resolved. However, there is agreement that any differences in rates are not true differences, but likely due to differences in sampling and methods between the studies (see note 2 for details). Moreover, although the rates of bipolar disorder are disparate between the ECA and NCS, the actual range of rates is not that large, and the demographic risk factors (discussed later) do not vary greatly between the two studies.

Table 5-5 compares the rates of bipolar-I disorder by demographic characteristics using an identical age group (18 to 54 years) to see whether the patterns of variation are similar. There are no significant differences in the rates of bipolar-I disorder by gender, educational level, or rural/urban domicile in either the ECA or the NCS. There is no difference in the rates by family income in the ECA. In the NCS, however, there is an inverse relationship between the rates of bipolar disorder and family income: the lower the income, the higher the rates ($p=.04$). Persons who are separated or divorced have higher rates in both the ECA ($p=.02$) and the NCS ($p=.002$). The age at onset is 5 years younger in the ECA compared with the NCS ($p=.001$).

Cross-National Collaborative Group

The success of the ECA in the United States led to the conduct of similar studies using the DIS in various parts of the world. Data from some countries began to appear in the late 1980s. However, it was difficult to make cross-national

comparisons, even with studies using the same diagnostic assessment methods, because of variability in the data presentation. As noted earlier, the Cross-National Collaborative Group was formed in the 1990s to directly compare rates and risks for psychiatric disorders and to help overcome this problem of disparate presentation of data by standardizing analysis across sites. The hope was that real differences in rates by country, not due to differing analytic methods, might thereby emerge. Ten countries, including the United States, that had used Version III of the DIS and DSM-III formed the collaboration. Only 7 of these 10 provided data

on bipolar disorder; nonetheless, these 7 countries represent diverse geographic, political, and cultural areas in North America, the Caribbean, Europe, Asia, and the Pacific Rim. The investigators in each country translated the DIS; details on the translation and the methodology employed are included in the references for each study. In addition to the ECA, data were obtained from the following sources:

- The Edmonton Survey of Psychiatric Disorders (Orn et al., 1988) was conducted in the city of Edmonton, Alberta, Canada.

TABLE 5–4. Comparison of the Epidemiologic Catchment Area Study (ECA) and the National Comorbidity Survey (NCS)

Instrument	DIS	CIDI
Diagnosis	DSM-III	DSM-III-R
Interviewers	Lay	Lay

CIDI = Composite International Diagnostic Interview; DIS = Diagnostic Interview Schedule; DSM = *Diagnostic and Statistical Manual*.

- The Puerto Rico Study of Psychiatric Disorders (Canino et al., 1987) included persons living in households throughout Puerto Rico, in addition to household members temporarily away and those in institutions.
- The Munich Follow-up Study (Wittchen et al., 1992) was a 7-year follow-up investigation of a stratified random general population sample drawn from the former West Germany.
- The Taiwan Psychiatric Epidemiology Project (Hwu et al., 1989) sampled three population areas representing metropolitan Taipei and township and rural areas.
- The Korean Epidemiologic Study of Mental Disorders (Lee et al., 1990a,b) sampled persons in urban Seoul and in scattered rural regions across South Korea.
- The Christchurch Psychiatric Epidemiology Study (Wells et al., 1989) included adults living in Christchurch on the South Island of New Zealand.

Table 5–6 shows the target population and sample size, response rate, and gender and age distributions for each study that collected data on bipolar disorder. Statistical analyses of these data standardized the rates at each site to the age and gender distribution of the ECA. Because of different age distributions at each site, analysis was restricted to the 18- to 64-year age group (26 to 64 years in West Germany). The standardization was performed according to methods described by Breslow and Day (1987). Weighted prevalence rates yielded estimates that would be derived if each site had the same age and gender distribution as the ECA. The ECA, Edmonton, Puerto Rico, Munich, Taiwan,

Korea, and Christchurch surveys collected data on both bipolar-I and bipolar-II disorder, which are the basis for the rates presented here; the NCS data are shown for comparison purposes. Note that both the ECA and NCS rates presented in the following tables may vary slightly from the rates presented earlier in Tables 5–2 and 5–3 because of the differing age ranges included.

The lifetime prevalence for bipolar-I range from 0.3 percent in Taiwan to 1.7 percent in the United States (NCS) (Weissman et al., 1996) (Table 5–7). The rates are moderately consistent cross-nationally. The male/female ratio is almost equal for the United States and Taiwan. Men have slightly higher rates than women in the Edmonton, Puerto Rico, and New Zealand surveys, and much higher rates in the Korea survey. Mean age at onset is on average 6 years younger for bipolar-I than for major depression, ranging from 17 in Edmonton to 27 in Puerto Rico (median 18 to 25). The West German rates are not stable because of the small sample size. The data on mean age at onset for bipolar-I may represent underestimates, because some of those surveyed had not yet passed through the age of risk, and no one older than age 64 was included.

The lifetime rates for bipolar-II are lower than those for bipolar-I, a result that probably reflects the difficulty of distinguishing mild highs from normal mood fluctuations in a community sample, as discussed previously. The rates are relatively consistent across sites (range 0.1 to 0.9 percent). There is no consistent gender ratio, although the rate of bipolar-II disorder is more often higher among females than males, a result suggested by clinical studies (Leibenluft, 1996). These rates, too, are probably underestimates. The lower rates of bipolar-II compared with bipolar-I reflect the uncertainty associated with diagnosis of bipolar-II in a nonpatient sample—a conclusion discussed previously and also reached by Kessler and colleagues (1997) in their validity study of the NCS.

Table 5–8 shows the very high rates of suicide attempts among persons with versus those without bipolar-I disorder in the United States and five other countries in the 1980s and 1990s (see Chapters 8 and 25). These figures were adjusted for age and gender at each site. Regardless of the variation in rates of bipolar disorder across countries, the association with suicide attempts is consistent and strong: the difference in prevalence of suicide attempts among those with and without bipolar disorder (odds ratio) ranges from 5.5 to 25.7/100.

Table 5–9 shows the significant association between panic disorder and bipolar disorder (see Chapter 7). Although the actual numbers of persons with this comorbidity were quite small in Puerto Rico, Taiwan, Korea, and Christchurch, the association is statistically significant across all sites. The association between the two disorders

has also been noted in genetic studies showing an increased familial aggregation of panic disorder in probands with bipolar disorder (MacKinnon et al., 1998). The meaning of these results and whether they represent a specific genetic subtype are unclear (see Chapter 13).

Table 5–10 shows the significant association between substance abuse or dependence and bipolar disorder in all countries except Puerto Rico and New Zealand. These results suggest that cultural differences in substance abuse may explain some of the association (see Chapter 7).

Other International Studies

The data reported in the preceding section are from seven countries that used the DIS in their surveys and provided raw data for analyses. The NCS used the CIDI, not the DIS, but the raw data were available so that direct comparisons, with standardization for age and gender, could be made, thus reducing methodological differences as a source of variance in rates. Other well-designed epidemiologic studies have been conducted cross-nationally and published in the last decade; these studies have limitations for present purposes, however, in that they group all affective disorders together and do not present rates for bipolar disorder separately. Results of studies that do report on bipolar-I or bipolar-II disorder are presented sepa-

rately from the results of the Cross-National Collaborative Group study in Table 5–11, even if the former studies used the same diagnostic measures, as they employed somewhat different methods for either data collection or analysis that could explain differences in the results. Because the raw data were not available, standardization for age and gender differences could not be performed. Therefore, only published rates are presented. A uniform presentation across sites as shown in Tables 5–7 through 5–10 is not possible.

Iceland

The Icelandic study was drawn from a case register and represented a birth cohort born in 1931 and residing in Iceland on December 1, 1986; 2,396 persons met these criteria. Among 1,195 persons randomly selected, 862 interviews (79 percent) were completed. DSM-III diagnoses were derived from DIS interviews administered by trained lay interviewers. The lifetime prevalence rates for bipolar-I (0.2 percent) and bipolar-II (0.5 percent) were low, with equal gender ratios (Stefansson et al., 1991). The sample of bipolar subjects was too small to permit interpretation of associations with marital status. The lower rates obtained in this study could be explained by the age of the cohort (about 56) at the time of the interview.

^dWeighted to 1989 National Health Interview Survey.

Shantin (Hong Kong)

A large-scale community survey was conducted in Shantin using the DIS and DSM-III (Chen et al., 1993). A two-phase design yielded 7,229 respondents. A flagged sample was given the Self-Reporting Questionnaire (SRQ) as a screen and the full DIS. The DIS was administered only to respondents among an unflagged sample who were positive on one of the screens of the SRQ. With this design, the lifetime prevalence of bipolar disorder was very low, and similar for males (0.15 percent) and females (0.16 percent). These rates are slightly lower than those reported for the two Asian countries (Taiwan and Korea) in the Cross-National Collaborative Group study (see Table 5–7). Chen and colleagues (1993) suggested that the difference could be due to the location of their study; because Shantin was a new town attracting healthy workers, people with serious mental illnesses would not have relocated there.

Hungary

A national community study was conducted in Hungary to estimate the prevalence of affective disorders in the adult population aged 18 to 64, sampled from the registries of 15 general practitioners in five different geographic areas

(Szadoczky et al., 1998). In this study, 2,953 respondents were interviewed using the DIS. The lifetime prevalence for bipolar-I was 1.5/100, similar to the U.S. rate; for bipolar-II, the lifetime rate was 2.0/100. There were few differences in the rates by gender. The first symptoms were reported slightly earlier for females (at 17.9 years) than for males (at 22 years), and the highest risk for first onset of bipolar-I was at ages 15 to 19. Persons with bipolar disorder had a higher level of education, a higher rate of unemployment in males, and a higher rate of marital disruption or never being married compared with those without the disorder.

Florence, Italy

This study included a community sample of 1,000 people in Florence, Italy, drawn from the registries of general physicians (Faravelli et al., 1990). In contrast to the majority of the other epidemiological surveys, the interviews were carried out by qualified psychiatrists or third-year trainees. The annual prevalence for bipolar-I was 1.9/100 for females and 0.6/100 for males, for an overall prevalence of 1.3/100. These rates are again in the same range as the U.S. rates, except for higher rates in females. For bipolar-II disorder, the overall prevalence was 0.2/100. The high annual rates of bipolar disorder are similar to lifetime rates

^bEuphoric type.

reported in other studies, a result that may be attributable to having the interviews conducted by psychiatrists, who were better able to probe for symptoms of mania. Also, this study assessed only mood disorders; therefore, the results may include other disorders with mood disturbance. The low rate of bipolar-II disorder found in this study again suggests the difficulty of discriminating between mild mood disorders and normal mood in a community survey. This was also the only epidemiologic study to report rates of recurrent depression (annual prevalence 2.6 percent).

Israel

In an epidemiologic study of mental disorders among young adults in Israel, a 10-year birth cohort (1949–1958) was interviewed by psychiatrists using the Israeli version of SADS, based on RDC criteria. A two-stage screening process was used. Subjects scoring positive on the screen (about a fifth of the sample) received the full diagnostic interview by a psychiatrist. The screened positive sample included 2,741 Israeli-born offspring of Jewish immigrants. The 6-month prevalence was 0.7 percent for bipolar-I disorder and 0.9 percent for bipolar-II disorder. Annual or lifetime prevalence rates were not reported. The rates did not vary significantly by gender. The 6-month prevalence of *definite* bipolar-I disorder was higher among Israelis of European ethnicity (0.61) compared with Israelis of North African ethnicity (0.15, $p < .05$) (Levav et al., 1993). There were no significant differences by education.

Zurich, Switzerland

Subjects for the Zurich Cohort Study were drawn from the total population of the canton of Zurich. The sample was the result of a two-stage design that selected subjects at high risk for psychiatric disorders and applied random controls for 4,547 subjects at the ages of about 19 (males) and 20 (females). Reassessments were conducted when the subjects were about 22, 27, 29, and 34 years of age. Screening took place in 1978, the first and second interviews were conducted in 1979 and 1981, and the last (fifth) interview was conducted in 1993. Each interview covered the previous 12 months. Symptomatology was assessed using SPIKE (Angst et al., 1984), administered by trained clinical psychologists in the subjects' homes. SPIKE is a semistructured clinical interview, which, as noted earlier, allows the assessment of 29 separate syndromes, including hypomania, in terms of symptoms, their length, their frequency of occurrence, subjective suffering, social consequence, treatment, and family history.

The 1-year prevalence of bipolar-I disorder was 0.7 percent (Angst et al., 1984). The study identified brief hypomania (recurrent and sporadic), a condition characterized

by short episodes of 1 to 3 days' duration and high recurrence, as a new diagnostic group with a 1-year prevalence rate (cumulative) of 2.8 percent (see later discussion).

The lifetime prevalence of bipolar spectrum disorder, which included a full range of manic symptoms (see the later discussion of bipolar spectrum) was 5.5 percent (Angst, 1995). Overall, the study demonstrated the high prevalence rates of DSM-IV hypomania and brief hypomania among the general population and the clinical and social relevance of these diagnoses. Because this was a prospective study with five waves of interviews focusing on rates from the previous year, it may have been more successful than other studies at identifying fluctuating hypomanic episodes. There have been no other epidemiologic studies of comparable design.

Ireland

A prospective study in rural Ireland of 29,542 subjects from 39 electoral districts was initiated in 1995–2000 to assess all *first episodes* of bipolar disorder. The SCID-III-R (Spitzer et al., 1992) and DSM-III-R were used. As of 2002, the annual incidence of bipolar-I for women was 0.0006 and for men was 0.00037; the overall incidence was 0.0022.⁵

Nottingham, England

This study estimated the incidence rate of ICD manic psychosis in first referrals to general adult psychiatric clinics over the 2-year period 1992–1994. It differs from the others reviewed here in that it was not community based. Therefore, patients who did not present for treatment—most likely milder cases—were not included (Brewin et al., 1997). New patients were evaluated with the Schedule for Clinical Assessment in Neuropsychiatry (SCAN) (WHO, 1994) and the Schedule for Assessment of Negative Symptoms (SANS) (Andreasen, 1982). Using the 1991 Nottingham population census as the population at risk (denominator) and new referrals meeting the ICD criteria for manic psychosis as the case (numerator), the incidence rate was 0.005, with a slightly higher rate among females (Brewin et al., 1997).

Norway

A sample of 2,066 subjects aged 18 to 65, randomly selected from the Norwegian National Population Registry, was interviewed with the CIDI between 1994 and 1997 (Kringlen et al., 2001). The overall annual prevalence of bipolar disorder was 0.9 percent (0.8 percent for males and 1.0 percent for females). The overall lifetime prevalence for bipolar disorder was 1.6 percent, with little difference by gender (1.7 percent for males and 1.4 percent for females). These rates are close to those found in the NCS, which also used the CIDI.

The Netherlands

A prospective survey of 7,067 subjects aged 18 to 64 years from the Dutch general population was conducted at three points in time between 1996 and 1999, using the CIDI (de Graaf et al., 2002; Regeer et al., 2002). Summing of the responses at the three points yielded a lifetime prevalence for bipolar-I or bipolar-NOS of 2.4 percent. A clinical reappraisal, blind to the original diagnosis, was conducted by trained clinicians using the SCID. The results led to a reduction of the rate to 2.0 percent. The annual incidence was 0.3 and was higher in females than in males, but these rates are based on small numbers (Bijl et al., 2002).

São Paulo, Brazil

A community survey of a sample of 1,464 adults living in one catchment area of a large hospital complex in São Paulo was conducted using the CIDI (Andrade et al., 2002). The lifetime and annual rates of bipolar disorder were 1.0 and 0.5, respectively. The rates among men and women were similar. Data on the association with other demographic characteristics were not presented for bipolar disorder separately from other mood disorders.

Chile

The CIDI was administered to a stratified random sample of 2,978 individuals from four provinces representative of Chile's population aged 15 and above (Vicente et al., 2006). The lifetime and annual rates of manic disorder were 1.9 and 1.4, respectively. Lifetime rates were higher in women (2.2) than in men (1.5).

Bipolar Spectrum

The rates of bipolar disorder reported above may be underestimates because many subjects who have brief recurrent hypomanic episodes may not be captured in surveys (see Chapters 2 and 3). Moreover, there is controversy about what symptoms should be included in the full spectrum of bipolar disorder. Some epidemiologic data on the spectrum that include hypomanic episodes are now available.

The relatively low reported rates of hypomania noted in previous surveys may be due to the fact that hypomania is frequently unrecognized by subjects themselves as a pathological condition. However, there may be a wide bipolar spectrum in clinical samples (Angst, 1998). The bipolar spectrum includes mania, hypomania, recurrent brief hypomania, sporadic brief hypomania, and cyclothymia. Modern concepts of bipolar disorder are still developing and can include bipolar-I and -II, hypomania, cyclothymia, mania with depression, and depression with hypomania, as well as highly recurrent major depression.⁶ Six subtypes of bipolar disorder were described by Klerman (1981): (1)

mania, (2) hypomania, (3) hypomania or mania precipitated by drugs, (4) cyclothymic personality, (5) depression with a familial history of bipolar disorder, and (6) mania without depression. The concept of "soft" bipolar spectrum (Akiskal, 1996) includes Klerman's subtypes 3 through 6, as well as recurrent depression without spontaneous hypomania but with hyperthymic temperament (Angst, 1998). Epidemiologic studies have found lifetime prevalence rates for certain segments of the bipolar spectrum that range from 3.0 to 8.3 percent (Table 5-12). The further the spectrum is extended, however, the lower is the diagnostic reliability.

In this context, longitudinal epidemiologic studies of young adults to determine instances of subtle onset of symptoms could provide data for use in testing the hypothesis of a bipolar spectrum. However, almost all epidemiologic studies are cross-sectional. One attempt to study the spectrum was the longitudinal study of Angst (1998), discussed previously. In that study, the cumulative prevalence (based on four interviews over 12 years) for DSM-IV hypomania/mania was 5.5 percent. Brief (recurrent or sporadic) hypomania had a prevalence of 2.8 percent. Therefore, the inclusion of brief hypomania raised the Zurich rate for bipolar spectrum to 8.3 percent (Akiskal 2000). All of the subgroups in this study—those that met the DSM-IV criteria for hypomania and those with sporadic or brief recurrent hypomania—had similar symptom profiles and a family history of depression (Angst, 1998). Angst recommended that the bipolar spectrum be broadened to include brief hypomania in light of its high prevalence and clinical relevance.

The largest study of bipolar spectrum disorder included more than 85,000 adults in the United States and used the Mood Disorder Questionnaire (MDQ), a screening instrument of uncertain reliability. This study found a rate of bipolar spectrum of 3.7 percent. The relationship between data on bipolar spectrum obtained from a screening questionnaire and from a full diagnostic interview is unclear, however (Hirschfeld et al., 2001, 2003a,b; see Chapter 11).

The recent NCS-R found a lifetime prevalence of bipolar spectrum of 4.4 percent: 1.4 percent for bipolar-I, 1.6 percent for bipolar-II, and 1.4 percent for bipolar subthreshold (defined as those individuals who have euphoria or irritability plus two other symptoms for 4 days or longer with at least mild impairment and a history of major depression). Males were more likely to be diagnosed with subthreshold bipolar disorder than were females (1.7 and 1.0 percent, respectively) (Kessler et al., 2006).

Bipolar spectrum is an ambiguous classification and includes subtypes that are subtle and difficult to diagnose. There is general agreement, however, that bipolar disorder encompasses a broad spectrum and that clinically

significant cases within that spectrum are not captured in epidemiologic or even clinical studies.

COMMUNITY SURVEYS WITH CHILDREN AND ADOLESCENTS

As discussed earlier, the onset and clinical presentation of bipolar disorder in children and adolescents are less clear than in adults (see also Chapter 6). Moreover, there is considerable controversy about clinical presentation in children (Geller et al., 2002; Lewinsohn et al., 2003; Biederman et al., 2004). In particular, there is controversy as to whether hyperactive, inattentive children with emotional lability represent early presentations of mania or ADHD. Biederman (1995), Farone and colleagues (1997), Geller and colleagues (1998), and Wozniak and colleagues (1995) examined ADHD uncomplicated by any other psychiatric disorder in an effort to understand the possible symptomatology of childhood mania. Biederman and colleagues (1995) found that 96 percent of children referred with symptoms of mania fulfilled criteria for a diagnosis of ADHD; however, only 16 percent of the children referred with symptoms of ADHD met the criteria for mania. The diagnosis of bipolar disorder in pediatric populations is complicated by insufficient information on the clinical development of childhood symptomatology into adulthood; a clinical bias against a diagnosis of mania in childhood (Carlson, 1996), similar to the bias seen 20 years ago against the diagnosis of depression in children (Angold, 1988); and overlap of symptomatology between bipolar

disorder and other, more prevalent childhood psychiatric illnesses (ADHD and conduct disorder) (see Chapter 6).

Compared with the gender distribution in adulthood, reports of mania in childhood based on clinical and epidemiologic studies suggest that prepubertal onset of mania may be more frequent in boys than in girls (Varanka et al., 1988; Geller et al., 1998). The incidence of mania appears to increase after the onset of puberty, and the prevalence of mania during late adolescence is estimated to approximate that in adulthood.⁷

Table 5–13 presents the prevalence rates of bipolar disorder from community-based epidemiologic studies of adolescents. Only the MECA study included children; all of the other studies included only adolescent samples. The table demonstrates the paucity of data in this area. Note that the considerable variation in age ranges included in the different studies affects the rates derived and accounts for discrepancies shown in the table.

Results of both the NCS and the MECA study are on public-use tapes, making it possible to undertake the analyses presented here. The NCS, as described previously, included subjects aged 15 to 54. In that study, the lifetime rate for bipolar-I was 1.3/100 among 468 adolescents aged 15 to 17.

The MECA study was conducted among a population-based sample of children and adolescents (see Table 5–13). As noted, this is the only published epidemiologic study to include children; however, the sample was too small to be divided by age, and pubertal status was not obtained. Probability household samples of 1,285 youths aged 9 to 17 were selected at four sites (Atlanta, Georgia; New Haven,

BP=bipolar; BP-NOS=bipolar disorder—not otherwise specified; CIDI=Composite International Diagnostic Interview; DISC=Diagnostic Interview Schedule for Children; KSADS=Kiddie Schedule for Affective Disorders and Schizophrenia; LIFE=Longitudinal Interval Follow-up Evaluation; MECA=Methods for the Epidemiology of Child and Adolescent Mental Disorder; NCS=National Comorbidity Study; SCAN=Schedules for Clinical Assessment in Neuropsychiatry.

Connecticut; Westchester County, New York; and Puerto Rico). Lay interviewers administered a computer-assisted version of the NIMH Diagnostic Interview Schedule for Children (DISC) 2.3 and structured interviews to assess demographic variables, functional impairment, risk factors, service utilization, and barriers to service utilization (Lahey et al., 1996). Data were collected from both children and their parents. A clinician interviewer, again using DISC 2.3, reassessed 247 of these parent-child pairs 1 to 3 weeks later. The test-retest reliability of the interviews with the parents was generally good for most diagnoses but less satisfactory for the interviews with the children. The current (6-month) prevalence for mania was 1.2/100 and for hypomania was 0.6/100 (unpublished data). Annual rates were not available.

Gould and colleagues (1998) examined the relationships among suicidal ideation, suicide attempts, and mania in the MECA study. They found that 4.5 percent of youths having had suicidal ideation and 7.1 percent of those having made a suicide attempt had experienced manic symptoms, compared with 0.9 percent of those who had neither had suicidal ideation nor made an attempt. The comparison of these two groups was statistically significant. There were 16 children with mania—3 with suicidal ideation (18.7 percent), 3 who had made a suicide attempt (18.7 percent), and 10 who had neither had suicidal ideation nor

made an attempt (62.5 percent; $p < .005$ ideation versus none; $p < .001$ attempt versus none).

A community sample of 1,709 adolescents (aged 14 to 18 years) was randomly selected from nine senior high schools representative of urban and rural districts in western Oregon (Lewinsohn et al., 1995). The adolescents were interviewed initially between 1987 and 1989 using KSADS (with combined features of the epidemiologic and present state versions). Parents were not interviewed. At approximately 1 year, a follow-up interview (the Longitudinal Interval Follow-up Evaluation [LIFE]; Keller et al., 1987) and KSADS were administered to determine the presence of psychiatric disorders since the initial interview. The lifetime prevalence of bipolar disorder (primarily bipolar-II and cyclothymia) was approximately 1.0 percent. An additional 5.7 percent of the sample (termed “core positive subjects”) reported experiencing a distinct period of abnormally elevated, expansive, and/or irritable mood, although they never met the criteria for bipolar disorder per se. Both bipolar and “core positive” patients exhibited significant functional impairment and high rates of comorbidity (anxiety and disruptive behavior), suicide attempts, and use of mental health services. The prevalence, age at onset, phenomenology, and course of bipolar disorder in adolescents were similar for both males and females.

To examine the course of adolescent depression, a follow-up was conducted to compare the rates of mood and other mental disorders between ages 19 and 24 for adolescents with a history of depression and those with adolescent adjustment disorder with depressed mood, those with nonaffective disorders, and those with no disorder. The study participants were followed-up again when they reached age 24. The follow-up sample (739 subjects) had low rates of dysthymia and bipolar disorder (less than 1 percent). In accord with other results, a small percentage (0.9 percent) of children and adolescents with major depression had experienced manic/hypomanic episodes.⁸

The same community sample in Oregon was used to compare the incidence and prevalence of bipolar disorder among adolescents and young adults, to explore the stability and consequences of adolescent bipolar disorder in young adulthood, to determine the rate of transition from depression to bipolar disorder, and to evaluate the significance of subsyndromal bipolar disorder (SUB) (Lewinsohn et al., 1995). The results show a lifetime prevalence of bipolar disorder of approximately 1.0 percent during adolescence and 2.0 percent during young adulthood. Lifetime prevalence of SUB was approximately 5.0 percent. Fewer than 1.0 percent of adolescents with depression had converted to bipolar disorder by age 24 (Lewinsohn et al., 2000). The bipolar disorder and SUB subgroups both had elevated rates of antisocial and other personality disorder symptoms. Both showed significant impairment in psychosocial functioning and had made greater use of mental health services. In general, adolescents with bipolar disorder showed significant continuity across developmental periods and had adverse outcomes during young adulthood. Adolescent SUB was also associated with adverse outcomes in adulthood, but not with increased incidence of bipolar disorder, a finding that questions the validity of the SUB diagnoses.

A study conducted in Bavaria, Germany, among a sample of 3,021 adolescents and young adults aged 14 to 24 using the CIDI and DSM-IV revealed a lifetime prevalence of 1.4/100 for bipolar-I and 0.4/100 for bipolar-II (Wittchen et al., 1998a). The annual rates were 1.3/100 and 0.4/100, respectively. The version of the CIDI used in this study also included questions about disabilities and impairment, operationalized as the assessment of economic, social, and leisure impairment during the worst episode and 1 month before the interview. Among those youths with any bipolar disorder, 94 percent considered themselves very impaired.

A 5-year follow-up of 647 high school students aged 20 to 24 in Helsinki, Finland, found 1-month prevalence rates of 0.2 percent for bipolar-I, 0.5 percent for bipolar-II, and 0.2 percent for bipolar-NOS, with a total rate of bipolar disorder of 0.9 percent (Aalto-Setälä et al., 2001). Given

that these rates are monthly, they do not diverge greatly from the annual rates reported in Germany among a similar age group.

GLOBAL BURDEN OF DISEASE STUDIES

In recent decades the patterns of disease and mortality in developing countries have grown to resemble those of high-income countries, with a preponderance of burden resulting from chronic diseases. To quantify these changes the World Bank, in collaboration with WHO, undertook a systematic assessment of the global burden of disease (GBD) in 1990 (World Bank, 1993b; Murray et al., 1994; Murray and Lopez, 1996). The burden of disease was measured in disability-adjusted life years (DALYs), which are the sum of life years lost to premature mortality (YLL) and life years lost to disability (YLD). The 1990 GBD assessment confirmed a major epidemiological transition resulting from both decreasing birth rates and decreasing rates of death from communicable diseases. As the birth rate of a population drops, the number of adults increases relative to the number of children, and a greater proportion of health care resources is accordingly focused on adults. Then, as fatalities from acute diseases become increasingly preventable, and public health and medicine achieve growing success in controlling and stabilizing the effects of such chronic diseases as cancer, cardiovascular conditions, and AIDS, people live longer with the disabling effects of their illness. The disability from disease results in the inability to work or carry out daily activities of living.

A major assessment of the global burden of disease and risk factors, updated to 2001, has recently been published (Lopez et al., 2006). Self-inflicted injuries, overwhelmingly attributable to psychiatric illnesses—especially unipolar and bipolar disorders—are the sixth leading cause of death in adults 15–59 in low and middle-income countries and the second in high-income countries (Table 5–14). Unipolar depression ranks first in disability in both low and middle-income and high-income countries (Table 5–15).

Questions have been raised about the severity weights for mental disorders used in the GBD study and whether the weights for depression and substance abuse may have been overestimated (Andrews et al., 1998; Vos and Mathers, 2000). In a study from the Netherlands in which the burden of disease in 1994 in terms of DALYs was estimated by using data from Dutch vital statistics, registries, and surveys with Dutch disability weights, depression ranked eighth, accounting for 112,800 DALYs in that year. This figure represented 4.4 percent of the DALYs for all diseases, compared with a figure of 3.7 percent in established market economy populations from the GBD study (Melse et al., 2000).

In a study from Victoria, Australia, rates of bipolar disorder were estimated from published studies by applying the Dutch disability weights (Vos and Mathers, 2000). The DALYs rates for depression were 7.7 for females and 5.3 for males, and those for bipolar disorder were 1.3 for females and 1.4 for males. These rates were lower than those for the established market economies in the WHO study—for depression, 10.7 for females and 6.0 for males, and for bipolar disorder, 2.1 for females and 2.2 for males. The burden of major depression was found to be higher for females than for males, but that of bipolar disorder did not differ by gender (Vos and Mathers, 2000), as determined from the gender ratios in the tables presented earlier.

Psychiatric disorders are expected to represent a greater global share of the disability burden than cardiovascular disease by 2020 (Murray and Lopez, 2000). Indeed, the results of the World Bank Development Study and the Murray and Lopez report caught the attention of the administration of WHO and helped spur the initiation of the World Mental Health Study, 2000, which is described next.

World Mental Health Study, 2000

The beginning of a new generation of cross-national studies of mental disorders was marked by a study in 2000 by the WHO International Consortium of Psychiatric Epidemiology (ICPE), which encompassed countries and geographic areas not included in previous cross-national studies.⁹ The first prevalence rates, based on use of the CIDI to generate DSM-IV diagnoses, were from a sample of 29,644 persons participating in population surveys in North America (Canada and the United States [the NCS]), Latin America (Brazil and Mexico), and Europe (Germany, the Netherlands, and Turkey). Although the rates for bipolar disorder were not presented separately, the lifetime rates of any mood disorder (depression, dysthymia, and/or mania) are as follows: Turkey, 7.3 percent; Mexico, 9.2 percent; Canada, 10.2 percent; Brazil, 15.5 percent; Germany, 17.1 percent; the Netherlands, 18.9 percent; and the United States (the NCS), 19.4 percent. These, the first estimates from the consortium, show that mood disorders are highly prevalent throughout the world.

Additional surveys are to be conducted by the consortium in Mexico, Colombia, France, Italy, Belgium, the Ukraine, South Africa, Indonesia, China, and New Zealand and may include an adolescent sample. Data from the ICPE on individual mood disorders, including mania and disorder subtypes, are forthcoming (R.C. Kessler, Department of Health Care Policy, Harvard Medical School, personal communication, 2002). These data will encompass bipolar disorder and bipolar spectrum, as well as impairment, course, and current symptoms. Reappraisals of clinical data are also under way.

ASSOCIATED FEATURES

In this section, we summarize what is known about the correlates of bipolar disorder. These variables are often called “risk factors,” but to avoid possible causal implications, we use instead the term “associated features.” Some of this information has been presented earlier (e.g., in our review of cross-national studies or variation in rates by marital status or age), and some is discussed in detail in other chapters. Here we summarize that material, along with other information available from analytical epidemiologic studies. Analysis of data on associated features from community surveys is problematic except for such broad factors as age and gender because large samples are necessary for a disorder of relatively low prevalence. Therefore, few community-based epidemiologic studies of bipolar disorder are able to examine associated features beyond age, age at onset, and gender.

Temporal Variations

Gershon and colleagues (1987) observed birth cohort changes in mania among relatives of bipolar and schizoaffective patients. Using life table analysis, they found higher rates of bipolar disorder among those cohorts born after the 1940s, suggesting that the cumulative hazard for the disorder in a given age group is greater in those born after that decade. Gershon and colleagues (1987) concluded that cohorts with the highest rates of affective illness appear to have been born in the decades after World War II (these findings are the same for bipolar and major depressive disorders).

Somewhat similar findings were derived independently in the ECA (Lasch et al., 1990). Respondents were divided into eight birth cohorts, each spanning a 10-year interval. Actuarial life table analysis showed variations in the risk of mania by birth cohort, with the greatest risk seen among the post-1935 cohorts.

Various explanations have been proposed to account for these results (Klerman and Weissman, 1989). The temporal variations noted could be due to differential mortality

and institutionalization, which could have removed older persons and earlier birth cohorts from the source populations, while changes in diagnostic criteria and the inclusion of persons with milder forms of bipolar disorder could have increased the rates in cohorts born after 1935. The onset of the “antidepressant era” in the early 1960s and the subsequent 10-fold increase in the use of this class of drugs, beginning with the appearance of “second-generation” antidepressants in the 1990s, may well have played a significant role. Dietary changes (including lower (compared with breast milk) concentrations of omega-3 fatty acids in infant formulas, discussed later, and younger age at first alcohol or drug use) and increased smoking in women must also be considered. It may be noted that there is some consensus that higher rates of bipolar disorder in the 1990 NCS compared with the 1980 ECA are due to methodological differences, as discussed earlier, rather than to temporal variations. Recall, memory, and a general reporting bias may also have contributed to the observed temporal variations in mania—specifically, a decline in the memory of lifetime events among the elderly or a conscious effort not to report them.

Gender

Mood disorders as a group are consistently more prevalent among women than men, but the difference is due to the higher prevalence of unipolar major depression in women. When only subjects with bipolar disorder are considered, nearly equal gender ratios have been found across most but not all national and cross-national studies, as reported earlier. Variations in one direction or another are likely due to the instability of small samples.

Social Class

In the first edition of this text, we reviewed more than 30 early studies of the association between social class and manic-depressive illness published between 1913 and 1989. We discussed in detail the considerable methodological problems involved in virtually every one of the studies but were impressed, nonetheless, by the overall association between bipolar illness and one or more measures reflecting upper social class.¹⁰ The complexities are many, of course. We discuss in Chapter 12 the possible links among creativity, educational and occupational achievement, and certain behavioral, temperamental, cognitive, and behavioral characteristics associated with bipolar illness. Education and occupational achievement are, of course, associated with higher social class. It is also possible that characteristics associated with mild manic states, such as increased energy, risk-taking sexual drive, productivity, and social outgoingness, make some individuals more attractive and therefore, on occasion, more likely to marry into a higher social class.

More recent epidemiologic data show an equal distribution of the disorder among all social classes and educational levels. While bipolar illness in a small minority of patients may facilitate achievement and may aid the creative process (see Chapter 12), it is likely that most of the earlier association between bipolar disorder and higher social class had to do with diagnostic practices and inaccuracies in the concept. Upper- and middle-class people were more likely to be diagnosed as bipolar, whereas lower-class individuals, especially the urban poor, were (and still are) more likely to be diagnosed as schizophrenic (often mistakenly so) and consequently treated as such. Criteria for social class also varied widely across studies. Nonetheless, these investigations remain interesting for their span over many decades, their historical significance, and their great range across countries and cultures.

Most newer studies have failed to find a significantly lower than expected rate of bipolar disorder associated with indices of upper social class (educational status, occupation, economic status, or parental social class). In both the ECA and the NCS, lower educational level was not found to be associated with an increased risk of bipolar disorder. The NCS found an association between rates of bipolar illness and lower family income; it is unclear, however, whether the latter is a direct consequence of the illness or a trigger for its onset. Aboot and colleagues (2002) examined 90 patients with bipolar-I disorder from a publicly financed service in Dublin to assess the association of the disorder with social advantage. Although not a representative sample, when compared with other psychiatric patients, excluding those with schizophrenia, the bipolar patients had similar demographic and socioeconomic characteristics (including more frequent residential moves).

On the other hand, a sample of 130 patients meeting DSM-III-R criteria for bipolar disorder and depression were compared on their and their relatives' occupational levels (Verdoux and Bourgeois, 1995). Occupational level did not differ significantly between unipolar and bipolar probands, although higher levels predominated among bipolar probands' brothers and children. A comparison of entire groups including probands and all their relatives revealed a social advantage for the relatives of bipolar patients. These results are consistent with the downward-drift hypothesis of bipolar disorder, which suggests that if there is any social advantage among bipolar patients, it may be reflected in the higher social class of their relatives. The devastation of the illness may erase these advantages and result in the association between the disorder and lower income seen in the NCS or the increased rates among the homeless discussed later. Consistent with this hypothesis is a recent study (Tsuchiya et al., 2004) finding that higher

parental educational level and greater parental wealth were associated with an elevated risk for bipolar disorder, but that the patients themselves were more likely to be unemployed and less well educated. The authors concluded that socioeconomic status may deteriorate as a result of the negative consequences of the disease (as described in Chapter 4). It may also be that milder forms of the illness on occasion lead to high achievement, but that the illness expressed in offspring of successful individuals is of a more severe nature (see Chapter 13, in particular the discussion of the phenomenon of anticipation).

Race/Ethnicity and Cultural Differences

A number of studies have examined racial similarities and differences in the prevalence and incidence of bipolar illness. Many factors apart from the previously discussed sources of variance cloud the accurate determination of these rates, including inadequate sampling from different socioeconomic groups, cultural differences and consequent problems regarding presentation, the misdiagnosis of schizophrenia noted earlier, and possible racial insensitivity among early researchers. These factors must be accounted for in such analyses.

Lewis and Hubbard (1931), Faris and Dunham (1939), Helzer (1975), and Weissman and Myers (1978) found equal rates of diagnosis of bipolar illness among African Americans and Caucasians. Likewise, the ECA revealed no significant difference in the prevalence or incidence of bipolar disorder among races (Robins and Regier, 1991). The NCS, on the other hand, indicated that African Americans had significantly lower rates of mania than Caucasians (Kessler et al., 1994). There is also some evidence that African Caribbean and African individuals are less likely to have experienced a depressive episode before the onset of first mania, and more likely to have more severe psychotic symptoms during their first mania, relative to Caucasian Europeans (Kennedy et al., 2004). In the study of the Cross-National Collaborative Group, the rates among the two Asian samples (Taiwan and Korea) and the Hispanic sample (Puerto Rico) were compared with those among the primarily Caucasian samples from Edmonton, Canada; West Germany; and Christchurch, New Zealand. The Asian samples clearly showed the lowest rates of bipolar disorder, but these rates were still within the same general range as those of the other sites. Moreover, the Asian sites (Taiwan, Korea, Hong Kong) generally showed the lowest rates for all psychiatric disorders.

In general, the newer epidemiologic data are consistent with the results of earlier studies in indicating no strong association between race/ethnicity and bipolar illness, with the possible exception of the unexplained lower rates of

many psychiatric disorders in Asian countries. Too few Asians were included in the ECA and NCS to study the consistency of this finding among Asians living in the United States. Such data could aid in understanding whether low rates of bipolar disorder are intrinsic to Asian people or affected by environmental factors. Selective migration could also be at play in that families or persons with bipolar disorder may be more likely to emigrate. Future studies and the new worldwide epidemiologic study of the ICPE, described previously, may clarify this issue.

Marital Status

Epidemiologic studies investigating marital status among bipolar patients have revealed that the disorder is slightly more common among single and divorced persons. The ECA revealed that individuals who are separated or divorced are more likely to suffer from bipolar disorder as compared with married or never-married individuals (see Table 5-7). In a Hungarian national survey (Szadoczky et al., 1998), bipolar disorder was found to be more frequent among those who were separated and divorced. The rate among those never married was high as well. Early onset of the illness may contribute to the latter phenomenon, negatively influencing personality development and thus causing difficulties in establishing and maintaining interpersonal connections.

As Krauthammer and Klerman (1979) pointed out, marital status may change as a result of the disorder, rather than leading to its onset. On the other hand, it is plausible that being single or divorced constitutes a risk for bipolar illness in some populations; it is also plausible, indeed likely, that stressful marriages may precipitate affective episodes and, conversely, that supportive marriages may have a protective effect.

While persons with bipolar disorder are more likely than those in the general population to be single, divorced, or in a disrupted marriage, we know of no evidence to support a causal relationship between the disorder and marital status. The establishment of such a link is hampered by small sample sizes and a lack of clarity as to the direction of causality in studies addressing the question. Therefore, although it is likely that symptoms of untreated mania are disruptive to forming or sustaining intimate relationships, this hypothesis is not supported empirically. (See Chapter 10 for further discussion of the effect of bipolar disorder on interpersonal relationships.)

Urban/Rural Comparisons

No urban/rural differences in rates of bipolar disorder were found in the ECA or the NCS. In Taiwan, the lifetime prevalence was higher in metropolitan Taipei (1.6 percent) than in small towns (0.7 percent) and rural villages (1.0

percent) (Hwu et al., 1989). In Korea, the lifetime prevalence of mania was similar in metropolitan Seoul (0.4 percent) and in rural regions (0.4 percent) (Lee et al., 1990b). Urban/rural differences in prevalence rates of affective disorders, when they exist, may relate to the interplay among such factors as place of residence, migration patterns, socioeconomic status, diet, and environment, rather than just one variable.

The Homeless and the Institutionalized

Homelessness and mental illness among the homeless population have become a special interest of many mental health professionals. The homeless population itself is difficult to define, and ascertaining the prevalence of mental disorders within this community is even more problematic. In 1990, the lifetime and 5-year prevalence of all types of homelessness in the United States was estimated at 14.0 percent (26 million people) and 4.6 percent (8.5 million people), respectively. Lifetime "literal homelessness" (sleeping in shelters, abandoned buildings, bus and train stations, and the like) was 7.4 percent (13.5 million people). Among those who had ever been literally homeless, the 5-year (1985–1990) prevalence of self-reported homelessness was 3.1 percent (5.7 million people) (Link et al., 1994). More recent follow-up studies of the homeless, however, indicate that these figures overestimate the persistence of the problem and the number of homeless with psychiatric problems (Phelan and Link, 1999).

Among the mental disorders that exist within this population, schizophrenia, substance abuse, personality disorders, and affective disorders are the most prevalent (Arce and Vergare, 1984). Affective disorders make up 5 to 30 percent of mental disorders found among the homeless. The most comprehensive and standardized of the studies addressing this issue (Koegel et al., 1988) used the DIS to diagnose mental disorders among the mentally ill homeless in Los Angeles. Over the course of their lifetimes, these homeless individuals were 3.4 times more likely to have had any affective disorder, 17.7 times more likely to have had a manic episode, and 2.9 times more likely to have had a major depressive episode relative to people in the general population. Similarly, over a period of 6 months, the risk ratios for a mental disorder were many times greater among the homeless than in the general population (6.1, 37.5, and 5.0, respectively).

One must keep in mind when examining these data that these are prevalence rates within the mentally ill homeless population, and not within the general homeless population. Still, when these data are converted to rates within the general homeless population, the resulting proportions are higher than those among the general population. One

other note regarding prevalence rates within this population is that substance abuse can easily coexist with or mask other underlying mental disorders, especially affective disorders. Therefore, these already high rates of bipolar disorder may be underestimates.

A more recent study of 1,022 homeless men living in shelters or on the street in Munich, Germany, using the SCID, also revealed high rates of mood disorders (lifetime prevalence of 32.8 percent for any mood disorder and of 5.2 percent for bipolar disorder). The highest rate was found for substance abuse (79.6 percent), particularly alcohol dependence (72.7 percent) (Fichter et al., 2001). A lifetime rate of bipolar disorder (3.6 percent), based on the CIDI, was found among 838 homeless men and women in a study conducted in Paris in 1996 (Kovess and Lazarus, 1999). Comparable studies in other European countries did not report bipolar disorder separately from other mood disorders (Vázquez et al., 1997; Muñoz et al., 1998; Babidge et al., 2002).

Some studies have oversampled the incarcerated (Buhrich et al., 2000) and the institutionalized (Robins and Regier, 1991). These groups were found to have higher rates of bipolar disorder than the general population. For example, Blazer (1985) found a lifetime prevalence of 5.4 percent for those living in prisons and 9.7 percent for those living in nursing homes. Yet the studies showed that the inclusion of these populations added only a small fraction (1.0 percent) to the estimated percentage of the general population having a mental disorder. Therefore, their inclusion or exclusion has little effect on community rates.

Pregnancy and Menopause

Childbearing represents a special risk for the onset of bipolar-I disorder in women. As shown by both epidemiologic and clinical studies, the first onset of bipolar disorder is almost always in the childbearing years (Blehar et al., 1998). As noted in Chapter 20, almost one-half of bipolar-I women who had been pregnant reported having experienced severe emotional disturbances in relationship to childbearing, with almost one-third citing episodes during pregnancy. Nair and colleagues (2000) hypothesized that subsets of women with a history of repeated reproductive-related mood disorders may be especially vulnerable to mood disturbances during perimenopause and menopause. In their study, two-thirds of perimenopausal bipolar-I women reported frequent mood disturbances, and almost 20 percent of postmenopausal bipolar-I women had experienced severe emotional disturbances during the menopausal transition.

Smoking

Bipolar disorder is associated with increased risk of smoking. A case-control study carried out in Alava, Spain, in-

cluding patients with a DSM-III-R diagnosis of bipolar-I disorder found that smoking was more prevalent among bipolar patients than among the general population. Most patients had begun to smoke before the onset of bipolar disorder; thus vulnerability to bipolar illness (not the illness itself) may make subjects more likely to become smokers (Gonzalez-Pinto et al., 1998).

The NCS included questions on smoking. About 69 percent of respondents with bipolar-I were current smokers, and 82 percent had ever smoked. These rates were quite different from those among respondents without mental illness or with other psychiatric disorders (Lasser et al., 2000). For example, the 82 percent of bipolar respondents who had ever smoked is a significantly higher proportion than the 59 percent of subjects with major depression and the 72 percent of drug abusers who had ever done so. Analysis of the 2001–2002 National Epidemiologic Survey on Alcohol and Related Conditions found that nicotine dependence occurred in 40 percent of all cases (Grant et al., 2005). Moreover, studies that have addressed smoking in bipolar patients have noted their difficulty in quitting (Glassman, 1993).

Comorbid psychiatric and medical conditions are discussed in Chapter 7.

Omega-3 Fatty Acids

Essential fatty acids are crucial components of synaptic cell membranes (see Chapter 14). The essential long-chain polyunsaturated fatty acids, omega-3 and omega-6, cannot be formed in the human body, so dietary intake is their only source. Sources of omega-3 fatty acids include fish and seafood, particularly oily fish (cod, salmon, tuna, haddock, and scallops).

Hibbeln (1998) found that greater seafood consumption was related to lower lifetime prevalence rates of major depression across nine countries ($r=.84$, $p < .005$). Frequent fish consumption (at least twice a week) was revealed to be an independent factor for a reduced risk of depressive symptoms (odds ratio = 0.63) and suicidal thinking (odds ratio = 0.57) in a restricted geographic region within a single country. The use of omega-3 supplements in the treatment of depression and bipolar disorder is discussed in Chapters 19 and 20.

Relating data on fish consumption in a country to independently collected epidemiologic data on rates of a disorder requires many assumptions about the quality, time, and sample structure of both datasets and yields at best a rough estimate of correlations. However, the data are consistent with a growing body of literature. Tanskanen and colleagues (2001) reported lower rates of suicidal ideation among frequent consumers of lake fish in Finland and a decrease in suicide risk among daily fish consumers in

Japan followed over 17 years. Nonetheless, well-controlled studies in bipolar and unipolar patients are needed before definitive conclusions can be reached about the role of omega-3 fatty acids.

Family History

There is strong agreement that bipolar disorder is heritable. While family studies cannot determine heritability, one of the strongest predictors of first onset of bipolar illness is a family history of the disorder. Unfortunately, family history is excluded from epidemiologic studies, mainly because collecting accurate information on family history is time-consuming.

As detailed in Chapter 13, the morbid risk for bipolar disorder among first-degree relatives of bipolar probands is elevated substantially over the risk in the general population. Furthermore, adoption studies have shown that the monozygotic-to-dizygotic concordance ratio is higher for bipolar disorder than for unipolar depression, indicating greater genetic involvement in the former condition. A number of genetic linkage and association studies are under way to determine the genes involved.

CONCLUSIONS

In its calculations of rates of disability, WHO has ranked bipolar disorder among the top 10 disabling disorders in both developed and developing countries. It is not easy to summarize the results of epidemiologic studies of bipolar disorder from around the world, especially in light of a number of methodological problems. Nonetheless, it is possible to derive reasonable estimates of the prevalence and incidence of the disorder.

Findings of recent studies generally indicate an overall lifetime prevalence of bipolar-I disorder of about 1 percent. The range of rates is not great, even from diverse countries. In the United States, Europe, Scandinavia, the South Pacific, South America, and the United Kingdom, the lifetime prevalence of bipolar-I disorder ranges from 0.2 percent (Iceland) to 2.0 percent (the Netherlands and Hungary). Most rates are around 1 to 1.5 percent. The exceptions are Iceland (0.2 percent) and three Asian countries with lifetime rates of 0.015 to 0.3 percent. The reasons for the markedly low Asian rates, which are also low for a number of other mental disorders, are unclear. Studies of Asians living outside the continent are needed to determine whether these low rates are related to genetic differences, to living in Asian countries, or to ascertainment factors.

Studies that include a broad bipolar spectrum produce much higher lifetime prevalence rates of 3.0 to 8.3 percent. While there have been efforts to determine the rates of bipolar-II and milder forms of bipolar disorder

in community surveys, it is difficult to distinguish between normal moods and mild hypomania in nonpatient populations, making the validity of these findings questionable. Moreover, all of these rates for bipolar spectrum may be underestimates because they do not include patients with highly recurrent major depression, some of whom may fall within the bipolar spectrum (see Chapter 1).¹¹

Several features associated with bipolar disorder have been studied. Most studies with large sample sizes have not shown strong differences in rates of bipolar disorder by gender. Persons who are separated or divorced have higher rates of the disorder than their married counterparts. Differences by social class and racial group have been less well studied. Smoking is more prevalent among those with bipolar disorder than among the general population. And pregnancy and menopause represent vulnerable periods for women in the development of manic episodes.

A family history of bipolar disorder in first-degree relatives remains the strongest predictor of risk of onset of bipolar disorder. However, it is also a risk factor not usually included in epidemiologic surveys.

NOTES

1. Cowley and Wyatt, 1993; World Bank, 1993a,b; Murray and Lopez, 1996.
2. In the ECA and the NCS, the diagnostic interviews (the DIS and the UM-CIDI, respectively) contained questions designed to determine the clinical significance of each symptom involved in the disorder (Narrow et al., 2002). Questions in the two surveys were similar, and information was obtained as to whether the symptom was severe enough to require telling a doctor or any professional about it, to take medicine for it, and/or to interfere with usual activities. Symptoms failing to meet any of these criteria were not identified as clinically significant and did not count toward making the diagnosis. The ECA used this approach for most disorders. However, neither the ECA nor the NCS applied these criteria at the symptom level for major depression or bipolar disorder. In both cases, questions about clinical significance were asked only after all symptoms had been obtained and diagnostic criteria met. Applying clinical significance criteria at the symptom level and not at the end of the diagnostic stage reduced the overall rates of mental disorders in both surveys. The impact was greater in the NCS, and the disparity in rates between the ECA and the NCS was reduced, with an estimated 18.5 percent annual rate of any disorder.

Applying the clinical significance criteria in the ECA reduced the annual rate of unipolar depression by about 18 percent and that of bipolar disorder by 44 percent (see Table 5-1) (Narrow et al., 2002). The rate of unipolar major depression was reduced to 4.0 percent, compared with 4.9 percent without the clinical significance criteria. The clinical significance criteria had a greater effect on major depression prevalence rates in the NCS than on those in the ECA, drawing the

two rates closer together. The annual prevalence estimate for unipolar major depression in the NCS fell from 8.9 to 5.4 percent. The annual prevalence of bipolar-I disorder did not change in the NCS and remained at 1.3 percent, but dropped to 0.5 percent in the ECA. Thus, the gap between the ECA and NCS widened. There is controversy about the manipulation of rates based on treatment need (Narrow et al., 2002). Wakefield and Spitzer (2002) noted that basing disorders on stringent impairment criteria, which led to reduced rates in the NCS, helped resolve discrepancies between the 1980 and 1990 surveys. However, they suggested that these revised prevalence rates are not necessarily a valid redefinition of the disorders, but may reflect an inadequate measure of treatment need. Use of the impairment or treatment criteria, they noted, means that disorders that are real but do not interfere significantly with life are ignored.

Another way of examining diagnostic validity, used in the NCS, is through a clinical reappraisal of potential mania cases. Kessler and colleagues (1997) concluded that validity was satisfactory on bipolar-I, as judged by the reappraisal, only for cases of mania with elevated mood or increased activity, decreased need for sleep, and elevated self-esteem or grandiosity. Requiring these symptoms reduced the prevalence of mania to 0.3 percent. However, the authors cautioned that, because of a significant number of CIDI false-negative findings in the clinical reappraisals, these clinically confirmed CIDI cases may underestimate by half the actual rate of mania in the community. If this statement holds true, the extrapolated estimate of 0.6 percent for bipolar-I disorder is closer to the ECA rate. The authors were unable to document an algorithm with acceptable concordance with clinical diagnosis for bipolar-II, and they concluded that bipolar-II prevalence was not valid in their sample.

Another analysis of factors that may have contributed to the differences between ECA and NCS rates was conducted by Regier and colleagues (1998). Their analysis produced rates of psychiatric disorder from each survey by controlling for demographic variables; standardizing the weights in both surveys to the age, sex, and racial distributions of the 1990 census; formulating diagnoses according to DSM-III; and restricting the age range to 18 to 54 years. Using this method, the lifetime rate of any DSM-III disorder for the first wave of interviews was 36 percent. Adding the cases from the second wave produced a rate of 47 percent, consistent with the rate of 48 percent from the single-wave NCS. Annual rates of mania produced in this way were almost identical to those in the

ECA and the NCS. The annual rate of bipolar-I for the first wave of the ECA using these conventions was 0.9 percent; adding cases from the second wave produced a rate of 1.0 percent. The annual rate in the NCS was 1.1 percent with these conventions.

That such modifications can reduce or increase disparate rates concerns health policy planners and insurers, who base the direct costs of service delivery for a disorder on its prevalence rate. The WHO initiative to revise the CIDI by including impairment criteria for each disorder is addressing this issue (Regier and Burke, 2000). However, there is still no fully satisfactory method of calculating the actual rates.

7. Research on minors often makes a distinction by pubertal status. Puberty has been shown to differentiate the onset and clinical course of mood disorders in longitudinal and epidemiologic studies (Angold et al., 1998, 1999; Weissman et al., 1999a,b). The rates and gender ratios of depression change dramatically at puberty, with a marked increase occurring in overall rates, especially among females. Some studies separate prepubertal children from adolescents, others focus on one or the other, and still others merge the two. Most studies use chronological age to designate pubertal status; a few use Tanner staging (see Angold et al., 1998, 1999). We recognize the importance of these age distinctions and make them where the necessary data are available. In the absence of such data or the need to make an age-specific point, however, we use the term *children* to describe minors.

6

Children and Adolescents

In rare cases the first beginnings can be traced back even to before the tenth year. . . . The greatest frequency of first attacks falls, however, in the *period of development* with its increased emotional excitability between the fifteenth and the twentieth year.

—Emil Kraepelin (1921, p. 167)

Bipolar disorder commonly manifests itself in adolescence or young adulthood, but classic descriptions and numerous case studies also demonstrate the existence of the disorder in children. In recent years, identification of these earliest forms of the disorder has been the subject of an explosion of interest among clinicians, scientists, the public, and the media.¹ This interest has been driven in part by the emerging hypothesis of bipolar disorder as a progressive neurobiological process that may worsen with succeeding episodes, so that early identification and treatment may have important implications for attenuating the course of illness. Increasingly, moreover, parents are seeking answers and help for their children who display bewildering or overwhelmingly severe symptoms and are at increased risk for serious behavioral and educational problems, as well as suicide (see Hellander and Burke, 1999; Lewinsohn et al., 2003). Aside from treatment considerations, childhood-onset bipolar disorder also raises important conceptual and etiological questions: Are there different subtypes with differing causes and courses? What are the defining distinctions between pediatric bipolar illness and other psychiatric disorders of childhood, such as attention-deficit hyperactivity disorder (ADHD)? Is the rate of childhood bipolar disorder increasing, and if so, why? Is the course of the disorder different for early versus adult onset? Although this book is about manic-depressive illness, which includes both bipolar and recurrent unipolar forms, the pediatric literature rarely distinguishes recurrent from nonrecurrent forms of unipolar depression; this chapter limits its focus to the bipolar subgroup.

We begin with a review of research on childhood- and adolescent-onset bipolar disorder. We then examine the epidemiology and implications of bipolar disorder in these populations. Finally, we present the findings of studies of

high-risk subjects that have attempted to identify characteristics of children of bipolar parents, with particular emphasis on early markers of potential bipolar illness. Unfortunately, many unresolved issues remain. The interest in manifestations of bipolar disorder among children and young adolescents is far greater than the yield from research addressing the key questions involved.

Throughout the discussion, we attempt to identify problems with the methods used in existing studies, as well as research needed to address important issues. One of the most pervasive difficulties stems from the failure of many studies to distinguish between childhood- and adolescent-onset bipolar disorder; this occurs, for example, when vague terms such as “juvenile-onset bipolar disorder” and “pediatric bipolar disorder” are used or when child and adolescent samples are combined in the same study. This is a widespread problem in the study of adolescent bipolar disorder, where distinctions are seldom made between childhood and adolescent *onset*. Some studies of adolescents with bipolar disorder include patients whose symptoms actually first occurred before age 12 or before puberty. As detailed in chapter 4, age at onset is also defined differently in various studies—for example, as age at first diagnosable symptoms of mania or at first symptoms of any affective disorder, or as age at first actual diagnosis of mania or depression by a mental health professional. Studies have employed different diagnostic criteria as well, and many have included clinical populations with a mix of bipolar-I and other bipolar spectrum disorders, despite the fact that there is very little information specifically on bipolar-II disorder in children or adolescents (see Chapter 3). Finally, one of the greatest methodological gaps is the paucity of longitudinal studies of either childhood or adolescent bipolar disorder. Such studies are essential to clarify diagnostic controversies and to

map the course of the disorder and the implications of its early onset.

CHILDHOOD-ONSET BIPOLAR DISORDER

Although occurrences of mania and depression in adolescence are well established, the frequency of early-childhood onset of bipolar disorder remains controversial. Kraepelin (1921) found that 0.4 percent of his patients had displayed manic features before age 10. Despite historical records of case studies documenting apparent bipolar illness in children, however, theorists believed for an extended period in the mid-twentieth century that bipolar disorder in children before puberty was not possible (reviewed in Faedda et al., 1995). For instance, Anthony and Scott (1960) examined the psychiatric literature from 1884 to 1954 and uncovered only 28 cases of alleged manic episodes in young children. After applying systematic diagnostic criteria to these clinical reports, they dismissed all of the cases as misdiagnosed and concluded that a classic clinical presentation of manic-depressive illness in childhood had yet to be demonstrated.

Recent years have seen a growing acceptance that prepubertal forms of mania can be identified. Opinions range from certainty that characteristic patterns of symptoms signal childhood bipolar disorder in substantial numbers, even if in a form that may not precisely follow that of classic forms of the disorder, to more cautious views that prepubertal mania exists, but that many such complex cases may be misinterpreted as bipolar disorder. Difficulty in applying the adult criteria for bipolar disorder in the *Diagnostic and Statistical Manual*, 4th edition (DSM-IV) to children is at the heart of the controversy. In the following sections, we present research on characteristics of bipolar disorder in children and discuss the controversies related to its diagnosis.

Symptoms and Clinical Presentation

Manic Features

The appearance and diagnosis of mania is considered a distinctive indicator of bipolar disorder in children. However, the diagnosis of mania in children is controversial and fraught with pitfalls, as reviewed below.

Even as young as preschool age, some children appear to present relatively classic manic symptoms, including DSM-IV-defined mania or hypomania with elated mood and/or grandiosity; flight of ideas or racing thoughts; poor judgment, such as excessive silliness, uninhibited people-seeking, hypersexuality, or daredevil acts; talking fast; and distractibility, with increased energy, activity, and agitation (e.g., Geller et al., 2000a, 2002c). In their study of 93 children

with prepubertal and early-adolescent onset of bipolar disorder (mean age at onset 7.3 years), Geller and colleagues (1998b, 2002c) found that five mania-specific symptoms were especially likely to discriminate bipolar children from children with ADHD or normal comparison groups: elation, grandiosity, flight of ideas/racing thoughts, decreased need for sleep, and hypersexuality. Table 6-1 presents examples of manic symptoms in children compared with normal characteristics of youngsters of similar age (Geller et al., 2002b).

Geller and colleagues (2002c) also found that 60 percent of their sample had symptoms of psychosis, including 50 percent who had grandiose delusions. In a later follow-up study, they found that psychosis predicted more weeks ill with mania or hypomania (Geller et al., 2004). In their review of psychotic symptoms in pediatric bipolar disorder, Pavuluri and colleagues (2004) found that the prevalence of psychotic features ranged from 16 to 88 percent; most common were mood-congruent delusions, especially of the grandiose type. Biederman and colleagues (2004c) found that nearly 1 in 4 of the 298 bipolar patients they studied were psychotic or had a history of psychosis. Likewise, in their study of 263 bipolar children and adolescents, Birmaher and colleagues (2005b) found that one-third (33.1 percent) of their subjects had a history of psychosis.

Geller and colleagues required elation and/or grandiosity for the diagnosis of mania in children, as did Leibenluft and colleagues (2003a). This is an important, if still preliminary, consensus of clinical researchers, although, as Carlson (2005) pointed out, uncertainty remains about what actually constitutes these two symptoms. Methods of assessment vary widely, as do cultural expectations and developmental factors, and all are likely to influence the ascertainment of both euphoria and grandiosity (Breslau, 1987; Shaffer, 2002; Harrington and Myatt, 2003). Some studies have defined mania by the presence of highly labile moods with intense irritability, rage, explosiveness, and destructiveness; extreme agitation; and behavioral dysregulation (e.g., Biederman et al., 2000a). Irritability, and indeed rage, are noted as prominent features in many bipolar children (e.g., Faraone et al., 1997b; Carlson and Kelly, 1998; Geller et al., 2002c). The children are often aggressive and frequently are described by their parents as "out of control." Not surprisingly, they are often seen in hospital settings, and overall their functioning is marked by severe impairment in social and academic as well as family roles (Geller et al., 2000a). Box 6-1 presents a mother's diary of the behaviors of her 9-year-old bipolar son, conveying a sense of the severe but characteristic features of the disorder. Suicidal thoughts and behaviors are not uncommon.

TABLE 6–1. Examples of Core Symptoms of Mania among Children

Normal Child	Child with Mania
	<i>Elated Mood</i>
Child was extremely happy on days family went to Disneyland, on Christmas morning, during grandparents' visits (joy appropriate to context, not impairing).	7-year-old boy repeatedly taken to principal for clowning and giggling in class; had to leave church for similar behaviors. 9-year-old girl continually danced around at home, stating, "I'm high, over the mountain high" after suspension from school.
	<i>Grandiosity</i>
After school hours, 7-year-old boy played at being a firefighter, directing other firefighters and rescuing victims. Child did not call fire station and tell firefighters what to do.	7-year-old boy stole go-cart because he wanted to have it; knew stealing was wrong, but did not believe it was wrong for <i>him</i> to steal. 8-year-old girl, failing in school, spent evenings practicing for when she would be the first female President. She was also planning how to train her husband to be the First Gentleman.
	<i>Decreased Need for Sleep</i>
Normal children sleep approximately 8 to 10 hours a night and are tired the next day if they sleep fewer hours than usual.	8-year-old boy chronically stayed up until 2 AM rearranging the furniture or playing games. He then awoke at 6 AM for school and was energetic throughout the day without evident fatigue.
	<i>Poor Judgment: Hypersexuality</i>
7-year-old child played doctor with a friend of the same age. 12-year-old boy looked at his father's pornographic magazines.	7-year-old girl touched the teacher's breasts and propositioned boys in class. 10-year-old boy used explicit sexual language in restaurants and public places. Girl faxed a note to the local police station asking police to ___ her.
	<i>Racing Thoughts</i>
Normal children do not report racing thoughts.	Children tend to give concrete answers to describe racing thoughts: A girl pointed to the middle of her forehead and stated, "I need a stoplight up there." Others: "It's like an energizer bunny in my head." "My thoughts broke the speed limit." "I don't know what to think first."

BOX 6-1. Twelve Days in May: Diary of a Mother of a Nine-Year-Old Bipolar Child

5/11	Hypomanic, bizarre evening. "I hate me; kill me; Why am I like this?" Very rough with younger brother.	5/18	"Mixed," very irritable to hypomanic—increase in goal-directed activities, very easily frustrated and angered.
5/12	Good morning, dropped off well at school. Pretty good mood coming off bus, but more defiance in the afternoon. Uneventful evening. Went to bed well.	5/19	Good and uneventful day.
5/13	Up early, dressed well, good mood but problems on the bus. Kids teasing him. Teacher called and reported very bizarre behavior at school. She also reported a lot of ADHD symptoms—very fidgety, unable to remain seated in the afternoon, cruises around classroom, ran out of classroom, pestering other kids, unable to follow directions, not remaining on task or completing work.	5/20	Very irritable in A.M.—threatened father—said: "I'm going to kill you someday." Manic after school—very goal-directed—taking all the tools out of the basement to use up in his room (hammer, sander, drill, staple gun). Very angry when I intervened—very loud, shouting, laughing, singing, dancing, "I don't feel good today. I want to kill myself. When I grow up, I am going to kill myself because being bipolar is bad." Hallucinating in afternoon—auditory and visual; goblin, clown, queen. "I hear the devil, I hear penises in your brain, Mom." Very hyperactive, and not rational. Gave him Risperdal and he went to sleep.
5/14	Teacher reported a great day in school. Good mood after school.	5/21	Hypomanic, happy in the afternoon.
5/15	Good A.M.—off to school well. Very defiant after school. Angered by new doctor. Got very angry in car—punching me, destructive to car, scribbling on dashboard, dumping over trash. Had to be restrained in office—punching, kicking, swearing—settled down at end of meeting and apologized.	5/22	Woke up laughing—found some needlepoint yarn and needles under the bed. "I'm giving myself a lab test"—trying to stick needles into his arm. Giddy, shouting "hubba, hubba, hubba, howdy, howdy" over and over again, very wound up. Settled down and watched some TV. Pleasant and more normal, but talkative in the afternoon. Easier to please. More irritable after dinner. Fascinated with knives, demonstrated how he would stab a wolf. Very quiet in my lap. He said: "I love you, Mom. You don't love me, you want me to die. I will if you want me to."
5/16	Happy mood in A.M., but doing goofy, impulsive things—squirted water on dad's work shirt, squirted water on table and floor. Very aggressive after school—threatening me, hitting, increase in defiance. Aggressive toward other students.		
5/17	Had a good time with grandparents. Crying a lot in the afternoon.

Depressive Features

For many individuals, bipolar disorder first emerges in the form of depressive episodes in childhood (e.g., Geller et al., 1994; Lish et al., 1994). Although depression in children may be readily diagnosed using adult criteria, the majority of such cases probably go undetected and untreated. Even if they are detected, however, there is presently no certain way of knowing the extent to which early-onset depression presages childhood-onset bipolar disorder; the issue is an important question not only clinically but for research as well.

As noted previously, studies of bipolar illness have often combined childhood- and adolescent-onset populations, and longitudinal studies of the outcomes of depression in children have been rare. Given that unipolar depression in children is substantially more prevalent than mania and is characterized by marked clinical and etiological heterogeneity, it is difficult to identify predictors specific

to eventual bipolarity. Wozniak and colleagues (2004) compared 109 children with unipolar depression and 43 children with bipolar depression (all had been diagnosed with ADHD as well) and found that the bipolar children were more severely depressed and anhedonic, were more often suicidal, expressed greater hopelessness, and were more likely to need medication and hospitalization. They also had higher rates of comorbidity with conduct disorder, oppositional defiant disorder, agoraphobia, obsessive-compulsive disorder, and alcohol abuse (see Chapter 7 for a detailed discussion of comorbidity in bipolar disorder). A family history of bipolar disorder was more than twice as likely in the bipolar group as in the unipolar children (20 versus 8 percent).

Most follow-up studies of depressed children have yielded little information on predictors of bipolarity because of the limited size of samples that have converted to a bipolar course. Recently, Luby and Mrakotsky (2003) attempted to identify differences in symptoms among

depressed preschoolers with and without a family history of bipolar disorder. Only one symptom (restlessness/“moves around a lot”) distinguished the groups, but its association with the emergence of bipolarity remains to be seen. Geller and colleagues (1994) found that among a sample of 79 severely depressed children (ages 6 to 12), 32 percent switched to bipolar-I or bipolar-II during a 2- to 5-year follow-up. When the same subjects were recontacted in young adulthood (mean age 21), 49 percent were found to have switched to bipolar disorder, including 33 percent with bipolar-I (Geller et al., 2001b). The authors found that parental and grandparental mania was a significant predictor of bipolar switching.

Unfortunately, this information has sometimes been misstated. Although Geller and colleagues (2001b) did indeed find a 33 percent rate of switching to bipolar-I disorder among their severely depressed sample of children, their sample may be atypical and perhaps biased by high rates of referral for suspected bipolar disorder. The rate of switching is likely to be substantially lower in more typical outpatient samples. For instance, Weissman and colleagues (1999b) followed up on outpatient children with prepubertal depression an average of 11 years later, and found that only 6 percent had developed bipolar disorder, although this rate was much higher than that among comparison groups. Lewinsohn and colleagues (2000) found that fewer than 1 percent of adolescents with depression in a community sample switched to bipolar disorder. Differences in rates among these studies are likely due to differing diagnostic and exclusion criteria in the samples. Most clinical samples are small and can be greatly affected by variations in level of severity; family history of bipolar disorder; use of alcohol, stimulants, antidepressants, or other drugs; and other unspecified or unknown factors. Clearly, further research is needed on the predictors of switching among depressed children so as not to exaggerate, or even mislabel, bipolarity in children, yet provide accurate information to enable early treatment of those who truly have or are likely to develop the illness.

Diagnostic Controversies

Despite general agreement that bipolar disorder can emerge in childhood, several problems make it difficult to validate some of the assertions made about diagnosis of bipolar children. Three related issues are discussed here: comorbidity and indistinct diagnostic boundaries, the validity and meaning of a diagnosis of mania, and the lack of developmental guidelines.

Comorbidity and Indistinct Diagnostic Boundaries

As noted earlier, the great majority of cases of childhood-onset bipolar disorder also meet criteria for other disorders, including ADHD, conduct disorder, and oppositional

defiant disorder.² Findings of the major studies of comorbidity in childhood-onset bipolar disorder are presented in Table 6–2. As can be seen in the table, many clinical investigations have documented a high rate of comorbid anxiety disorders as well.³ (There is some indication that bipolar-II children and adolescents, like adults, are more likely to have comorbid anxiety disorders than those with bipolar-I disorder [Axelson et al., 2006].) Perhaps nothing has fueled the controversy as much as the potentially confusing overlap of symptoms between mania and disruptive behavioral disorders.

Many studies have shown that children with a bipolar diagnosis have a high probability of being diagnosed with ADHD. Geller and colleagues (2000a), for example, found this to be the case in 98 percent of their sample (see also Biederman et al., 2000a; Sachs et al., 2000; Spencer et al., 2001). Considerably lower rates have been found by other researchers, however (Masi et al., 2003; Faedda et al., 2004; Jaideep et al., 2006). Some investigators have argued that many children diagnosed with ADHD also have bipolar disorder. Biederman and colleagues (1996) identified psychiatrically referred children with ADHD, who were then assessed for the presence of mania at baseline and at 1 and 4 years later. Bipolar disorder was diagnosed in 11 percent of the ADHD children at baseline and in an additional 12 percent at the 4-year follow-up. Arguing that a substantial number of children diagnosed with ADHD may actually have unrecognized bipolar disorder, Biederman fueled a controversy that is still active (Wozniak et al., 1995; Faraone et al., 1997b; Biederman, 1998). Many investigators have also observed high rates of conduct disorder and oppositional defiant disorder (e.g., Biederman et al., 2000a; Geller et al., 2000b; Wozniak et al., 2001), as well as substance abuse and anxiety disorders (e.g., Birmaher et al., 2002), among bipolar children (see also reviews in Biederman et al., 2000a, and Papolos, 2003).

What is the meaning of the overlap between mania and ADHD (or other disruptive behavior disorders)? There are several different perspectives on this question. One general argument is that the comorbidity is simply an artifact of overlapping symptomatology. Three more specific arguments are that the ADHD–mania overlap is (1) true comorbidity (coexistence of separate disorders), potentially marking a genetically mediated subtype; (2) artifactual, reflecting severe psychopathology that is not specifically bipolar; and (3) artifactual, possibly reflecting a developmental manifestation of bipolar disorder in children.

The general argument that bipolar comorbidity may be a result of overlap of symptoms suggests that diagnostic inaccuracies are caused by indistinct symptom boundaries, clinician bias, or biased diagnostic expectations due to ascertainment source. Biederman and his colleagues at

Massachusetts General Hospital studied large numbers of children with comorbid ADHD and bipolar disorder. They argued, through the use of various diagnostic algorithms, that the presence of the two separate diagnoses was valid and was not a result of overlapping symptoms such as talkativeness, hyperactivity-psychomotor agitation, or distractibility (e.g., Milberger et al., 1995; reviewed in Spencer et al., 2001). Moreover, Biederman and colleagues (1998) found that children with comorbid diagnoses of mania and ADHD ascertained from ADHD clinics and from a study of mania differed minimally in symptoms of either mania or ADHD.

Additionally, Biederman and colleagues (2004c) hypothesized that the comorbid combination of the two disorders may mark an etiological subtype. In family-genetic studies, Faraone and colleagues (1997b) found that first-degree relatives of children with bipolar disorder and ADHD had both disorders at rates greater than would be expected by chance alone. On the basis of these and other family patterns observed across several studies, they posited that the combination of ADHD and bipolar disorder is familial distinct and may be a marker of a subtype of very early-onset bipolarity.

Geller and colleagues (1998a, 2002b) also found high rates of comorbid ADHD and bipolar disorder. ADHD

occurred among 97 percent of prepubertal bipolar children and 74 percent of bipolar adolescents. Even with ADHD, the bipolar children were distinctly different from ADHD-only children in symptoms of mania, as illustrated in Figure 6–1 (Geller et al., 1998b). As noted earlier, in a study comparing 93 participants with childhood- and early-adolescent-onset mania, 81 with ADHD and no mania, and 94 community controls, Geller and colleagues (2002b) found that, despite the high rate of ADHD-bipolar comorbidity, five symptoms distinguished most clearly between bipolar and ADHD samples: elation, grandiosity, flight of ideas/racing thoughts, decreased need for sleep, and hypersexuality. These findings appear to argue against the possibility that ADHD comorbidity is an artifact of overlapping symptoms—provided, as noted later, that children otherwise meet the full criteria for mania in DSM-IV.

Whereas Biederman and colleagues (1996) argued that the combination of ADHD and bipolar disorder in children marks a subtype of bipolar disorder, Geller and colleagues (1998a) suggested that ADHD in child bipolar samples may be a “phenocopy” ADHD, driven by developmentally prevalent high energy in children. That is, high energy combined with emerging bipolar symptoms promotes the hyperactivity, impulsivity, and attentional problems that are viewed as ADHD. Geller predicted that the

ADHD will “decrease” to population levels by adulthood (e.g., Geller and Luby, 1997). Thus, ADHD may be a prodrome or developmentally expressed version of bipolarity in some children, rather than a separate disorder. Obviously, prospective longitudinal follow-up of samples of young bipolar patients would help resolve such diagnostic issues through clarification of clinical course and outcome (see reviews by Kim and Miklowitz, 2002; Kent and Craddock, 2003).

While it is doubtless likely that comorbid conditions can obscure the recognition of an underlying bipolar illness, the complex symptomatology involved may also have the opposite effect: clinicians are urged to consider bipolar disorder as an explanation for diffuse and difficult symptoms. A widely visible Web site for bipolar disorder in children, for example, listed the following as possible symptoms, among others more specific to typical mania: explosive, lengthy, and often destructive rages; separation anxiety; defiance of authority; hyperactivity, agitation, and distractibility; bed-wetting and night terrors; strong and frequent cravings; and daredevil behaviors.⁴ Obviously,

although such symptoms may occur in children with bipolar disorder, each is also nonspecific. Precise diagnostic definitions that can help separate truly bipolar manifestations from overlapping conditions are needed to avoid misdiagnosis, as well as to facilitate recognition of bipolar illness.

Questions about the Validity of the Diagnosis of Mania in Children

Is severe behavioral dysregulation “mania,” and does “mania” always mean bipolar disorder? Multiple, intense, and severe symptoms may be caused by brain injury, other forms of organic disorder (e.g., Carlson and Kelly, 1998), or severe disinhibition related to adverse medication responses (Carlson and Mick, 2003) (see also Chapter 3). Carlson (1998) noted that, in the child psychiatry literature, several nonspecific terms—such as “multidimensionally impaired” and “multiple complex developmental disorder”—are used to describe children with numerous, severe, disruptive behaviors that do not fit any typical diagnostic picture, as well as children suffering from some forms of head injury,

pervasive developmental disorder, or other medical conditions. In the past, some of these children were labeled as "minimally brain damaged" or "hyperkinetic." Many of these historical syndromes have been described in terms that bear a marked resemblance to contemporary descriptions of childhood mania.

A related issue raised by Carlson and others is the possibility that mania or manic-like symptoms may occur as a dimension of disorder or serve as a marker of severe psychopathology without necessarily indicating the presence of a bipolar syndrome. Carlson and colleagues (1998) recruited a sample of boys aged 6 to 10 who had heterogeneous disruptive and/or depressive symptoms. The boys' mothers were asked about the presence of manic symptoms, and their responses led the researchers to distinguish three groups: those boys with at least two manic symptoms, and two matched comparison groups—those seen immediately next in the series of interviews but without manic symptoms, and those matched on the first group's comorbid disruptive symptoms (conduct disorder, ADHD, or oppositional defiant disorder) but without manic symptoms. The authors found that although the boys with symptoms of mania differed significantly from the non-mania "next" control group, most of those differences disappeared in a comparison with the group with comorbid conditions. The presence of manic symptoms uniquely predicted significant emotionality and generally predicted more severe psychopathology (Carlson and Youngstrom, 2003). The investigators are continuing to study these children over time, attempting to determine whether some are truly bipolar, while in others the manic-like symptoms may serve mainly as markers for "behavioral and emotional multimorbidity." Similarly, Hazell and colleagues (2003) followed up boys aged 9 to 13 who met criteria for ADHD plus mania. When the boys were reevaluated after 6 years, there were no clear cases of bipolar disorder among those with prior manic symptoms; however, the boys with earlier manic symptoms had lower overall global functioning.

Geller and colleagues (2002) have reoperationalized several of the DSM criteria (most notably euphoria and grandiosity) to make them what the authors believe to be developmentally appropriate for children. Not everyone agrees with this reformulation, however (Harrington and Myatt, 2003). In a recent cross-national (United States and United Kingdom) study of five cases of children with mood symptoms in whom bipolar disorder might have been a diagnostic consideration, disagreement on diagnosis occurred in three of the five cases. The reason for this appears to be differing interpretations of specific symptoms. DSM's reliance on symptom counts (used in the United States) may result in a conceptualization that dif-

fers from the gestalt of bipolar disorder as described in the International Classification of Diseases (ICD)-10, used in the United Kingdom. Specifically, in a preadolescent patient with classic mania, agreement was close (96.4 percent of United States and 88.9 percent of United Kingdom physicians made a manic diagnosis). In the prepubertal child with both ADHD and manic-like symptoms, however, 86.2 percent of U.S. child psychiatrists diagnosed mania, in contrast to only 31.1 percent of their U.K. colleagues (Dubicka et al., 2005).

It may be noted that among adolescent samples in community populations, Lewinsohn and colleagues (1995) and Klein and colleagues (1996) observed manic-like symptoms or hypomania associated with impairment and various forms of psychopathology. Upon follow-up at age 24, those diagnosed earlier with bipolar disorder (mostly bipolar-II or cyclothymia) continued to show recurrent or chronic bipolar symptoms, but few of those with adolescent "subclinical" bipolar symptoms of mania/hypomania had developed full-blown bipolar disorder (Lewinsohn et al., 2000). Overall, studies of manic symptoms in children and adolescents may indicate true bipolar disorder in some cases, but in other cases these symptoms may be mainly markers for severe emotionality and disruptive behaviors.

Finally, a significant issue in the diagnosis of mania concerns the duration of affective cycles. Many children labeled "bipolar" may have numerous mood shifts within a day and have chronic symptoms and impairments not consistent with the adult concept of "episodes." As noted by Leibenluft and colleagues (2003a), in the absence of validated criteria for the duration of an episode in children, some investigators have defined episodes to be as brief as a few hours. Leibenluft and colleagues (2003b) suggested that within such brief periods, it is quite difficult to determine whether episodes are accompanied by the required DSM-IV criterion B changes in behavior. Thus, investigators' and parents' subjective impressions may be used to make diagnoses, contributing to the diagnostic confusion and heterogeneity in research samples. Tillman and Geller (2003) have proposed specific definitions of rapid, ultrarapid, and ultradian cycling, as well as distinctions between episodes and cycles. If used systematically in research, such definitions might help characterize the course of illness in bipolar children and contribute to diagnostic validity.

Lack of Data and Insufficient Knowledge of Developmental Issues

A further challenge to diagnosing bipolar disorder in children is the limited utility of applying to this population features of adult bipolar symptoms and course. Diagnostic confusion about how to interpret specific symptoms (e.g., hyperactivity, irritability) arises in part from developmental

considerations for which little information is presently available. As Carlson (1998) noted, many of the other features of bipolar syndrome, such as grandiosity and elation, have not been systematically defined in developmentally appropriate and precise ways or evaluated in context. Simply hearing a child utter the words "I can fly," for instance, without considering the child's developmental stage and environmental context, could lead clinicians to misinterpret the statement as indicating grandiosity when it means nothing of the kind. Geller and colleagues (2002b) would argue that such states can be distinguished from normal childhood experiences; however, the issue must not hinge only on the experience and skill of a researcher or clinician, but rather on developmentally informed and validated criteria.

An intriguing suggestion that symptoms of bipolar disorder may have a developmental progression has been made by Post and colleagues (2002). These investigators studied three volunteer samples of parents: those with children who had been diagnosed with bipolar disorder or with psychiatric (nonbipolar) disorders, and those who were not ill. The parents were asked to identify their children's symptoms retrospectively during each year of life. Ages at which children displayed empirically derived clusters of symptoms were compared for the three groups. It appeared that among the bipolar children, an irritability-dyscontrol factor (e.g., impulsivity, tantrums, aggression, hyperactivity), emerging at age 1 to 3 years, was the first feature to distinguish among the groups. A depression factor began to differentiate the bipolar children from others by age 8 to 12. A mania factor (e.g., racing thoughts, grandiosity, mood elevations, bizarre behavior) did not begin to differentiate the bipolar children until ages 7 to 12, whereas a distinguishing psychosis-suicidality factor emerged at ages 9 to 12. Despite significant methodological limitations (including a lack of confirmatory diagnosis of the bipolar children, a mixed-disorder comparison group, and parental retrospective accounts), this study highlights the need for further investigation of the possible developmental progression of manifestations of bipolar symptoms.

Researchers have also urged further study of child-appropriate definitions of mania, as well as attention to traits and behaviors that may represent prodromal or subsyndromal forms of bipolar disorder (Shaffer, 2002; Coyle et al., 2003; Carlson, 2005). As we argue later, studies of children of bipolar parents may be an especially fruitful way to help identify some of the early indicators of mania and progression of symptoms in children known to be at risk for bipolar disorder.

Finally, it may be noted that boys tend to predominate in research samples of bipolar children (e.g., Faraone et al.,

1997b; Geller et al., 1998b). Indeed, this is true for most forms of childhood disorder, particularly disruptive disorders (ADHD, oppositional defiant disorder, conduct disorder), but also anxiety and depression prior to adolescence. Thus, gender differences may not be remarkable in young samples. In a study of 298 bipolar patients under the age of 18, Biederman and colleagues (2004a) found few significant differences in clinical features between males and females, although males were more likely to have ADHD as well as bipolar disorder; they were also less likely to have a chronic course. On the other hand, it is possible that this gender distribution in research samples signals under-recognition of mania in girls, inasmuch as they tend to be less aggressive and therefore may not attract as much attention as boys exhibiting destructive and risk-taking behaviors. Also, girls' initial mood disorder may more often be depression rather than mania. Therefore, developmental studies of bipolar disorder and manic symptoms need to address gender-relevant manifestations.

Current Suggestions for Assessment and Diagnosis of Bipolar Disorder in Children

In view of the varied opinions and relative paucity of data on assessment and diagnosis of bipolar disorder in children—and mindful of the high stakes involved in terms of accurate detection and early treatment—the National Institute of Mental Health (NIMH) convened the Bipolar Child Research Roundtable in 2000 (NIMH Research Roundtable on Prepubertal Bipolar Disorder, 2001) to share information and make recommendations. The roundtable members recommended that children who clearly meet current DSM-IV criteria for symptoms of bipolar-I or bipolar-II disorder—including core symptoms of grandiosity and/or elation (e.g., Geller et al., 2000a)—be distinguished from those with heterogeneous presentations who do not meet the full criteria but suffer from mood and behavior disturbances (prototypically, irritability or rage episodes) and severe impairment and *may* have bipolar disorder (e.g., Carlson et al., 1998; Biederman et al., 2000b). It was recommended that the latter be diagnosed as bipolar—not otherwise specified (NOS). The roundtable members noted that both of these groups are likely to have mixed states, chronic symptomatology, or long episodes with ultradian or continuous cycling. They speculated that many if not most suspected cases of bipolar disorder in children would be diagnosed bipolar-NOS, with a minority representing classic bipolar-I disorder. They also recommended that children be evaluated by clinicians who are well trained in mood disorders in youth, although there is a scarcity of such training (e.g., Coyle et al., 2003). The *Treatment Guidelines for Children and Adolescents with Bipolar Disorder*, published by the Child Psychiatric Workgroup

on Bipolar Disorder, additionally stresses the importance of interviewing at least one parent, and ideally both; obtaining comprehensive school and medical histories; and encouraging family members to keep daily logs of the child's mood, energy, sleep, and unusual behaviors in the 2 weeks before the first visit to the clinician (Kowatch et al., 2005).

Leibenluft and colleagues (2003b) have suggested even further distinctions to improve the validation of diagnostic criteria for childhood bipolar disorder, proposing a phenotypic system of four categories ranging from narrow- to broadband subtypes. Their narrow phenotype includes the classic hallmark symptoms (e.g., elevated mood, grandiosity) and full-duration episodes. This phenotype is distinct from ADHD, despite overlapping symptoms, because ADHD is not episodic, and the associated symptoms occur only during hypomanic or manic episodes. At the broadest end of the spectrum, the system includes many children who are currently labeled as bipolar but do not meet criteria for the authors' narrower definitions. These children have severe mood and behavioral dysregulation, chronic hyperarousal, and negative reactivity to emotional stimuli, including severe rages, with no intervening periods of normal mood or adaptive functioning. Between these narrow and broad extremes lie two intermediate phenotypes: (hypo)mania-NOS, including hallmark symptoms but short episodes (although lasting at least 1 to 3 days), and irritable (hypo)mania, lacking elevated or expansive mood but with distinct episodes that meet DSM-IV duration criteria. Thus far, however, there are limited data to support these distinctions. Whether the proposal of Leibenluft and colleagues proves useful or not, it clearly addresses the crucial need for more homogeneous research samples that can help clarify and validate the construct of bipolar disorder in children.

Course of Disorder

Children diagnosed with bipolar disorder typically do not display course features commonly associated with classic bipolar disorder in adults, such as distinct mood episodes that endure for days or weeks (often clearly manic or depressive) separated by periods of being relatively well. Instead, bipolar children frequently display mixed mood states, extremely rapid cycling, and chronic psychopathology. The controversy over diagnostic criteria, including duration of episodes in children with purported bipolar disorder, is discussed further below.

Faraone and colleagues (1997b) found mixed states in 59 percent of children diagnosed with bipolar disorder, while Geller and colleagues (2002a) reported a rate of 55 percent. Geller's group (2002b) found that 87 percent of their sample had ultradian cycles (variation within a 24-hour period). Moreover, these children were chronically ill and

had been mood-disordered for an average of more than 3 years before entering the study. Craney and Geller (2003) concluded that typical youngsters with childhood-onset bipolar disorder in their sample were more severely ill than typical individuals with young adult-onset mania, and much more likely to display mixed mania, ultradian cycling, psychosis, and treatment resistance. Biederman and colleagues (2004a) found that the course of pediatric bipolar disorder was severe and chronic and was frequently characterized by severely impaired psychosocial functioning; they also observed chronic symptomatology in their bipolar-ADHD sample (Biederman et al., 1998). A prospective follow-up study of pediatric bipolar disorder in 22 boys with comorbid ADHD found that although 50 percent had remitted from the full syndrome of bipolar disorder at follow-up, 80 percent had failed to attain functional remission or euthymia over a course of 10 years (Biederman et al., 2004a). The course of the disorder, the investigators concluded, was "chronic, protracted, and dysfunctional" (p. 521). Many other investigators also have found that early onset of bipolar illness is associated with a poorer course (Carlson et al., 2002; Schneck et al., 2004; Birmaher et al., 2006). Some have argued that there may be periods of exacerbation of manic symptoms despite interepisode persistence of less severe mania, as is the case for many adult bipolar patients (Staton and Lysne, 1999).

Longitudinal research on the course of the disorder among carefully diagnosed bipolar children is sparse and greatly needed. Geller and colleagues (2000a) found 1-year mania recovery rates of 37 percent in their combined sample of youngsters with childhood- and early-adolescent-onset bipolar disorder, and substantial relapse rates within the year among those who recovered. At 2-year follow-up, the recovery rate was 65 percent, but 55 percent of those who had recovered relapsed (Geller et al., 2002a; Craney and Geller, 2003).

Thus the few outcome studies of childhood bipolar illness that exist indicate a highly pernicious course with substantial chronicity. Findling and colleagues (2001), for example, found that none of the 56 bipolar-I children they studied had interepisode recovery (defined as a 2-month period of remission of affective symptoms). Further longitudinal research is needed, however, to learn more about long-term course and outcome in children and their predictors, as well as to resolve some of the perplexing diagnostic issues in childhood bipolar disorder discussed above.

ADOLESCENT-ONSET BIPOLAR DISORDER

The onset and first diagnosis of bipolar disorder frequently occur in adolescence. For the most part, adolescent-onset

bipolar disorder is clinically similar to adult bipolar disorder. Until recently, however, relatively little research had been conducted in adolescent populations.

Despite current awareness, adolescent bipolarity often was not recognized as such in the past. Diagnostic errors were common, reflecting biases of the time. These biases included the above-noted reluctance to accept the existence of youthful onset of bipolar disorder and a common tendency to assume that psychotic symptoms such as thought disorder, grandiosity, and bizarre delusional and hallucinatory phenomena are pathognomonic of schizophrenia (Carlson and Goodwin, 1973). Additionally, morbid preoccupations, frenzied behavior, moodiness or rapid mood swings, irritability, defiance, and a host of other disturbances were often regarded as exaggerations, if not typical manifestations, of adolescence. As discussed earlier, moreover, even when recognized as clearly pathological, disturbed behaviors in youths have been difficult to distinguish from alcohol and drug abuse disorders, conduct and other disruptive behavior disorders, and personality disorders. These diagnostic challenges remain today.

In recent years, however, several factors have contributed to the increased recognition and accurate diagnosis of adolescent bipolar disorder. These factors include greater awareness of the existence of severe mood pathology in adolescents, improved diagnostic criteria and interview methods for identifying depression and mania in younger populations, and increased availability of effective pharmacological and psychotherapeutic treatments for mood disorders. Increasingly, adult diagnostic criteria are being applied reliably and effectively to the diagnosis of bipolar disorder in adolescents. There is a general consensus that adolescent-onset bipolar disorder is a relatively common presentation and that, as noted, it essentially resembles the disorder in adults.

Symptoms and Clinical Presentation

Diagnosis

Adolescent onset of bipolar-I disorder may first present with major depression, mania, or a mixed state. The diagnosis is typically defined by DSM-IV criteria or by equivalent criteria used for adults (see Chapter 3; see also McClellan and Werry, 1997; Lewinsohn et al., 2003). Manic episodes, of course, provide the most unambiguous indicator of bipolar disorder. Symptoms such as elated mood, grandiosity, excessive activity, decreased need for sleep, hypersexuality, and racing thoughts are similar in both adolescents and adults, with differences only in developmental presentation. Geller and Luby (1997), for example, described grandiose beliefs in adolescents who, despite a lack of talent, believe they can become a rock star; whose excessive

activity takes the form of making curtains, illustrating a book, rearranging furniture, and making multiple phone calls all within a relatively brief period; or whose reduced need for sleep may take the form of sneaking out and partying all night. Engagement in high-risk pleasurable activities may involve a heightened interest in sex and risky sexual experiences, excessive spending through the use of parents' credit cards, taking dares, or driving more recklessly than their peers.

The assessment of bipolar illness in adolescents can be complicated. Tillman and colleagues (2004) found poor concordance between the symptom descriptions given by parents and offspring. Children and adolescents, for example, report the presence of racing thoughts and decreased need for sleep significantly more than do their parents, perhaps reflecting the reality that external and disruptive behaviors are more likely to be noted by parents. Other investigators have found high rates of bipolar spectrum in young people with recurrent depression (Smith et al., 2005), findings consistent with those of studies showing that adults with bipolar disorder tend to underreport hypomanic symptoms and impairment (Angst et al., 2003; Judd and Akiskal, 2003; Youngstrom et al., 2004). Supplemental assessment measures, such as the General Behavior Inventory and the Young Mania Rating Scale, add to diagnostic validity (Youngstrom et al., 2001, 2003; Findling et al., 2002). (See Chapter 11 for a more detailed discussion.)

Manic Features

Although the phenomenology of adolescent-onset mania has been studied incompletely, existing research clearly indicates a heterogeneity that may reflect different subgroups. Pooled data from several investigations of mania in adolescents have revealed pressured speech, euphoria, and hyperactivity to be the most common symptoms, similar to what has been found for adults (Faedda et al., 1995). Lewinsohn and colleagues (1995) noted a much higher frequency of elevated-expansive mood than irritability in their community sample (which, however, consisted primarily of those with bipolar spectrum rather than bipolar-I disorder). Faraone and colleagues (1997b), on the other hand, found relatively high rates of irritability and low rates of euphoria in their clinical sample of young manic patients. Both the Lewinsohn and Faraone subjects reported high rates of increased activity, grandiosity, and distractibility.

In an analysis of the symptoms of mania in 115 adolescents with manic or subsyndromal manic episodes, Lewinsohn and colleagues (1995) identified two factors: (1) behavioral disorganization, consisting of decreased need for sleep, flight of ideas, distractibility, and poor judgment; and (2) inflated self-esteem and increased activity. The

former factor was correlated more highly than the latter with functional impairment (school, family, and social), and the authors speculated that individuals scoring high on this factor might be more likely to experience psychotic symptoms during severe manic episodes. Even in adolescents with only subthreshold bipolar disorder, Lewinsohn and colleagues (2003) noted substantial impairment, comorbidity, and increased risk of suicide attempts (18 percent, compared with 3 percent in never mentally ill controls).

Mania in adolescents often includes psychotic features (see Chapter 2). Several studies have found that between one third and one half of adolescent bipolar patients have prominent psychotic symptoms.⁵ Kafantaris and colleagues (1998) found that half of the bipolar youths in their study who presented with psychotic mania had no prior psychiatric history and appeared to have experienced an acute onset after having functioned relatively well to that point. The authors suggested that this sudden-onset, psychotic subgroup may represent “classic” bipolar disorder. A recent study of 43 bipolar adolescents found that, in most, the prodromal onset was either slow with gradual deterioration (47 percent) or slow with quick worsening (39 percent). Rapid onset of illness was relatively uncommon (14 percent) (Correll et al., 2005). There is suggestive evidence that there are ethnic differences in psychotic features expressed during mania. A recent study compared clinical features in 17 bipolar African American adolescents and 61 bipolar Caucasian adolescents. Fully 90 percent of the African Americans had psychotic symptoms, as compared with only 30 percent of the Caucasian adolescents ($p < .001$) (Patel et al., 2006). These results are consistent with differences found between Caucasian and African American adult bipolar patients (Strakowski et al., 1996; Kirovetal, 1999).

Mixed mania and rapid-cycling mania are also common in those adolescents with bipolar disorder. Kutcher and colleagues (1998) studied a small, carefully ascertained clinical sample of 28 bipolar-I youths and found that the majority had mixed mania (74 percent), rapid cycling (76 percent), or both during their first (retrospectively assessed) episode. Fewer than 10 percent of the sample demonstrated a classic euphoric mania during their initial manic episode. Mixed episodes were reported by Faraone and colleagues (1997b) in 71 percent of a sample of 17 patients with adolescent onset of mania. McElroy and colleagues (1997) found that adolescents with bipolar disorder had a higher frequency of mixed episodes than was the case among comparison adult bipolar patients, but the investigators did not distinguish between childhood and adolescent onset in their adolescent sample. Findling and colleagues (2001) compared 56 children and 34 adolescents

with bipolar-I disorder and found that 56 percent of the adolescents had rapid cycling and 21 percent mixed states; proportions among children with bipolar-I disorder were similar. However, many of the adolescents with bipolar disorder in that study appeared to have had childhood onset. Finally, Strober and colleagues (1995) reported that the index episode in their inpatient sample (which was the first episode in 56 percent of the cases studied) was mixed in 19 percent and rapid cycling in 19 percent, with the other cases being “pure” depression or mania. An unresolved issue is whether rapid cycling or mixed states are particularly associated with bipolar adolescents with childhood onset, a typical developmental manifestation of bipolar illness in young people, or a subtype of bipolar-I disorder marking a course that may differ from more “classic” cycling episodes.

Depressive Features

For a substantial number if not the majority of individuals with adolescent-onset bipolar disorder, the illness starts with depression, thereby delaying recognition and diagnosis of the bipolar course. Kutcher and colleagues (1998) found that depressions were the first affective episodes in 75 percent of their sample of adolescents with bipolar-I disorder. Likewise, a community sample of adolescents with bipolar spectrum disorders revealed that 61 percent had experienced an initial depressive episode before mania or hypomania occurred (Lewinsohn et al., 1995). And among those who responded to a volunteer survey of members of the National Depressive and Manic-Depressive Association (now called the Depression and Bipolar Support Alliance), both early age at onset (childhood or adolescence) and female gender were associated with higher rates of initial depressive symptoms or both depressive and manic symptoms (Lish et al., 1994). The studies of Kutcher and colleagues (1998) and Lewinsohn and colleagues (1995) did not evaluate initial symptom presentation by gender status.

The switch rate of adolescent major depression to eventual mania or hypomania is quite variable across studies. Interpretation of this variation is complicated by the above-noted common practice of mixing children and adolescents in the same study samples. For instance, in a review of seven studies of more than 250 depressed children and adolescents followed for 2 to 4 years, Faedda and colleagues (1995) found a mean rate of switch from depression to eventual mania of about 25 percent. A review by Kovacs (1996) yielded a switch range of 8 to 37 percent; her own longitudinal study of 92 depressed children followed for 5 to 10 years yielded a rate of 21 percent. More recently, Birmaher and colleagues (2006) conducted a 2-year prospective study of 263 children and adolescents (mean

age 13 years) with bipolar-I ($n=152$), bipolar-II ($n=19$), and BP-NOS ($n=92$). Of the bipolar-II subjects, 21 percent converted to bipolar-I; 20 percent of the bipolar-NOS subjects converted to bipolar I, and 10 percent converted to bipolar-II. Females were more likely to convert than males (odds ratio, 3.2; 95 percent confidence interval [CI] 1.33–7.50). The findings are of considerable interest but somewhat difficult to interpret because of the mixed age range of the sample. Such variations in rates of switching among studies may depend on the mean age and age ranges of the sample, the diagnostic criteria used, the ascertainment source (that is, whether the study involved community, outpatient, or inpatient populations), and the extent to which the initial depressive episode was treated with antidepressants (see Chapter 23). In contrast to the high switch rate in Kovacs' childhood sample, for instance, Weissman and colleagues (1999a) revisited 10 to 15 years later an outpatient sample that had been diagnosed with major depression during adolescence, and found that only 4.1 percent had developed bipolar-I disorder and 1.4 percent bipolar-II disorder. As discussed earlier, severe depression during childhood (rather than adolescence) may portend higher rates of eventual bipolarity (e.g., Geller et al., 1994).

Further studies are needed not just on adolescent depression switch rates, but also on characteristics that link adolescent and childhood depression to eventual bipolar disorder (e.g., State et al., 2002). Strober and Carlson (1982) studied 60 inpatient depressed adolescents and identified several features predictive of eventual bipolarity: rapid onset of the depressive episode, psychomotor retardation, psychotic features, family history of mood disorders (especially bipolar), and antidepressant-related onset of mania or hypomania. It should be noted, however, that a recent study of switching during a 2-year period among adults with first-onset psychotic depression showed no association of switching with medication use, earlier age at onset, or family history of bipolar disorder (DelBello et al., 2003). A 15-year follow-up study of 74 young adults hospitalized for major depression (average age 23) found that 27 percent of the study group had experienced at least one episode of hypomania and another 19 percent an episode of mania (Goldberg et al., 2001). Psychosis during the depressive episode was significantly correlated with a switch into manic states (see Chapter 19). Predicting bipolar switching in cases of adolescent depression is an important area for further study because of speculation that treatment with antidepressant medications in the absence of knowledge of underlying bipolarity precipitates switches from depression to mania or hypomania and predicts a more adverse course of bipolar disorder with rapid cycling (see Chapter 19).

Depressive symptoms in adolescents with bipolar disorder tend to be quite similar to those seen in adults, although psychotic features are more common in the younger age group (Carlson and Strober, 1979; Chambers et al., 1982; Friedman et al., 1983). Preoccupation with death and thoughts of suicide are common, and suicide attempts are frequent (see Box 6-2 for one 15-year-old bipolar girl's account of her experience during a suicidal depression). Lewinsohn and colleagues (2003), for example, found that 44 percent of the bipolar adolescents in their sample had attempted suicide; in comparison, 22 percent of the adolescents with major depression had attempted suicide, as had 18 percent of those with subsyndromal bipolar disorder syndrome (defined by the investigators as abnormally and persistently elevated, expansive, or irritable mood plus one other DSM-III-R manic symptom, but never having met criteria for full bipolar disorder).

Course of Disorder

Longitudinal studies of youths with bipolar-I disorder are rare; therefore, most data on the course of the illness come from retrospective accounts or short-term treatment outcome studies (e.g., Kafantaris et al., 1998; Kutcher et al., 1998). The latter studies certainly document the likelihood of further episodes and hospitalizations, but more information is needed to clarify the predictors of relatively better or worse outcomes and responsiveness to treatment in patients with adolescent onset.

Strober and colleagues (1995) conducted one of the few longitudinal studies, a 5-year naturalistic follow-up of 54 adolescents (mean age 16.0) who had been inpatients diagnosed with bipolar-I disorder (although age at first diagnosable episode was not reported). The rate of recovery from the index episode was high (96 percent), with only 2 of the patients failing to achieve recovery during the 5-year period. However, time to recovery was affected by the polarity of the index episode: median time to recovery was significantly longer for those who had pure depressive episodes (26 weeks) compared with those who had pure manic (9 weeks) or mixed (11 weeks) episodes. The majority (56 percent) of those who recovered remained free of major relapses during the follow-up period, and the probability of relapse did not vary by polarity of the index episode (although among those who had multiple relapses, most had mixed or cycling index episodes). Suicide attempts sufficient to require medical attention occurred in 20 percent of the adolescents during the 5-year follow-up (Strober et al., 1995). None of the clinical or demographic factors that were evaluated in the study significantly predicted relapse, and all participants were treated aggressively. Thus it is important to note that the information on course derived from this study cannot be generalized to untreated bipolar disorder in adolescents.

BOX 6-2. Drowning in My Personal Hell

I'm being plunged into dark and murky waters
 Someone or something is holding me there
 I can't see—everything is black
 I try to swim, to get away, back to the top, but the force
 is holding me too tight
 Reluctantly I give up
 I feel myself slipping down
 Down, down, I am slipping down
 My head aches with the pressure, but I keep sinking
 With each inch, I grow colder
 With each second, my lungs grow tighter
 I pray to God to save me
 There is no answer
 I am deep now, buried under the layers of the sea
 The water seems to be eating me
 I wonder if I have entered Hell
 All I want is to die
 I want to relieve the pressure, the cold, the dark
 I've already lost myself
 My self is looking at me from above
 She is miles from me
 She is happy—she was me, but no more
 It doesn't matter anymore
 I'm not mad, not sad or scared
 I am no one; I am nothing
 I feel myself slipping down to the sea floor
 And I watch shadows of the sun laugh at me as I die

—Katrina Skefos, 15-year-old girl with bipolar disorder. Reprinted with permission.

A 2-year prospective study of adolescent-onset psychotic disorders by McClellan and colleagues (1999) included a comparison of a small group of bipolar youths with patients who had schizophrenia. The results indicated that 50 percent of the bipolar youths had an episodic course, and 40 percent were chronically impaired (but fared significantly better than the schizophrenic youths). Rajeev and colleagues (2003) observed adolescent-onset patients with bipolar mania for 6 months; like Strober and colleagues (1995), but unlike McClellan and colleagues (1999), they found 96 percent recovery and very little chronicity. Recently, researchers at the University of Pittsburgh, Brown University, and the University of California-Los Angeles conducted a longitudinal study of 263 bipolar children and adolescents (13.0 ± 3.1 years old); they interviewed their subjects on average every 35 weeks for 94.8 ± 51.5 weeks using the Longitudinal Interval Follow-up Evaluation. Although two thirds of the subjects recovered

from the index episode, 50 percent had at least one syndromal recurrence (Birmaher et al., 2005b). Subjects were symptomatic for the majority (60 percent) of the follow-up period; almost one quarter (22 percent) of the time was spent in full syndromal episodes.

Additional research is needed on predictors of treatment responsiveness in bipolar adolescents (see Chapter 23). Moreover, given the potential for misdiagnosis of bipolar disorder in youths, further studies of the potentially adverse effects of antidepressant medications and stimulants used to treat ADHD are warranted (e.g., Soutullo et al., 2002).

Pre- and Postmorbid Adjustment and Functioning

Premorbid adjustment would appear to be an important clue to the possible presence of subclinical symptoms in childhood prior to the onset or diagnosis of bipolar disorder (see also Chapter 4). However, relatively few studies have reported information on prior adjustment. In the study by Kutcher and colleagues (1998), 90 percent of bipolar-I patients with adolescent onset had excellent or average peer relationships, and more than 60 percent had good to excellent academic achievement, before their diagnosis. Such findings suggest that many youths with adolescent-onset bipolar disorder have relatively good functioning before being diagnosed. In the study by McClellan and colleagues (1999), better premorbid functioning predicted higher levels of functioning over 2 years and was a more significant predictor than diagnosis in a sample of schizophrenic and bipolar adolescents.

Once initiated, however, the course of bipolar disorder in adolescents is associated with considerable impairment. Kutcher (2000) found that a bipolar-I adolescent-onset sample followed for a mean of 4.6 years after their initial manic episode had lower rates of high school graduation and lower full-scale IQ scores than those of unipolar and non-ill controls (see also Quackenbush et al., 1996). They also had significantly worse problems with peers and greater dissatisfaction with peer relationships than the comparison groups. Likewise, in a cross-sectional study that included adolescents with mania and distinguished between childhood and adolescent onset, Faraone and colleagues (1997a) found significantly worse functioning on most social, peer, recreational, and family variables, as well as school performance, among bipolar youths compared with normal controls. Few differences in functioning were observed between childhood- and adolescent-onset bipolar youths, except that manic adolescents generally had worse relationships with parents than did manic children. A recent comparison of 18 bipolar adolescents and 18 normal control subjects found that adolescents with bipolar

BOX 6-3. One Adolescent's Experience with Bipolar Illness

The following is a first-person account of a hypomanic episode followed by severe depression in a 17-year-old girl. She went on to experience several further depressive and hypomanic episodes before becoming floridly manic in her 20s. This passage depicts the resilient recovery described by Carlson and Strober (1979), but it also underscores the disconcerting ability of some adolescents to continue the illusion of normal functioning even though seriously ill. It also illustrates many of the obscuring issues of adolescence and the effects of intense peer loyalties.

I was a senior in high school when I had my first attack of manic-depressive illness; once the siege began, I lost my mind rather rapidly. At first, everything seemed so easy. I raced about like a crazed weasel, bubbling with plans and enthusiasms, immersed in sports, and staying up all night, night after night, out with friends, reading everything that wasn't nailed down, filling manuscript books with poems and fragments of plays, and making expansive, completely unrealistic, plans for my future. The world was filled with pleasure and promise; I felt great. Not just great, I felt *really* great. I felt I could do anything, that no task was too difficult. My mind seemed clear, fabulously focused, and able to make intuitive mathematical leaps that had up to that point entirely eluded me. Indeed, they elude me still. At the time, however, not only did everything make perfect sense, but it all began to fit into a marvelous kind of cosmic relatedness....

Unlike the very severe manic episodes that came a few years later and escalated wildly and psychotically out of control, this first sustained wave of mild mania was a light, lovely tincture of true mania; like hundreds of subsequent periods of high enthusiasms it was short-lived and quickly burned itself out; tiresome to my friends, perhaps; exhausting and exhilarating to me, definitely; but not disturbingly over the top. Then the bottom began to fall out of my life and mind. My thinking, far from being clearer than a crystal, was tortuous. I would read the same passage over and over again only to realize that I had no memory at all for

what I just had read. Each book or poem I picked up was the same way. Incomprehensible. Nothing made sense. I could not begin to follow the material presented in my classes, and I would find myself staring out the window with no idea of what was going on around me. It was very frightening....

Each day I awoke deeply tired, a feeling as foreign to my natural self as being bored or indifferent to life. Those were next. Then a gray, bleak preoccupation with death, dying, decaying, that everything was born but to die, best to die now and save the pain while waiting. I dragged exhausted mind and body around a local cemetery, ruminating about how long each of its inhabitants had lived before the final moment. I sat on the graves writing long, dreary, morbid poems, convinced that my brain and body were rotting, that everyone knew and no one would say. Laced into the exhaustion were periods of frenetic and horrible restlessness; no amount of running brought relief. For several weeks, I drank vodka in my orange juice before setting off for school in the mornings, and I thought obsessively about killing myself. It was a tribute to my ability to present an image so at variance with what I felt that few noticed I was in any way different. Certainly no one in my family did. Two friends were concerned, but I swore them to secrecy when they asked to talk with my parents. One teacher noticed, and the parent of a friend called me aside to ask if something was wrong. I lied readily: I'm fine, but thank you for asking.

I have no idea how I managed to pass as normal in school, except that other people are generally caught up in their own lives and seldom notice despair in others if those despairing make an effort to disguise the pain. I made not just an effort, but an enormous effort not to be noticed. I knew something was dreadfully wrong, but I had no idea what, and I had been brought up to believe that you kept your problems to yourself. Given that, it turned out to be unnervingly easy to keep my friends and family at psychological bay.

disorder displayed significantly more deficits in social skills performance; however, no significant differences emerged between the groups in social skills knowledge (Goldstein et al., 2006).

Thus whereas some individuals with adolescent-onset bipolar disorder—especially those with severe childhood psychopathology—may have a relatively poor course of illness and adjustment, many cases of more “classic” bipolar

disorder emerge in adolescence. Such individuals may have relatively favorable outcomes in the long run and adequate if not excellent adjustment in the short run (Carlson and Strober, 1979). Box 6-3 presents a first-person account of a posthypomanic depressive episode in an adolescent who, although she subsequently developed full-blown psychotic manias, went on to have good academic and social functioning.

Comorbidity

Comorbidity complicates the diagnostic and clinical picture of adolescent-onset bipolar disorder, as it does for childhood-onset illness. Tables 6-3 and 6-4, respectively, display the results of the major studies of comorbidity among adolescent-onset and combined samples of adolescent- and child-onset bipolar subjects. Nowhere is the question of the meaning of comorbidity more complex than with adolescent-onset bipolar disorder, because the co-occurrence of psychiatric syndromes can be due to several factors. There are, for example, indistinct diagnostic boundaries and overlapping symptoms. Irritability, impulsivity, and excessive activity, for instance, are symptoms shared by bipolar and other syndromes. Moreover, there is a causal relationship between bipolar illness and other disorders, in that symptoms of mania or depression may lead to substance or alcohol abuse. (Likewise, substance abuse can precipitate mood disorders.) Too, there are shared genetic or other risk factors, such as parental assortative mating, and similar or related genes may be implicated in both ADHD and bipolar disorder. Considerable research, including carefully designed longitudinal studies, is needed to help clarify the meaning of comorbid conditions in those with childhood- and adolescent-onset bipolar disorder.

Comorbid conditions that commonly complicate differential diagnosis include drug or alcohol abuse, conduct disorder, and ADHD, all of which may involve manic-like symptoms of irritability, disruptiveness, hostility, impulsiveness, distractibility, antisocial behaviors, and the like. Psychotic symptoms may be mistaken for schizophrenia, and drug and alcohol abuse may obscure and complicate the diagnosis of mania, depression, or mixed states.

Comorbidity with personality disorders may also complicate the diagnosis of bipolar disorder in adolescents. Although relatively few studies of Axis II disorders in bipolar youths have been conducted, this important topic should be pursued because personality pathology not only makes differential diagnosis potentially difficult; it also affects the interpretation of studies of course and treatment outcome. A small study by Kutcher and colleagues (1990), for example, revealed a rate of 15 percent for borderline personality disorder among euthymic bipolar adolescents, and the presence of that disorder predicted worse responsiveness to lithium. Mood instability, impulsiveness, an inclination to suicide, irritability, and other characteristics of borderline personality disorder represent a conceptual challenge in determining the boundary between severe mood disorder and personality pathology. Such issues are pursued in greater detail in Chapter 10. It

is likely that mood instability and cognitive and behavioral dysfunction due to bipolar disorder in childhood and adolescence contribute to the development of personality pathology.

Studies vary in the rates of comorbid diagnosis reported among individuals with adolescent-onset bipolar disorder. Lewinsohn and colleagues (1995, 2003) found high rates of comorbid anxiety disorders (33 percent), substance abuse, and disruptive behavior disorders (22 percent each), as well as ADHD (11 percent), in their community sample of youths with bipolar spectrum disorders. Kutcher and colleagues (1998) found that 61 percent of their adolescent-onset sample had no psychiatric diagnoses other than mood disorders; among those who did, generalized anxiety disorder (21 percent), ADHD (11 percent), and conduct disorder (11 percent) were observed most frequently. Findling and colleagues (2001) also observed high levels of comorbidity (76 percent overall, including 62 percent with ADHD) among adolescents with bipolar-I disorder (many of whom, however, probably had had childhood onset). ADHD as a comorbid condition is of particular interest, as discussed earlier, because of the problem of differential diagnosis, markedly different treatment strategies, and the possibility that comorbid ADHD may identify a genetic subtype and predict a worse course and poorer response to lithium (e.g., Strober et al., 1998).

A recent European study of 98 consecutively referred bipolar children and adolescents found that 38 percent

were comorbid for ADHD (Masi et al., 2006). The mean age at onset for bipolar disorder was 10.0 ± 3.2 years and for ADHD was 3.7 ± 1.1 years. The bipolar patients with comorbid ADHD were predominantly male (73 percent) and younger, had an earlier age at onset of their bipolar illness (8.1 ± 2.8 years versus 11.1 ± 2.9 years, $p < .000$), were more likely to exhibit a chronic rather than episodic course (67 versus 33 percent), were more likely to have irritable rather than elated mood (62 versus 36 percent), and were likely to have overall greater psychiatric impairment. As the authors of the study pointed out, these differences are important:

An identification of ADHD may help to identify a specific subgroup of patients, with a more homogeneous course, outcome, and response to treatments. From a neurobiological standpoint, the identification of common biological pathways may help to more deeply define the links in the pathophysiology of both disorders, which are still under question. (p. 380) (see also Geller et al., 2006)

Neurodevelopmental Aspects of Adolescent Bipolar Disorder and the Issue of Puberty

Many studies use the term “prepubertal” or “pubertal” onset, but the vast majority have neither verified the pubertal status of research participants nor articulated a model of early-onset bipolar disorder in which “puberty” plays a role in pathophysiology. The issue is important, however, given

the frequent onset of bipolar disorder in adolescence, apparently after pubertal changes.

A neurodevelopmental emphasis has emerged in the field of schizophrenia (e.g., Lenzenweger and Dworkin, 1998), helping to identify early markers of neurocognitive impairment that are predictive of eventual schizophrenia, as well as to generate etiological models pertinent to abnormal brain development. Benes (1999) and others have noted the significance of puberty for the development of neural circuits that are relevant to mental disorders. Walker (2002), for example, explored the role played by hormones in neuromaturation, speculating that vulnerability to mental disorders such as schizophrenia, severe depression, and bipolar illness is mediated in part by the effects of hormones on gene expression. Further research on the development of the brain and on the role of pubertal changes in neurodevelopmental processes might help clarify whether pubertal effects are indeed significant in triggering underlying vulnerabilities to bipolar disorder.

A small body of research has begun to emerge on the neurocognitive, neuroanatomic, and neurochemical correlates of bipolar disorder in adolescents (e.g., Davanzo et al., 2003; DelBello et al., 2004; see also Chapters 9, 14, and 15). Sigurdsson and colleagues (1999), for example, reviewed chart notes for a sample of bipolar adolescents and found significantly greater evidence of delays in linguistic, social, and motor development among bipolar youths compared with those with early-onset unipolar depression, and especially among those who developed psychotic symptoms. Although the neurodevelopmental differences were relatively general and nonspecific, these findings are compatible with the hypothesis that such impairments are indicators of neurocognitive vulnerability factors for bipolar disorder. A growing literature suggests that bipolar youths are more likely than controls to demonstrate impairment on a wide variety of neuropsychological measures, including executive functioning, sustained attention, and working memory (Dickstein et al., 2004; Meyer et al., 2004; Doyle et al., 2005). These deficits, in turn, contribute to substantial academic difficulties (Pavuluri et al., 2006). There is accumulating evidence that comorbid ADHD significantly contributes to the cognitive deficits (McClure et al., 2005; Rucklidge, 2006).

In related work, Friedman and colleagues (1999) conducted a magnetic resonance imaging (MRI) study of adolescent bipolar and schizophrenic patients compared with non-ill youths. They found few differences among the patient groups, but the schizophrenic and bipolar youths differed significantly from normal controls on various measures, including reduced intracranial volume and increased frontal sulcal prominence, among others. These results are consistent with neurodevelopmental abnormalities and

raise many intriguing questions for further study (see also Botteron et al., 1995, and the review by Todd and Botteron, 2002). It should be noted, however, that such studies need to verify age at onset and clarify whether state or trait markers of disorder are being identified. Recent studies by Blumberg and colleagues (2003a, 2003b) found that adolescents with bipolar illness show decreased volumes of medial temporal lobe structures (with greater effect sizes in the amygdala than in the hippocampus) and signal increases in the subcortical portions of the frontal striatal circuits. Additional discussion on the need to pursue potential markers of neurodevelopmental vulnerability for bipolar disorder is presented in our later review of the offspring of bipolar parents (see also Chapters 13, 14, and 15).

EPIDEMIOLOGY OF BIPOLAR DISORDER IN CHILDREN AND ADOLESCENTS

Three problems limit understanding of the prevalence of bipolar disorder in young populations: epidemiologic surveys encompassing children and adolescents have been rare (see Chapter 5); few have included bipolar disorder as an object of inquiry; and in most of the studies that are available, data have not been presented separately for children and adolescents or specified age at onset.

Chapter 5 (see especially Table 5–13) presents the results of community-based epidemiologic studies that have included children and adolescents, and those findings are not duplicated here. The sparse data available from representative community and psychiatric samples illustrate several patterns that are generally accepted and confirmed by clinical studies. First, childhood bipolar-I disorder is rare in community samples (although, of course, more prevalent in clinical samples). Second, bipolar disorder occurs among adolescents at about the same rate as in the general adult population. Third, subsyndromal forms of bipolar disorder can be identified in child and adolescent samples, and can reflect prodromal or stable dimensional traits of the bipolar spectrum that may be associated with impairment of functioning.

Some have asserted that the frequency of bipolar disorder in youngsters is increasing. There has been some evidence that rates of childhood- or adolescent-onset bipolar disorder have increased in more recent cohorts (e.g., Rice et al., 1987; Chengappa et al., 2003; Kessler et al., 2005) and that this increase is not due to increased ascertainment alone. It is difficult to determine the validity and generalizability of this conclusion, however, given the lack of epidemiologic surveys with comparable data over time, as well as the lack of consistent diagnostic criteria. Moreover, increasing rates of apparent mania in clinical samples of children and adolescents may reflect methodological

matters, such as age-related changes in awareness and memory, temporal changes in morbidity and sample availability, and diagnostic practices (see Chapter 5).

At the same time, it has been argued that changes in health practices and environmental factors may induce earlier expression of bipolar disorder—or actual increased rates of bipolarity. Such factors may include widespread and increased use of stimulant and antidepressant medications (e.g., Zito et al., 2002) that could trigger bipolar rapid-cycling patterns in susceptible children or decrease the age at onset (DelBello et al., 2001); alcohol and drug use at younger ages, possibly inducing earlier onset of bipolar symptomatology; earlier onset of puberty; and exposure to maternal health risks during pregnancy (e.g., smoking, drug and alcohol intake, dietary reductions in omega-3 fatty acids, social stressors). Also, as noted in Chapter 13, genetic anticipation effects may promote earlier onset. These issues are clearly important, with critical implications for etiology and treatment, and require further study.

IMPLICATIONS OF CHILDHOOD AND ADOLESCENT ONSET OF BIPOLAR DISORDER

Other chapters in this volume address some of the implications of the onset of bipolar disorder in childhood and early adolescence, including effects of age at onset on course (Chapter 4), epidemiology and the possibility of cohort changes in age at onset (Chapter 5), genetic implications of early onset (Chapter 13), and treatment considerations (Chapter 23). A few important issues merit emphasis here, however, including the implications of childhood and adolescent onset for treatment and prevention.

Clinical Implications

Even apart from the goal of validating the diagnostic features of childhood bipolar disorder, it is important to study whether the outcomes and features of childhood-onset cases of the disorder differ from those of adolescent- and adult-onset cases. If, as discussed earlier, childhood onset reflects a particularly virulent form of the disorder, then relatively chronic symptomatology, mixed-state episodes, and rapid cycling might be expected to continue. It is possible, however, that such atypical features reflect developmental manifestations of nonspecific severe dysregulation, with maturity revealing a more recognizable episodic course with relatively better interepisode functioning. To answer this question, relevant longitudinal studies would need to separate out the effects on course and functioning that are due to comorbid childhood psychopathology—and indeed, to determine whether such

clinical conditions reflect true cases of multiple disorders or diffuse, severe bipolar symptomatology.

Preliminary studies suggest that early onset may indeed portend a worse course. Unfortunately, these studies do not always differentiate childhood from adolescent onset. Carlson and colleagues (2000) found that early-onset psychotic manic patients (onset before 21 years of age) had significantly poorer recovery between episodes, more manic episodes, and more time in the hospital during 2-year follow-up as compared with later-onset psychotic manic patients. Early-onset patients also were more likely than later-onset patients to have mixed episodes. The early-onset patients were significantly more likely to be male, high school dropouts, and never married. In a subsequent study of the same sample, Carlson and colleagues (2002) performed a separate analysis for the effects of “early onset” of bipolar disorder and comorbid childhood psychopathology. They determined that the two factors had somewhat independent effects in predicting outcome, with childhood disorders being more likely to predict poor functional outcome and early age at bipolar onset being related to continuing symptoms.

Similarly, Schurhoff and colleagues (2000) found that a group of bipolar patients with early onset (before age 18) was significantly more impaired, had more psychotic features, and had poorer response to lithium prophylaxis than a group with late onset (after age 40). Also, the early-onset group had more first-degree relatives with bipolar disorder. These findings are consistent with those of the above-noted retrospective self-report volunteer survey of members of the National Depressive and Manic-Depressive Association (Lish et al., 1994). Those who reported early (childhood/adolescent) onset (60 percent) were compared with adult-onset respondents on various indicators of functioning. Onset in childhood and adolescence was associated with significantly greater likelihood of social morbidity, as indicated by dropping out of school, financial difficulties, marital problems, being unmarried, alcohol and drug abuse, injury to self or others, and minor crime. Those with early onset also reported significantly more recurrent bipolar illness. Statistical analyses indicated that the effects on social morbidity were due to independent contributions by frequency of recurrences and early onset. Those with early-onset bipolar disorder reported that their initial symptoms were more likely to be depressive than manic and that their recurrences were predominantly depressive as well.

Neither the study of Schurhoff and colleagues (2000) nor the National Depressive and Manic-Depressive Association survey evaluated effects of childhood comorbid disruptive disorders. However, this is an important consideration in interpreting the effects of early age at onset, because

those conditions may confound the results of such analysis, with outcomes perhaps being attributed inaccurately to bipolar disorder. A further consideration is that childhood or early-adolescent onset of bipolar disorder may cause later comorbid conditions (see the earlier discussion of comorbidity). For instance, Tohen and colleagues (1998) found that early age at onset, male gender, and the presence of mixed states predicted the development of substance abuse in bipolar patients (see Chapter 7).

Other methodological issues also need to be considered in studies of the effects of age at onset. As noted, few longitudinal studies exist; most data are therefore based on retrospective reports or short-term follow-up. Moreover, many studies have had small sample sizes. In addition, studies may differ as to whether they assess separately for psychotic features, effects of prior depressive histories and comorbid childhood disorders, and clinical presentation (such as mixed or cycling episodes)—all of which may affect prognosis. Despite these limitations, it appears that childhood and adolescent onset may portend greater functional impairment, and possibly a more difficult clinical course.

Implications for Treatment and Prevention

As noted elsewhere in this volume, two treatment issues are salient in considering the implications of childhood and early-adolescent onset of bipolar disorder (see Chapter 23). One is that misdiagnosis may worsen the course of bipolar illness. For instance, antidepressant-induced rapid cycling in adults may have a counterpart in children who have been erroneously diagnosed as having nonbipolar depression. It has been speculated that some cases of rapid or ultra-rapid cycling in children may stem from antidepressant treatment for depression—although the role of such treatments in this age group has not been thoroughly investigated. It has also been theorized that stimulants used to treat ADHD may worsen the course of bipolar disorder in children. Some have suggested that the widespread use of antidepressant and stimulant medications in U.S. children may have led to more cases of childhood onset of bipolar disorder in the United States than in European and other nations, where such medications are used less frequently in children (e.g., Rechard et al., 2000). These hypotheses require empirical validation, and in fact one review of the findings of preliminary studies casts doubt on notions of the negative impact of antidepressants and stimulants (e.g., Meyer et al., 2004). Further studies are vital to provide guidelines for maximally effective interventions for children with probable mood disorders.

The second treatment issue is the widely cited hypothesis that bipolar disorder is a progressive illness with neurobiological “kindling”—that is, episodes beget episodes (see,

for example, Post, 2006, and Chapter 4). If this were in fact the case, vigorous early intervention with mood-stabilizing drugs to prevent episodes would have critical and positive implications for long-term outcome. The successful use of such interventions would then depend on research aimed at identifying the earliest valid markers of bipolar disorder. At the very least, early recognition and diagnosis of established cases could have important consequences for treatment and eventual course. These are not easy tasks, however. Underrecognition of childhood disorders and underutilization of treatment are rampant problems in public health, not limited to mood disorders.

STUDIES OF CHILDREN AT HIGH RISK

Children at risk for bipolar disorder as a result of parental bipolar illness represent an ideal sample for the study of potential antecedents (see Chapter 13 for a full discussion of the genetics of bipolar disorder). The high-risk methodology in psychopathological research—that is, the study of children of psychiatrically ill parents—has been employed productively for more than 25 years to accomplish several interrelated goals. First, examination of early signs of a disorder in offspring helps clarify the course of the illness from its initial expression to its unfolding over the course of development. Identification of early signs of bipolar disorder in a prospectively followed high-risk sample is an especially useful approach to validation of the developmental manifestations of symptomatology and establishment of diagnostic certainty. Second, assessment of putative markers of a disorder can help flag those who will eventually develop it, and thereby identify possible targets for early intervention (a potentially important accomplishment for children with bipolar disorder, as discussed earlier). Third, study of such markers and other environmental and contextual factors that influence children’s development can help clarify the psychological processes by which possible genetic predispositions are, or are not, manifested as disorders.

Despite their usefulness, however, offspring studies of bipolar disorder have limitations. For one thing, these high-risk children represent a unique sample not necessarily generalizable to the entire population of bipolar probands. By definition, youngsters in families with a bipolar parent experience both the genetic risk (perhaps a uniquely strong one) and the environmental impact of living with such a parent. The challenge to researchers is to disentangle these interrelated factors. Eventually, more precise knowledge of genetic factors will yield a greater understanding of the contributions of psychological and environmental factors to bipolar outcomes among those at risk. At the same time, while the majority of current offspring studies, as designed, do not clarify genetic contributions as such,

they do shed light on early signs of bipolar disorder in children and young adolescents.

There are numerous methodological obstacles to be overcome in studies of high-risk children, including issues of diagnosis (how broad a spectrum of bipolarity to include, how comorbid conditions should be conceptualized and analyzed), evaluation of outcomes, and assessment of the many factors in families with bipolar illness that contribute to children's adjustment. Too, because the age range for the onset of bipolar disorder extends over decades, a cross-sectional evaluation of children is likely to be misleading (some children diagnosed with major depression or ADHD, for example, may later convert to bipolarity). Moreover, sample sizes in many high-risk studies have been small, and interviewers have not been blind to parental diagnosis. Finally, the majority of high-risk studies of children having a parent with bipolar disorder were not specifically designed to assess early signs of bipolarity and thus may not have realized their full potential. Research on children at risk for bipolar disorder is less well advanced than is the case for other major disorders, such as schizophrenia or unipolar depression. The latter fields have produced intriguing insights into the neurodevelopmental and neurocognitive markers of schizophrenia and of family and psychosocial risk factors in depression. Studies of families at high risk for bipolar disorder, by contrast, have been less common and less methodologically sophisticated. However, this situation is changing rapidly with improved diagnostic methods, theoretical developments to guide the search for potential markers and risk factors and mechanisms of action, and increased interest among researchers and affected families alike in learning more about options for early intervention.

Recent and Direct-Interview Studies of Children of Bipolar Parents

Early offspring studies were unsystematic or methodologically limited but still contributed important evidence regarding the risk to children of bipolar parents. Information from these early studies is presented in Box 6-4. In the following sections, we summarize the results of more methodologically sophisticated work. Before proceeding, however, we must make clear that the term "children" of bipolar parents refers generally to both preadolescent and adolescent offspring; as with the early-onset literature generally, the results of the great majority of studies have not been separated out by age.

Clinical Outcomes in Controlled Studies

Table 6-5 summarizes numerous high-risk studies that we selected because they had comparison groups and used adequate measures for assessing children's clinical status.

Specifically, both the child and a parent were interviewed, using well-established structured or semistructured interview methods to assign diagnoses. Many of the studies were attentive to matching bipolar and comparison families on demographic factors, and several also included diagnostic information on the nonproband parent. These studies represent the current state of the art of research on the offspring of bipolar parents.

The studies are relatively consistent in reporting higher rates of lifetime diagnosis among children of bipolar parents compared with those of non-ill controls. The diagnoses include the full range of childhood mood, anxiety, and behavioral disorders. Most of the studies found that children of bipolar parents were particularly likely to display mood disorders—chiefly depression, but also forms of bipolar disorder. A recent study (Klimas-Dougan et al., 2006) found slightly increased rates of major depressive disorder in children of mothers who had bipolar disorder (12 percent) or major depression (17 percent) as compared with children of mothers who were psychiatrically well (8 percent). Much more striking, however, the children of bipolar mothers showed far more neurocognitive deficits—in executive functioning, perceptual memory, and sustained attention—than the children of either the unipolar or psychiatrically well mothers. There were no differences in verbal memory between the high-risk and control children.

Only a few investigators looked for sampled subclinical manifestations of bipolar illness. Decina and colleagues (1983) observed the presence of subclinical symptoms—including expansiveness, excitability, need for constant attention and admiration, need for reassurance, and other traits potentially suggestive of hyperthymic or depressive personality—in half of nondiagnosed offspring. Depressive traits were observed in a substantial proportion of children of bipolar parents by Grigoriu-Serbanescu and colleagues (1991). Reichard and colleagues (2005) administered the General Behavior Inventory (GBI) and the Kiddie Schedule for Affective Disorders and Schizophrenia (KSADS) to 129 adolescents and young adult offspring of bipolar parents at initial assessment and 14 months later. At 5-year follow-up, both the GBI and the Structured Clinical Interview for DSM (SCID) were administered. The scores on the Depression scale of the GBI for the offspring who later developed bipolar disorder were significantly higher than those for the offspring who did not. For the offspring with unipolar depression at the first assessment, the scores on the Depression scale were significantly higher for those who converted to bipolar disorder than for those who did not. Carlson and Weintraub (1993) found that young-adult offspring of bipolar parents scored significantly higher on a scale rating of subsyndromal bipolarity than

BOX 6-4. Early Studies of Children of Bipolar Parents

The earliest studies of the impact on children of having a bipolar parent either were uncontrolled observations with no systematic comparison groups or consisted of psychiatric comparisons in studies of children of schizophrenic patients. Typically, the clinical studies had very small samples, and the assessment of the children was conducted by investigators who were not blinded to the parents' diagnosis. Early methods of assessing children typically relied on unsystematic observations or parent reports, which may be biased. In addition, the initial studies were generally guided by the assumption that risk was due exclusively to genetic factors, so that family (and spousal) characteristics were largely unreported. Despite these limitations, however, intriguing patterns began to emerge.

The earliest high-risk studies were conducted on schizophrenic patients and often included a comparison group of parents with affective disorders or psychotic mood disorders. As a result of the use of earlier diagnostic frameworks, such as DSM-I or DSM-II, the affective disorder groups contained a mix of unipolar and bipolar families, and some of those diagnosed as schizophrenic may have been bipolar. The St. Louis High-Risk Study (e.g., Worland et al., 1979) and the Stony Brook High-Risk Project (Weintraub and Neale, 1984) included hospitalized depressed comparison subjects, both unipolar and bipolar. The Stony Brook sample represents what is probably the largest comparative high-risk study, involving 113 children of unipolar parents, 73 of bipolar parents, 57 of schizophrenic parents, and 297 of normal parents.

Other studies were well designed in terms of careful diagnostic evaluations and comparisons with at least one other normal or psychopathological group but were limited in their assessment of the children (e.g., parent report only, nondiagnostic methods) or had small samples. These included studies by Conners and colleagues (1979) comparing children of 16 bipolar and 43 "other psychopathology" (primarily unipolar depressed) groups, and those by Greenhill and colleagues (1980) reporting on offspring of 7 bipolar and 2 unipolar parents. Other studies did not include a comparison group: Kuyler and colleagues (1980) studied 49 children of 27 parents, and Waters and colleagues (1983) sampled adult offspring of 17 bipolar parents. Investigations by McKnew and colleagues (1979) and Cytryn and colleagues (1982) were forerunners of later well-designed work by Gershon and colleagues (1985), which is listed in Table 6-2 as an example of a good case-control study with direct diagnostic evaluations of children. A study by LaRoche and colleagues (1987) that included 37 offspring of 21 bipolar families is unique because it reported 3 to 7 years of follow-up data on the children.

Virtually all of these studies found high rates of psychiatric disorders among children of bipolar parents—higher than in normal comparisons or than would be expected in the general population. Most of the studies specifically indicated higher levels of affective disorders in offspring. Among the adult offspring studied by Waters and colleagues (1983), 9 (17 percent) of 53 had been diagnosed as bipolar by young adulthood. The LaRoche and colleagues (1987) follow-up, including offspring up to age 25, found that 24 percent had been diagnosed, mainly in the affective disorder spectrum. Two studies compared offspring of bipolar and unipolar parents. Conners and colleagues (1979) found higher rates of symptoms and disorders among the children of unipolar depressed parents, whereas offspring of unipolar and bipolar parents in the Stony Brook sample did not differ from each other but were significantly more symptomatic than children of non-ill controls (Weintraub, 1987).

Two additional studies from the 1980s are informative. Zahn-Waxler and colleagues (1988) compared 7 children of bipolar parents with 12 control children. The unique features of this investigation were the inclusion of infants studied up to age 5 or 6 years and the intensive study of family relationships and children's psychosocial development. The offspring of the bipolar parents displayed a range of behavioral and adjustment difficulties that persisted at follow-up. This study was eventually expanded as the Radke-Yarrow and colleagues (1992) investigation, which is reported in the text, along with the data yielded on toddler development and parent-child relations.

An investigation by Akiskal and colleagues (1985) focused on affective symptoms in referred children who were known to be offspring or siblings of adult bipolar patients. Although not a traditional high-risk study, the work was aimed at identifying possible signs and symptoms of bipolarity in youngsters at risk. Using the investigators' Mood Clinic Data Questionnaire, which included diagnostic criteria as well as subclinical symptoms, the study revealed several features characteristic of the sample. Onset of systems before puberty was rare, and all bipolar diagnoses occurred after puberty. Acute depressive episodes and dysthymic-cyclothymic disorders were the most common symptom patterns. By the end of 3 years of follow-up, bipolar outcomes were prominent: 19 (28 percent) of 68 children were bipolar-I, and 12 (18 percent) were bipolar-II; 2 were rapid cyclers, and 6 were cyclothymic. There were no signs of bipolarity in 43 percent of the children; the authors argued, however, that 7 of these children were "pseudo-unipolar" and potentially at risk for bipolarity, as suggested by pharmacological hypomania.

TABLE 6–5. High-Risk Studies with Comparison Groups and Direct Assessment of Children: Clinical Findings

Study	HIGH RISK		COMPARISON		ASSESSMENT	
	Parents	Children	Parents	Children	Method	Findings
Decina et al., 1983	11 BP-I, 7 BP-II (7 fathers, 11 mothers)	14 M, 17 F (ages 7–14)	14 with no disorder	10 M, 8 F (ages 7–14)	Direct interview of child and parent; semistructured interview with some KSADS items.	Significantly higher rates of mood disorders in bipolar offspring than in offspring of non-ill parents; 50% of bipolar offspring had some psychi- atric diagnosis. Presence of subclinical affective symptoms suggestive of depressive or hyperthymic personality.
Klein et al., 1985 ²⁰⁹	24 BP (11 fathers, 13 mothers)	19 M, 18 F (ages 15–21)	14 with psychiatric disorders (outpatient) (10 fathers, 4 mothers)	13 M, 9 F (ages 15–21)	Direct interview of child; structured interview (KSADS) modified to include cyclothymia.	Significantly higher rates of mood disorders (38%) in offspring sample compared with psychi- atric sample (5%). High rate of cyclothymia (9 of 16 youths). Higher risk of mood disorders if mother bipolar.
Gershon et al., 1985	19 BP-I (sex unspecified) and spouses; (12 had unspecified diagnoses)	12 M, 17 F (ages 6–17)	22 with no disorder (sex unspecified)	16 M, 21 F (ages 6–17)	Direct interview of child and parent; structured interview (KSADS-E); used “NIMH criteria,” similar to RDC.	3 (10%) of 29 offspring of bipolar parents had mania/hypomania vs. none for controls. Overall, 66% of offspring of bipolar parents vs. 43% of controls had some diagnosis. No significant effect of two ill parents.

TABLE 6–5. High-Risk Studies with Comparison Groups and Direct Assessment of Children: Clinical Findings (*continued*)

Study	HIGH RISK		COMPARISON		ASSESSMENT	
	Parents	Children	Parents	Children	Method	Findings
Nurnberger et al., 1988	(1) 23 BP or schizoaffective (sex unspecified; one parent ill); (2) 9 families with two ill parents (both BP or schizoaffective, or one ill and the other with “loaded” family history of disorder; sex unspecified)	(1) 15 M, 23 F (ages 15–25); (2) 9 M, 6 F (ages 15–25)	39 with no disorder (sex unspecified)	18 M, 21 F (ages 15–25)	Direct interview of child; structured interview (SADS-L adapted for children).	67–74% of offspring of one or two ill parents had disorders vs. 31% of normal controls. Over 1- or 2-year follow-up, increased rates of disorder were found in offspring of bipolar parents, including major affective illness and affective spectrum disorders.
Grigoroiu-Serbanescu et al., 1989	28 BP-I mothers, 19 BP-I fathers; spouses (34 no disorder, 13 other disorder)	34 M, 38 F (ages 10–17)	61 couples with no disorder	34 M, 38 F (ages 10–17)	Direct interview of child and parent; structured interview (KSADS-E); reported point prevalence.	7 (10%) of 72 offspring had affective disorder (1 bipolar); there were also significantly higher rates of anxiety disorders, ADHD, and personality disorders than in control offspring. Severity of illness in offspring was related to severity of illness in parent and psychopathology in spouse of bipolar parent.
Hammen et al., 1990	14 BP mothers ^a and spouses (7 fathers with no disorder, others with varied disorders)	8 M, 10 F (ages 8–16)	(1) 16 unipolar mothers and spouses (5 fathers no disorder, others with varied disorder); (2) 14 medically ill	(1) 10 M, 12 F; (2) 9 M, 9 F; (3) 19 M, 19 F (all groups ages 8–16)	Direct interview of child and parent; structured interview (KSADS-E).	Rates of current and past affective and disruptive behavior disorders were significantly higher in unipolar and bipolar groups. Cumulative probability of major depression was .67 in

		mothers and spouses (5 fathers no disorder, others varied disorders); (3) 24 non-ill mothers and spouses (15 fathers with no disorder, others varied disorders)	unipolar, .33 in bipolar, .45 in medical, and .12 in non-ill groups through 3-year follow-up. By age 19, the cumulative probability of any significant diagnosis in bipolar offspring was .75 (.85 in unipolar group). Bipolar offspring had later age at onset.			
Radke-Yarrow et al., 1992	22 BP mothers ^b (5 BP-I, 17 BP-II) and spouses (14 unipolar fathers, 8 fathers with no disorder)	Sibling pairs: 22 ages 1½–3½ ^c , 22 ages 5–8 ^b (gender not specified, stated as "approximately equal" in each group)	(1) 41 unipolar mothers ^d and spouses (22 fathers with depression or anxiety disorder, 19 fathers with no disorder); (2) 37 mothers with no disorder and spouses (37 fathers with no disorder) ^c	(1) Sibling pairs: 41 ages 1½–3½ ^c , 41 ages 5–8 ^c ; (2) sibling pairs: 37 ages 1½–3½ ^c , 37 ages 5–8 ^c	Age <4 yr: psychiatric evaluation based on observation of standardized play sessions, mothers' reports on CBCL; age >4 yr: CBCL, structured interview of child (Child Assessment Scale), DSM-III criteria	Outcomes varied by children's age and maternal group, mother or psychiatrist report. Generally, children of bipolar and unipolar mothers were more likely than control children to have disruptive and depressive disorders. Offspring of bipolar mothers had later onset than those of unipolar mothers. No differences between groups with one and two ill parents.
Carlson and Weintraub, 1993 (follow-up of Weintraub and Neale, 1984)	134 children of BP parents originally studied at ages 7–16; follow-up of 125 after age 18	211 of 240 in original group of children of parents with unipolar depression, schizophrenia, substance abuse; 98 of 108 in original group of children of normal controls	Results reported on adult follow-up based on SCID interviews, DSM-III criteria.	4.8% of offspring of bipolar parents had definite bipolar disorder, 53% had some diagnosis overall. In childhood, 28% had behavior problems, 30% attention problems (all significantly higher than normal controls but not "other" controls). Such problems predicted mood disorders in adulthood.

TABLE 6–5. High-Risk Studies with Comparison Groups and Direct Assessment of Children: Clinical Findings (*continued*)

Study	HIGH RISK		COMPARISON		ASSESSMENT	
	Parents	Children	Parents	Children	Method	Findings
Todd et al., 1996	30 families selected because adult bipolar proband or proband's adult sibling was in bipolar pedigree study (NIMH Genetic Initiative Study); 12 parents affected: 8 BP-I, 1 BP-II, 3 unipolar depressed	Total sample across 30 families: 24 M, 26 F (ages 6–17); 23 offspring of affected families	18 sets of parents with no disorder	27 offspring of nonaffected families	Direct interview of child and parent, structured interview (Diagnostic Interview for Children and Adolescents-Revised) with revised mania sections.	9 offspring of 23 affected parents had affective disorder (including 5 bipolar), compared with 3 of 27 with unaffected parents.
Birmaher et al., 2005 ²¹²	132 BP: 56% BP-I, 36% BP-II, 8% BP-NOS or cyclothymia (79% mothers)	210: 49% F (average age = 12.0 yr)	79: 29% MDD, 9% dysthymia (90% mothers)	138: 57% F (average age = 11.5 yr)	Parental interview. Children assessed by KSADS-PL, K-MRS, KSADS-P. Family history obtained via FHRDC, DSM-IV diagnosis.	Offspring of BP parents showed 7.7-fold higher risk for any BP disorder, 4.0-fold risk for any mood disorder, and 2.2-fold risk for anxiety disorders.
Jones et al., 2006	19 BP-I, 1 BP-II (5 fathers, 15 mothers)	6 M, 19 F (ages 13–19)	19 with no disorder	6 M, 16 F (ages 13–19)	SADS-L, Self-report measures, actigraph, Social Rhythm Metric, diaries	Significantly higher rates of mood disorders in children of bipolar parents (CBP) (14/19) than in offspring of non-ill parents (CC) (2/19), $p < .001$. CBP had stronger ruminative coping styles and significantly greater self-esteem variation, but did not differ in positive affect. CBP exhibited shorter and less variable sleep latency.

Klimas-Dougan et al., 2006	25 BP mothers 37 MDD mothers	43: 61% F (average age = 15.1 yr) 72: 64% F (average age = 16.0 yr)	26 psychiatrically well mothers	50: 48% females (average age = 15.3 yr)	Administered a battery of neuropsychological tests, including Wisconsin Card Sorting Test, Trail Making Test, California Verbal Learning Task, Continuous Performance Task, and WISC-R/WAIS	Lifetime MDD diagnosis: children of bipolar mother, 12%; MDD mother, 17%; well mother, 8%. Children of BP mothers exhibited deficits in executive functioning, perceptual memory, and sustained attention, but not in verbal memory. These deficits were not found in children of MDD mothers or in healthy control mothers.

did the offspring of both normal and "other" parents. A study by Klein and colleagues (1985) is noteworthy for the development and testing of a scale specifically for cyclothymic symptoms; it was found that more than half of the offspring of bipolar parents who had a diagnosis of affective disorder met criteria for cyclothymia.

Hirshfeld-Becker and colleagues (2006) compared 34 offspring of bipolar parents with 244 offspring of parents without bipolar disorder. Children (ages 2–6) had been classified in laboratory assessments as behaviorally inhibited, disinhibited, or neither. Offspring of bipolar parents had significantly higher rates of disinhibition than offspring of parents without bipolar disorder (53 versus 34 percent; odds ratio = 2.62, 95 percent CI = 1.22–5.62). The association between parental bipolar disorder was even stronger among the offspring of parents with bipolar-I illness (67 versus 34 percent; odds ratio = 5.01, 95 percent CI = 1.84–13.62). There was no difference in the rate of inhibition between the offspring of parents with and without bipolar disorder.

In one of the rare follow-up designs, Hammen and colleagues (1990) found that, despite relatively high rates of diagnosis over time, children of bipolar mothers were generally less chronically and severely impaired than those of unipolar mothers. The largest follow-up study, conducted by Carlson and Weintraub (1993) with 125 young-adult offspring of bipolar parents, found a rate of definite bipolar disorder of nearly 5 percent, as well as higher rates of diagnosis overall relative to normal comparison groups; generally, however, the bipolar offspring did not differ in symptoms and functioning from offspring of parents with other disorders (e.g., unipolar depression, schizophrenia, substance abuse).

A recent 5-year prospective study of adolescent offspring of parents with bipolar disorder found that the lifetime prevalence rate of bipolar disorder in the offspring increased from 3 to 10 percent at follow-up. The lifetime prevalence of overall mood disorders increased to 40 percent and of overall psychopathology to 59 percent (Hillegers et al., 2005). With the exception of one individual, all of the adolescent subjects subsequently diagnosed with bipolar illness first presented with a unipolar expression; this initial diagnosis occurred an average of 4.9 years (standard deviation = 3.4 years) before the first hypomanic or manic expression.

In their longitudinal study of young children of unipolar and bipolar mothers, Radke-Yarrow and colleagues (1992) initially found worse functioning in offspring of unipolar mothers, but in later analyses (Radke-Yarrow, 1998), the differences between unipolar and bipolar groups were negligible. This work is unique in that the sample was recruited to include mothers with sibling pairs—one of

toddler age (1½–3½) and the other of early school age (5–8); the families were studied at three points in time over a 10-year period. The young children of bipolar mothers, who suffered mainly from depression (bipolar-II), tended to have depressive and disruptive disorders; offspring in early adolescence had a diagnosis rate of 58 percent, especially for depressive and anxiety disorders, but they also had higher rates of disruptive disorders than children of well mothers. At younger ages, the offspring of unipolar mothers tended to have slightly more diagnoses than those of bipolar mothers, but both groups were substantially more likely to have disorders than the children of well mothers. By early adolescence, however, the children of bipolar mothers had similar rates of disruptive and anxiety disorders and higher rates of depression than children of unipolar depressed women. Of interest, it appeared that those offspring in all groups with early signs of disruptive disorders (20 percent) were more likely than those without such signs (2 percent)¹ to develop bipolar disorder by adulthood. The combination of a bipolar mother and an early history of chronic disruptive disorder was highly predictive of eventual bipolar disorder by adulthood—although the actual number of cases was small (Meyer et al., 2001).

A recent University of Pittsburgh study (Birmaher et al., 2005a) evaluated the lifetime prevalence of psychiatric disorders in 210 offspring of 132 parents with bipolar disorder. Rates of illness in these high-risk children were compared with those in 138 offspring of 79 community controls who were healthy or had nonbipolar psychiatric illnesses and who were matched by age, sex, and neighborhood. The offspring of parents with bipolar illness showed a 7.7-fold higher risk for bipolar disorder and a 4-fold increased risk for any mood disorder. The median age at onset for bipolar illness in the offspring was 9, but the rates of mood disorders rose steeply during adolescence. There were no differences in the rates of ADHD between the offspring of bipolar parents and those of controls.

The studies listed in Table 6–5 generally indicate few gender differences overall, although there may be gender-typical patterns of disorders, such as more disruptive behavior disorders in boys and more depressive disorders in girls. Moreover, although a few studies compared outcomes for children with one versus two ill parents, no definite conclusions could be drawn. There appears to be an increased likelihood that a bipolar adult will marry a person who also has a diagnosable disorder (nonrandom mating), thereby making it more likely that the couple's children will acquire a mix of genetic predispositions, in addition to being raised in a potentially disruptive family environment as a result of parental impairment or marital distress. There is a need for further evaluation of the impact

of the marital relationship, as well as the gender and mental health of the spouse, as psychosocial contributors to outcomes among offspring (see Chapter 10).

The results of these case-control studies, along with those of other designs that did not include comparison groups but did report children's diagnoses, were summarized in a meta-analysis by Lapalme and colleagues (1997). They concluded that 52 percent of the offspring of bipolar parents met criteria for a diagnosis of at least one psychiatric disorder, compared with 29 percent of children of parents with no disorders—a highly statistically significant difference. (Note that these figures should be viewed as approximations because some of the samples overlapped, potentially causing cases to be counted more than once.) Aggregating across various samples makes it easier to see the specific concentration of mood disorders in the offspring. In total, 26.5 percent of the offspring of bipolar parents had an affective disorder (including major, minor, and intermittent depression and dysthymia, as well as mania, hypomania, cyclothymia, and hyperthymic states), compared with 8.3 percent of children of non-ill parents. Bipolar disorder occurred in 5.4 percent of the offspring of bipolar parents but in none of the children of non-ill parents. Obviously, this figure cannot be taken as a final estimate of risk for bipolarity because most of the children had not passed—or even entered—the age of risk. However, the figure does suggest that the majority of offspring of a bipolar parent fail to manifest diagnosable bipolar disorder at an early age.

Despite the overall consistency of the findings of these studies, there remain significant gaps in our knowledge of children's risk. Few of the studies included young children, while most included both older children and adolescents. The developmental manifestations of bipolar disorder, therefore, have not been fully tested in adequately large samples. The general lack of longitudinal studies means that the continuity or changes in symptom expression over time remain obscure. Although several studies attempted to evaluate subsyndromal symptoms of mood disorders or personality characteristics,⁶ there is currently little consensus on the best and most valid instruments for this purpose. Additionally, future researchers will need to articulate theoretical models with specific variables—including both neurobiological and psychological factors—that might be measured as markers or mechanisms of risk. To date, little information exists about the predictive value of the bipolar parent's clinical history—including not only course subtypes, but also the role of the history of manic and depressive features of the illness, age at onset, and response to treatment. Moreover, virtually no studies have considered the potential impact on children of parental comorbidity, such as substance abuse or ADHD.

Most of the early studies and the case-control investigations discussed previously reported clinical diagnostic outcomes but did not include measures of children's personality, adaptive behaviors, and functioning in typical roles. Such variables are important to characterize potential markers of bipolar disorder—unique attributes that define both positive aspects of bipolar heritage and predictors of later adjustment, including coping capabilities that may affect mental health status. A brief review of relevant findings is presented in Box 6-5.

Recent Offspring Studies with Novel Designs

Several more recent studies have provided useful information about future directions for research on risk factors and mechanisms in bipolar families. Duffy and colleagues (1998) reported on a pilot study comparing adolescent children of bipolar parents who were characterized as responsive or nonresponsive to lithium monotherapy. Children of lithium-responsive parents had fewer psychiatric disorders and good premorbid adjustment, and their disorders tended to be mood related, compared with the children of lithium-nonresponsive parents, who had a broad range of psychopathology and more frequent comorbidity. Of interest, over follow-up of up to 5 years, all of the affectively ill children of lithium-responsive parents had remitting episodes and/or episodic courses, whereas the affectively ill children of lithium-nonresponsive parents had chronic mood disorders and continuing comorbidity (Duffy et al., 2002).

Todd and colleagues (1996) used a unique offspring design to examine psychiatric disorders in children with extended bipolar pedigrees (see Table 6-5). They evaluated children and adolescents from 14 extended families with at least two adult bipolar members. The sample included children in 12 families in which a parent was a bipolar proband or an affectively ill sibling of a bipolar proband, and 18 families in which neither parent had an affective disorder. As expected, offspring who had a parent with a mood disorder had a five-fold higher risk for developing an affective disorder than children of healthy parents. Degree of risk was associated with genetic relatedness to the affected members of the pedigree. Children of ill parents were also at apparent risk for anxiety disorders, but not for disruptive behavior disorders. The use of within-pedigree comparisons helps control for environmental factors that might contribute to disorder, and the results of such comparisons further support the hypothesis of genetic factors as a mechanism of risk.

Chang and colleagues (2000) documented initial results of a study of 60 offspring of 37 families (no comparison group). The mean age of the children was 11.1 years (standard deviation = 3.5 years), and the youngsters were evaluated by both parent and child interviews. Overall, 51 percent

BOX 6-5. Assessment of Children's Personality and Functional Status

In addition to the subclinical affective traits and related characteristics noted in the text, several early studies identified personality traits associated with children at high risk for bipolar disorder; these included aggressiveness (e.g., Worland et al., 1979; Kron et al., 1982), extraversion, introversion, and impulsiveness (Kron et al., 1982).

Data collected on participants in the Gershon and colleagues (1985) study and reported by Pellegrini and colleagues (1986) documented personal and social resources of the children of bipolar parents. There were no overall differences between offspring of bipolar versus control parents on such variables as IQ, social problem-solving ability, self-esteem, and perceived competence. LaRoche and colleagues (1987) also found no significant overall differences in self-esteem. However, Pellegrini and colleagues (1986), reported that those offspring of bipolar parents who did not have psychiatric disorders scored significantly in the more positive direction on the measures, relative to all the other groups, whereas those with psychiatric disorders had significantly less positive scores. Also, nondisordered offspring of bipolar parents reported significantly more supportive relationships and resources available to them than did the disordered youths. Although the direction of causality cannot be determined, superior competence and self-esteem may serve as resilience factors for children at risk and help protect them from the development of psychological disorders.

The findings of Pelligrini and colleagues (1986) are consistent with those of a Stanford study of 53 children and adolescent offspring of bipolar parents that found "super-normal" temperamental characteristics in the offspring who were diagnosis-free. That is, unaffected children and adolescents were more likely to approach new situations, things, and people; to have regular sleeping patterns; and to have lower energy and activity levels (Chang et al., 2003). The authors posited that these "exceptional" temperaments may protect against, or reflect an inherent brain chemistry that is resistant to, psychiatric disorders. Because there were no follow-up data on these offspring, however, it may be that the "exceptional" temperament only postpones onset, although that in its own right would be beneficial. It is possible that some of these well "super-normal" offspring may have inherited very mild subsyndromal variations of a hypomanic temperament; this may in turn provide a protective resilience and energy.

Nurnberger and colleagues (1988) included in their study measures of subsyndromal affective symptoms, as well as the personality trait of sensation seeking. On this measure, they found that children of bipolar parents displayed personality patterns suggestive of disinhibition, and they speculated that such offspring may be prone to respond to dysphoria with disinhibitory behaviors such as drug and alcohol abuse and high-risk behaviors.

Although based on only 7 boys of bipolar parents and 20 controls, a study by Zahn-Waxler and colleagues (1984a, 1984b) is unique in the intensity of its observations and in the young age (2–3yr) of the children involved. In laboratory observations of numerous real-life situations, the investigators found that the toddlers of bipolar parents displayed notable interpersonal difficul-

ties and emotionality. For instance, they showed difficulties in peer interactions (e.g., sharing) and maladaptive aggression, as well as heightened distress and preoccupation in response to simulated conflict and suffering, among others. Although the children of bipolar parents did not display cognitive deficits, they did show more insecure attachment and deficits in taking another's perspective (Zahn-Waxler et al., 1984c). Radke-Yarrow's (1998) report on the expanded study also indicated significantly higher rates of insecure attachment among the children of bipolar mothers, compared with both the well and the unipolar groups. Nevertheless, these toddlers were seen as being relatively socially skilled. As they grew older, however, more disruptive and emotional disorders emerged that were associated with impaired functioning. For instance, peer relationships were rated as poor for 42 percent of the offspring of bipolar women, and 23 percent were doing poorly academically. The investigators found that, overall, 27 percent of the younger and 30 percent of the older siblings showed significant functioning problems in multiple areas (compared with very few of the children of well mothers). The findings of these studies suggest the value of intensive observation of high-risk children in stressful and challenging situations as a way of identifying potential deficits in emotional and behavioral regulation that may portend bipolar disorder.

Anderson and Hammen (1993) compared offspring in the University of California-Los Angeles (UCLA) high-risk study on social competence and academic functioning measures. They discovered that, although the offspring of unipolar mothers were the most impaired of all of the groups, the children of bipolar mothers were actually comparable to the children of non-ill mothers. The investigators predicted that, despite the symptomatology of the bipolar group and the likely increasing risk as they grew older, they were somewhat protected by positive social skills and successful academic achievement, compared with children in the unipolar group. Carlson and Weintraub (1993) evaluated young-adult functioning in their follow-up study of children of bipolar parents compared with a mixed group of offspring of parents with "other" psychopathology and with offspring of non-ill parents. They found that the Global Adjustment Scale scores of the young-adult offspring of bipolar parents were significantly lower than those of children from normal families but did not differ from the scores of offspring of parents with "other" psychopathology. Osher and colleagues (2000) compared the Rorschach responses of a small sample of offspring of manic-depressive parents and controls. They found indicators of thought disorder and unconventional perceptions, suggesting that these might be markers for manic-depressive illness.

The differing results across studies of offspring characteristics reflect a lack of standard batteries of measures (or theoretically driven explorations). The varying methods employed reveal an array of both positive and problematic attributes of children at risk for bipolar disorder. Future studies will be needed to determine whether there are consistent patterns of traits and characteristics that can inform predictions of eventual outcomes.

of the children had a definite diagnosis—chiefly ADHD, depressive disorders, and bipolar disorder (15 percent). Predictors of (childhood) bipolar disorder in the offspring were early onset of parental bipolar disorder and parental childhood ADHD. Children who had two parents with a mood disorder (bipolar or unipolar) tended to show somewhat different symptoms than those with only one ill parent, including increased severity of depressed mood and irritability and rejection sensitivity.

Egeland and colleagues (2003) reported on possible prodromal signs of bipolar disorder in 100 Amish children with a bipolar-I parent and matched controls. Annual evaluations of the children for 7 years, up to age 19 (mean age 14), were retrospectively reviewed and rated blindly by clinicians according to level of possible risk for future development of bipolar-I disorder. On the basis of their symptoms, 38 percent of the children of a bipolar parent were rated as being “at risk,” compared with 17 percent of controls. The authors found many depression-related symptoms, as well as anxiety/fearfulness, hyperalertness, and anger dyscontrol, among others. In contrast to the findings of some other studies, however, they found little evidence of disruptive disorders, ADHD, or conduct problems in the Amish sample, and the symptoms observed had an episodic rather than a continuous and chronic course. Further follow-up of the offspring will be useful to determine whether the “risk” symptoms identified by these investigators do indeed portend bipolar-I disorder.

Relatively unremarkable rates of disorder among adolescent offspring were observed in a Dutch volunteer sample (largely from a manic-depressive association; see Wals et al., 2001). A 27 percent lifetime rate of mood disorders was found—not dissimilar to Dutch national norms—although there was no directly studied comparison group. The investigators speculated that the sample may have included relatively healthier bipolar parents than those ascertained primarily from treatment sources.

Mechanisms of Risk to Children of Bipolar Parents

Perhaps with the exception of the study of Todd and colleagues (1996), which linked children’s psychopathology to the degree of genetic relatedness in a bipolar pedigree study, the high-risk offspring studies reviewed here cannot serve to confirm a genetic mode of transmission of risk for psychopathology. Rather, most of the studies were designed on the assumption of genetic transmission. Nonetheless, it is recognized that children in such families not only inherit whatever genes predispose to bipolar illness, but also “inherit” parents who are potentially impaired in the parental role at least periodically, and whose environments may be stressful because of instability in marital, occupational, and financial circumstances associated with the effects of

the illness. Moreover, a diathesis–stress perspective shared by most forms of psychopathology would lead to the expectation that even in the presence of genetic diatheses, information on additional variables, such as neurocognitive and biological factors, may be needed to determine whether—or when and how—an at-risk person develops a disorder. And because bipolar disorder manifests very different courses among affected individuals, it is important to link course and outcome features of the illness in parents to children’s risk for disorder; also of interest are certain parental demographic features. Additional analyses are therefore needed to advance understanding of the varied outcomes of high-risk offspring of bipolar parents, and perhaps to shed light more generally on factors that affect the nature and timing of the course of the illness.

Family Life and Environment

Few bipolar high-risk studies have examined the association of children’s psychiatric outcomes with characteristics of family life and environment. Marital conflict and disturbances of family climate and parent-child communication almost certainly have significant negative effects on children’s adjustment. Obviously, the quality of relationships in families with bipolar parents is likely to play an important role in children’s risk or resilience in the face of genetic predisposition (see Chapter 10 for further discussion of parenting characteristics in bipolar families).

A few bipolar high-risk studies have examined the role of such factors. LaRoche and colleagues (1987) found that among families with a bipolar mother, the father’s report of marital dissatisfaction was the strongest predictor of the presence of a diagnosis in the offspring; in slightly different analyses, the mother’s report of marital distress was also a significant predictor. The offspring who had disorders reported more negative quality of their relationship with both parents, compared with youngsters who did not have a diagnosis. Hammen (1991) also assessed marital functioning and other forms of stress in high-risk families. Both unipolar and bipolar mothers had high rates of divorce and current relationship stress compared with controls. In all groups, mothers’ chronic stress and negative life events contributed to the prediction of worse outcomes in their children. Grigoriou-Serbanescu and colleagues (1989) performed descriptive evaluations of “familial atmosphere” and determined that the greatest severity of psychopathology in offspring was associated with the highest levels of physical and verbal conflict within the family. Geller and colleagues (2002a) found that bipolar youths who lived in intact biological families were significantly more likely to recover than those in other living situations (Fig. 6–2).

A National Institute of Mental Health study found that bipolar women had higher levels of marital stress than

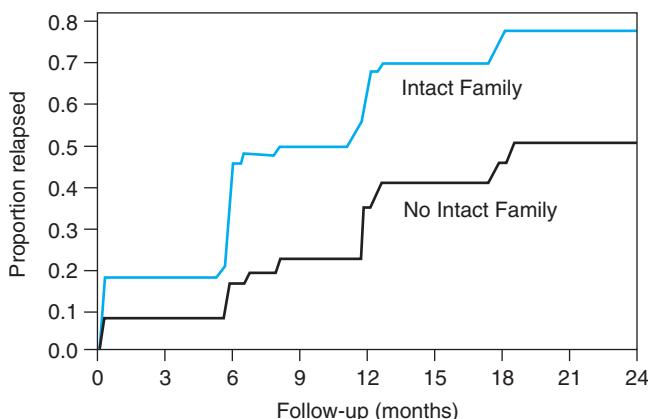

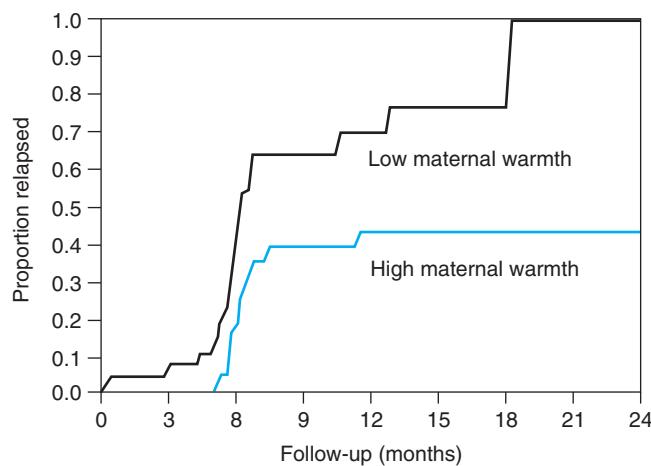

Figure 6-2. Two-year rate of recovery by living situation in subjects with a prepupal and early adolescent bipolar disorder phenotype. Fifty-eight of the 89 subjects had recovered by 24 months. There was a significant difference between the 39 recovered subjects who lived with their intact biological families and the 19 who resided in other living situations (Cox model $\chi^2=7.40$, degrees of freedom [df]=1, $p=.007$). The Kiddie Mania (K-M) estimate for recovery in intact families was 76.5% (95% confidence interval [CI]=64.8–88.1), and for recovery in other living situations it was 50.0% (95% CI=34.1–65.9). (Source: Geller et al., 2002. Reprinted with permission from the *American Journal of Psychiatry*, Copyright 2002, American Psychiatric Association.)

unipolar or well women; marital stress tended to be associated with other forms of family stress and maladaptive functioning as well, however, which made the effects difficult to disentangle (Radke-Yarrow, 1998). The combination of low maternal scores on global functioning and high indices of family stress (including marital conflict) was a strong predictor of depression in offspring, especially older children. In a more recent analysis, Meyer and colleagues (2004) reported that frequent maternal expressions of anger and irritability (perhaps themselves manifestations of mixed mania and therefore of genetic importance) during children's early years were associated with the development of mania in adulthood, even after controlling for maternal psychiatric features. Although based on a small sample, the results of this study hint that highly stressful family environments may contribute to the timing—or even the expression—of bipolar features in those at genetic risk (see also Miklowitz et al., 1988). In a 4-year prospective study of 86 prepupal and early-adolescent bipolar patients, Geller and colleagues (2004) found that low maternal warmth predicted faster relapse after recovery from mania. In an earlier study, the same investigators had found that patients with prepupal and early-onset adolescent bipolar disorder who were exposed to low levels of maternal warmth were four times more likely to relapse after recovery than those exposed to high levels of maternal warmth (Geller et al., 2002b). This effect

is clearly shown in Figure 6-3. It is not clear to what extent maternal warmth reflects an additional underlying vulnerability factor or if maternal warmth is decreased or adversely affected by the demands of caring for a child with bipolar illness.

One particularly dramatic example of family and environmental dysfunction concerns physical and sexual abuse. Analysis of data collected by the Stanley Foundation Bipolar Network showed that early traumatic abuse experiences were associated with a worse course of illness, including earlier onset, suicidality, and more rapid cycling (Leverich et al., 2002). Other investigators found elevated rates of childhood sexual abuse—significantly higher for males—among bipolar adults compared with those with unipolar depression (Hyun et al., 2000). There is also a highly significant association between those reporting childhood sexual abuse and auditory hallucinations (Hammersley et al., 2003). The findings of these studies suggest that among those with a predisposition to develop bipolar disorder, childhood trauma may play a role in the course of the illness; that parents who abuse children have a more severe or comorbid form that is genetically transmitted (as well as psychologically traumatic); or that children with early onset and impaired functioning may experience more severe abuse. It may be noted that self-reports

Figure 6-3. Two-year rate of relapse after recovery by high versus low levels of maternal-child warmth in subjects with a prepupal and early-adolescent bipolar disorder phenotype. Thirty-two of the 58 recovered patients relapsed after recovery. There was a significant difference between the 21 relapsers with low maternal-child warmth and the 11 with high maternal warmth (Cox model $\chi^2=9.84$, degrees of freedom [df]=1, $p=.002$). The Kiddie Mania (K-M) estimate for relapse by low maternal-child warmth was 100.0% (95% confidence interval [CI]=not applicable when K-M=100.0%) and by high maternal-child warmth was 42.2% (95% CI=23.2–61.2). (Source: Geller et al., 2002a. Reprinted with permission from the *American Journal of Psychiatry*, Copyright 2002, American Psychiatric Association.)

of trauma may overestimate its actual incidence, although this possibility has not been sufficiently investigated in bipolar illness.

A recent Dutch study of 132 offspring (mean age 16) of bipolar parents found that the relationship between stressful life events and the onset or recurrence of a DSM-IV mood disorder was almost entirely accounted for by the offspring's prior symptoms of depression and anxiety. The researchers concluded that the frequently hypothesized association between stressful life events and the precipitation of mood disorders may be a spurious one (Wals et al., 2005). The association between stressful life events and the onset or recurrence of a mood disorder was also independent of gender and familial loading. See Chapters 4 and 10 for a more complete discussion of life events and bipolar illness.

Neurocognitive and Biological Studies of High-Risk Youth

To date, few studies have included evaluation of potential neurocognitive and structural and functional brain markers of bipolar disorder. (See Chapters 9 and 15 for a detailed discussion of neurocognitive features of bipolar illness in general.) Because this approach has proven to be extremely fruitful in high-risk studies of schizophrenia, it is likely that such research on bipolar disorder will proliferate. Preliminary studies are beginning to emerge. For example, small samples of children at risk because of parental bipolar disorder or children/adolescents diagnosed with bipolar disorder have shown significant differences from normal controls on neurochemical abnormalities (Cecil et al., 2003), neuroanatomical features (DelBello et al., 2004), and neuropsychological performance (Dickstein et al., 2004). One study of neurocognitive effects in at-risk youth is especially interesting. Meyer and colleagues (2004) examined the outcomes after 23 years of offspring of bipolar, unipolar, and control women in the NIMH's longitudinal study of young children of women with affective disorders (Radke-Yarrow et al., 1992). They found that the majority of the offspring of bipolar mothers who later developed bipolar disorder had shown impairment on a neurocognitive test of executive functioning when they were adolescents.

In their analysis, Meyer and colleagues (2004) found that offspring in families with maternal bipolar disorder were substantially more likely to show impairment in neurocognitive functioning when tested in adolescence if they were also exposed to high levels of maternal anger and irritability during childhood. The investigators hypothesized that the maternal behavior was a potent stressor interacting with their offspring's genetic liability for bipolar disorder, potentially affecting brain development

and increasing their risk for eventual development of the disorder. Direct causality has not been established, however, and it should be kept in mind that severely ill children have an impact on the degree of maternal irritability that is expressed. One study of 140 offspring of parents with bipolar disorder found lower birth weight in offspring to be significantly correlated with greater psychopathology (Wals et al., 2003); the authors suggested that this observed relationship might be due to a shared environmental or genetic factor that influences both. Other investigators have reported a more general association among birth weight, cognitive functioning, and psychopathology (Eaton et al., 2001).

Potential mechanisms underlying bipolar disorder were suggested by Leibenluft and colleagues (2003a), who specifically indicated possible applications to childhood-onset mania (and presumably, by extension, to children at risk because of parental bipolar disorder). Drawing on the work of various investigators, they suggested paradigms for physiological assessment, along with functional neuroimaging measures, of latency, magnitude, and recovery of emotional reactions to affective stimuli—as well as the relationships between attentional and emotional regulation processes in possibly bipolar children. Research aimed at clarifying underlying maladaptive processes in bipolar disorder that can be identified in at-risk samples of children holds promise for advancing understanding, and possibly detection, of bipolar disorder in the young.

Parents' Clinical and Demographic Features and Children's Outcomes

Findings thus far have been mixed on the extent to which there is increased risk to children if both parents are bipolar or if psychiatric disorder occurs in the first-degree relatives of a parent with bipolar disorder.⁷ These mixed findings are likely attributable to design and sampling variations.

Few studies have examined features of parental bipolar course and their influence on children's disorders. An exception is Duffy and colleagues (1998), whose earlier-cited work suggests that parental responsiveness to lithium, which in turn is related to the presence of more "classic" bipolar illness, may be an important predictor. The most comprehensive analyses of clinical features as predictors of children's outcomes were reported by Grigorioiu-Serbanescu and colleagues (1989), who determined that severity of children's psychiatric disorders was significantly related to severity of the illness in the bipolar parent, number of manic and mixed (but not depressive) episodes, younger age at onset in the parent, and presence of psychopathology in the coparent. LaRoche and colleagues (1987) found that duration of parental illness was

related to children's risk for disorder, but the nature of the episodes and the age at onset were not specified. Radke-Yarrow (1992) and Radke-Yarrow and colleagues (1998) reported a significant correlation between mothers' time in affective episodes and low levels of functioning (as assessed by the Global Assessment of Functioning) on the one hand and several measures of children's symptoms on the other, but did not distinguish between maternal manic and depressive symptoms.

Of interest, the study of Radke-Yarrow and colleagues (1992) included an evaluation of maternal Axis II disorders. It was found that two thirds of the bipolar mothers had at least one personality disorder, and personality disorder pathology measured dimensionally was significantly related to the extent of children's symptoms and disorders. Likewise, Hodgins and colleagues (2002) speculated that bipolar parents' high levels of trait neuroticism may expose their children to relatively stressful environments and models of poor coping, as well as to the genetic transmission of neuroticism that influences susceptibility to stress reactivity. Their proposal, similar to models of intergenerational transmission proposed by Hammen (1991), is that family discord and stress factors contribute to the risk of development of disorders in children.

It may be noted that there is a lack of information on the similarity of parent and child bipolar symptoms in cases of early-onset bipolar disorder. Follow-up studies are needed as well to evaluate possible similarities in course and treatment responsiveness.

Demographic factors have likewise not been fully explored, although they have been addressed in a modest number of studies. Grigoriu-Serbanescu and colleagues (1989) found that gender of the bipolar parent did not make a difference in children's outcomes. On the other hand, Klein and colleagues (1985) found that bipolar mothers, compared with bipolar fathers, were more likely to have children with affective symptomatology. Several studies have included or controlled for socioeconomic status of bipolar parents. Grigoriu-Serbanescu and colleagues (1989), for example, reported that lower socioeconomic status in their Romanian sample was associated with greater psychopathology in children.

Clearly, more research is needed to shed light on both clinical and demographic factors associated with bipolar parents that may moderate the effects of their disorder on outcomes among their offspring.

CONCLUSIONS

Increasing interest in mood disorders of children and adolescents has stimulated research and careful clinical

observations aimed at identifying the clinical features, precursors, and course of bipolar disorder in these populations. However, numerous gaps in knowledge remain. For many years, unclear diagnostic criteria led to frequent misdiagnosis of bipolar disorder in children and adolescents. Today, pediatric bipolar disorders are increasingly being diagnosed and treated. Nonetheless, additional studies are needed to refine the predictive utility of age at onset of first symptoms, and to determine the correlates of illness course and level of functioning. Although "classic" bipolar features, including distinct affective episodes and good interepisode functioning, appear to be rare in children, some children display severe and chronic signs of emotional instability, behavioral dysregulation, and cognitive changes that are consistent with mania, and that appear to resemble bipolar mixed states and ultrarapid cycling. Whether such patterns mark developmentally consistent manifestations of bipolarity or reflect other traits or disorders not yet understood remains uncertain, however.

Diagnostic problems are compounded by the considerable overlap between presumed mania and ADHD, as well as other comorbid disorders, such as substance abuse, anxiety, and disruptive behavior disorders. Clearly, longitudinal studies are needed to determine the unique developmental manifestations of manic symptoms and whether possible manic syndrome or symptoms in children portend bipolar disorder in adolescence or later. Moreover, the significance of manic symptoms in children remains to be clarified, in particular whether they represent an especially severe and disabling form of the illness or a nonspecific indicator of psychopathology. Some have proposed that early-onset mania presenting with comorbid ADHD may represent an etiological subtype marked by familial concentrations of bipolar disorder and ADHD. Presently, it is recommended that a diagnosis of bipolar disorder be reserved for children who meet DSM-IV criteria for mania, and that bipolar-NOS be used for those with severe emotional and behavioral dysregulation when boundaries with disruptive behavior disorders are unclear.

Parental bipolar disorder in families of children with manic symptoms would appear to be a potentially validating criterion, but further research is needed to identify early markers (endophenotypes) of childhood bipolar disorder. The stakes are high for such severely ill children, because early valid diagnosis and empirically supported treatment could greatly improve their lives and future functioning. Studies of children of bipolar parents employing the high-risk methodology (that is, the study of children of psychiatrically ill parents) represent a design uniquely suited to refining the assessment

and diagnosis of precursor forms of bipolar disorder. Moreover, such studies may prove crucial in identifying markers of risk processes that interact with genetic diatheses, although few studies to date have examined the neurobiological or developmental abnormalities that may signal onset of or vulnerability to bipolar disorder. The studies of high-risk children conducted thus far have clearly indicated that the offspring of bipolar parents have elevated rates of psychopathology, developing in childhood and adolescence. A significant proportion develop bipolar disorder—and the rate is likely to grow still higher as these offspring pass through the age of risk in late adolescence and adulthood. Longitudinal research on such samples is needed to help clarify the developmental progression of the disorder; its earliest symptoms; and predictors of its course, including adverse family and environmental experiences.

The patient who has for years before his illness shown morbid traits, who has been anxious, or quarrelsome, or suspicious, or odd, or solitary, or obsessional, or in some other way has shown that he is constantly at odds with himself, as well as with his surroundings—such a patient is not going to be cured of his maladjustment by having an affective flare-up. A sortie does not end a siege.

—Sir Aubrey Lewis (1936, p. 997)

Comorbidity in manic-depressive illness, in which the mood disorder is complicated by the presence of one or more additional disorders, is the rule rather than the exception, especially for the bipolar subgroup. Data from the Stanley Foundation Bipolar Network, a consortium of bipolar specialty clinics in academic health centers around the world, indicate that 65 percent of patients with bipolar disorder have a comorbid condition. Of these patients, almost a quarter have three or more diagnoses (Fig. 7-1) (McElroy et al., 2001).

Unfortunately, disorders that can accompany affective illness tend to be underrecognized and undertreated (Simon et al., 2004a). Poor recognition of comorbid conditions may be related to the way in which clinicians diagnose their patients. Psychiatric evaluation is often directed toward identifying a single diagnosis that will account for all or most of a patient's symptoms, rather than identifying multiple conditions. This expectation can lead to important disorders being overlooked, and the partially diagnosed and incompletely treated patient may be left with considerable symptomatology and disability, even after the primary disorder has been effectively treated. In the case of bipolar disorder, which can be destabilized by certain classes of medication, the clinician must also be wary of worsening one illness while treating another. For example, treating panic disorder with a selective serotonin reuptake inhibitor (SSRI) may trigger a switch to a manic or mixed episode. (The difficulties involved in the treatment of comorbid conditions are addressed in Chapter 24.) Proper attention to management of comorbidities can reduce their impact on a patient's functioning and general health. Unfortunately, even with the best treatment, the presence of one or more comorbid disorders tends to lead to a poorer outcome compared with uncomplicated manic-depressive illness.

Some investigators have evaluated the total burden of comorbidity by surveying multiple diagnostic categories, while others have focused in more detail on specific conditions. Studies taking a comprehensive approach to the presence of comorbidity have found that, especially for the bipolar subgroup, an uncomplicated recurrent mood disorder is unusual. The National Comorbidity Survey (NCS) of more than 58,000 individuals found that, among bipolar patients with "classic" features such as euphoria, grandiosity, and the ability to maintain energy without sleep, all met the *Diagnostic and Statistical Manual* (DSM)-III-R criteria for at least one other mental disorder. Fully 95 percent met the criteria for three or more disorders (Kessler et al., 1997). This, for reasons discussed below, is almost certainly a considerable overestimate. Another study, involving 3,258 randomly selected household residents of Edmonton, Alberta, found similarly high rates of comorbidity. Based on surveys performed by trained lay interviewers using the Diagnostic Interview Schedule (DIS), comorbidity with other disorders occurred in 92 percent of subjects who had experienced a manic episode. The generalizability of this particular study may be limited, however. The lifetime prevalence of mania identified by the lay interviewers was lower than in most other studies—only 0.6 percent. Consequently, the interviewers may have been identifying only a subset of patients with bipolar disorder who had more severe psychopathology. Also, as discussed later, there are significant discrepancies between the high rates of comorbidity identified by nonclinician versus clinician interviewers. For example, experienced clinicians in the Stanley Network identified social anxiety disorder in only 16 percent of their bipolar patients, compared with nearly 50 percent identified by nonclinicians in the NCS study.

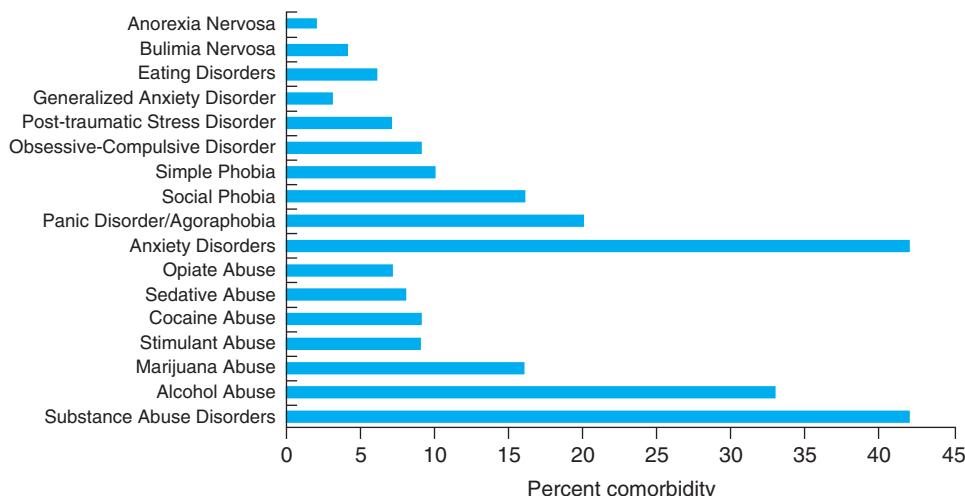

Figure 7–1. Axis I psychiatric comorbidities. Percent comorbidity in bipolar patients enrolled in the Stanley Bipolar Treatment Network. (Source: Adapted from McElroy et al., 2001. Reprinted with permission from the *American Journal of Psychiatry*, Copyright 2001. American Psychiatric Association.)

Guo and colleagues (2005) used a claims database to evaluate rates of bipolar comorbidity. They analyzed a large managed-care population of 123,292 patients who had been given an *International Classification of Diseases 9* (ICD-9) diagnostic code for bipolar disorder by their treating clinician. The prevalence of comorbid anxiety disorders was 36.7 percent, but the rate of comorbid substance disorders was only 12.0 percent. The low level of comorbid substance abuse/dependence in this population may have been due to the fact that individuals with commercial health insurance were more likely to be employed, whereas substance-related disorders often lead to the loss of a job or chronic unemployment (Leino-Arjas et al., 1999).

Data obtained from structured clinician interviews also reveal high levels of comorbidity in bipolar patients. Bauer and colleagues (2005) evaluated intake assessment data, obtained by clinicians using the Structured Clinical Interview for DSM (SCID), on subjects recruited as part of the Veterans Affairs (VA) Cooperative Study No. 430. In this sample of hospitalized bipolar veterans, 57 percent had at least one current comorbid disorder. More than one comorbid disorder was found in 30 percent of the patients, and 9 percent had three or more comorbidities. As in the preceding studies, the two most common comorbidities were anxiety and substance abuse disorders. At least one anxiety disorder was currently present in 38 percent of the sample; the lifetime rate was 43 percent. The similarity between current and lifetime rates suggests a high degree of chronicity. Post-traumatic stress disorder (PTSD) was present in 25 percent, panic disorder in 17 percent, and obsessive-compulsive disorder (OCD) in 8 percent. Current substance abuse disorders were present in 34 percent; alcohol (26 percent), marijuana (7 percent), and cocaine

(7 percent) were the most commonly abused substances. The lifetime rate for substance abuse disorders was considerably higher, 72 percent.

The VA investigators also evaluated correlates of anxiety and substance-related disorders and found them to be distinct. Compared with bipolar patients with no comorbidity, those with comorbid substance abuse/dependence had more marital problems and a higher probability of presenting with depression; they also had more medical conditions during the index hospitalization and were less able to work. Comorbid anxiety disorders were associated with earlier age at onset of bipolar disorder, rapid cycling, a greater likelihood of presenting with depression, a higher rate of suicide attempts, and a greater number of manic and depressive episodes in the year preceding hospitalization. Vieta and colleagues (2001), in their Barcelona Stanley Foundation Study of 129 bipolar-I outpatients in remission, found that comorbid bipolar patients had a higher number of mixed features, depressive episodes, and suicide attempts. The different patterns of correlates led Bauer and colleagues (2005) to speculate that distinct genetic subtypes of bipolar disorder were represented by patients who had comorbid anxiety disorders compared with those with comorbid substance abuse disorders. The association of discrete subtypes of bipolar disorder with specific comorbid presentations is discussed in further detail later.

Patients in the Bauer and colleagues (2005) VA study were all hospitalized and had either bipolar-I or bipolar-II disorder. However, it is not only the most severely ill patients who experience comorbid conditions. Patients with soft-spectrum bipolarity—those who, although they do not meet the full DSM criteria for bipolar disorder, nonetheless experience significant symptoms of depressed and

elevated moods—also have high rates of comorbidity (Maremmani et al., 2006). For example, in the Zurich cohort study (Angst, 1998), a 15-year prospective study of 4,547 young adults, 78 percent of patients with brief hypomanic episodes had a lifetime prevalence of at least one anxiety disorder. Panic disorder was the most common anxiety disorder, affecting 12 percent of all patients; 32 percent experienced panic attacks without meeting the full criteria for panic disorder. Binge eating (13 percent) and alcohol abuse disorders (23 percent) were also common in this cohort. Patients with major depressive disorder have more anxiety and substance abuse disorders than the general population, but significantly fewer than patients with bipolar disorder (Chen and Dilsaver, 1995b).

Although comorbid conditions tend to be underdiagnosed, they can also be overdiagnosed. Manic-depressive illness, as we have emphasized, is highly variable in its presentation. Patients with completely different clinical presentations and courses are given the same DSM-IV diagnosis. Diagnostic criteria for mood disorders include symptoms of anxiety; conduct disturbance; cognitive impairment; and changes in eating, energy levels, sleeping, and sexual functioning. Comorbid diagnoses can be inflated by the confounding of symptoms with diagnoses. Nonclinician interviewers in particular, who estimate the presence of psychiatric disorders using a symptom checklist, are at greater risk for overestimating comorbidity than are experienced clinicians, who use pattern recognition to make diagnoses. Thus before one can properly interpret studies of comorbidity, the method used to establish diagnoses must be explicit.

In the remainder of this chapter, we review the findings of the literature on the major comorbid conditions in manic-depressive illness, with an emphasis on the bipolar subgroup. There is little published information on the more recurrent forms of unipolar depression *per se*. We address in turn alcohol and drug abuse/dependence disorders, anxiety disorders, other psychiatric illnesses, and medical illnesses.

ALCOHOL AND DRUG ABUSE/DEPENDENCE DISORDERS

Several general methodological issues arise in the study of alcohol and drug abuse/dependence in manic-depressive patients. We begin by considering these, and then turn to specific diagnostic issues. First, it is often difficult to obtain accurate histories of alcohol and drug abuse from patients; compounding the problem, clinicians tend to skirt this general line of inquiry. Second, patients vary tremendously in the development and expression of both manic-depressive illness and substance abuse/dependence disorders. Third,

many studies do not adequately differentiate substance abuse from the more serious and persistent disorder of true alcohol or drug dependence.

Inconsistency and unreliability of diagnostic criteria are particular problems when investigators attempt to diagnose and study more than one disorder and then to determine which is primary and which secondary. Schuckit (1986) summarized several major sources of diagnostic confusion related to alcohol and mood disorders: (1) alcohol can cause depressive symptoms; (2) signs of temporary serious depression can follow prolonged drinking; (3) drinking can escalate during affective episodes in some patients, especially during mania; (4) depressive symptoms and alcohol problems occur in other psychiatric disorders; and (5) a subset of manic-depressive patients have independent alcohol abuse disorder. Differentiating symptoms caused by a primary psychiatric disorder from those secondary to substance abuse can be difficult. Affective, cognitive, and psychotic symptoms can result from alcohol and from a wide variety of classes of drugs, such as amphetamines, cocaine, and hallucinogens. Likewise, alcohol and other drugs can both mask and precipitate affective symptoms. Indeed, Kraepelin (1921) observed many years ago that manic attacks occasionally begin with delirium tremens. More recently, manic attacks induced by lysergic acid diethylamide (LSD) and phenylcyclidine (PCP) have been observed in biologically vulnerable individuals. These issues are discussed in more detail later in this chapter. Obtaining a detailed chronology of the onset of symptoms (*i.e.*, whether difficulties with substance abuse predated affective symptoms or vice versa), ascertaining the severity of presenting symptoms, and taking a thorough family history can aid in making a correct differential diagnosis (Hesselbrock et al., 1985; Schuckit, 1986). Correct diagnosis, in turn, is essential to good medical and psychological care (see Chapter 24). In a 5-year prospective study of 27 bipolar-I patients in whom the onset of alcohol abuse disorder preceded the onset of bipolar disorder, and 33 patients in whom that order was reversed, Strakowski and colleagues (2005) found that those who abused alcohol first were more likely to recover and recovered more quickly. Those whose illness preceded their alcohol abuse spent more time affectively ill and experienced more symptoms of alcohol abuse.

Alcohol Abuse/Dependence

In a letter to a friend, the poet Edgar Allan Poe wrote about alcohol and mental illness from a deeply personal perspective:

I became insane, with long periods of horrible sanity.
During these fits of absolute unconsciousness I drank,
God only knows how much or how long. As a matter of

course, my enemies referred the insanity to the drink, rather than the drink to the insanity.

Separating the insanity from the drink remains a difficult problem in the differential diagnosis and treatment of affective illness and substance abuse disorders. A relationship between alcohol and mood disorders has been observed for more than 2,000 years. Plato (cited in Ackernknecht, 1959) referred to alcoholism as a demonstrable cause of mania. Soranus (c. 100 AD, cited in Zilboorg, 1941) echoed the sentiment that excessive use of alcohol frequently caused mania and criticized those who prescribed it as a treatment. Aretaeus (c. 90 AD, cited in Whitwell, 1936) suggested that symptoms of mania may be produced by an excess of wine or opiates but concluded that the resulting states cannot properly be termed mania, just temporary deliria. Early in the twentieth century, Kraepelin (1921, p. 178) summarized his findings on alcohol dependence in manic-depressive illness as follows:

Alcoholism occurs among male patients in about a quarter of the cases, but is to be regarded as the consequence of debaucheries committed in excitement, not as a cause.

Differing views about whether alcohol abuse disorder precedes or follows the onset of manic-depressive illness persist today, and there is a growing appreciation of the importance of recognizing this comorbidity (dual diagnosis).

Rates of Mood Disorders among Patients with Alcohol Abuse/Dependence

The lack of consistency in diagnostic criteria has led to widely disparate estimates of the rates of mood disorders in patients with alcohol abuse disorder. These estimates

have ranged from 3 to 98 percent, depending on whether clinical scales or more formal diagnostic criteria were used (Keeler et al., 1979; Himmelhoch et al., 1983). Estimates of the prevalence of mood disorders in those with alcohol dependence range from 12 to 57 percent when mood disorders are defined by formal diagnostic criteria, but are as high as 98 percent when rating scales are used (Bernadt and Murray, 1986).

Rates of Alcohol Abuse/Dependence among Patients with Mood Disorders

The Epidemiological Catchment Area (ECA) data for alcohol abuse/dependence in patients with affective illness show a high lifetime prevalence rate (Table 7-1) of 17 percent in unipolar depressed patients (the proportion with recurrent depressions was not specified) and a strikingly higher rate, 46 percent, in bipolar-I patients (Regier et al., 1990). Three other studies (Freed, 1969; Morrison, 1974; Estroff et al., 1985) found that when bipolar patients in clinical settings were systematically queried, they reported rates of alcohol abuse/dependence of about 60 to 75 percent. Compared with patients with other psychiatric diagnoses, those with bipolar disorder were at particularly high risk of developing an alcohol problem during their lifetime. This can be seen in Figure 7-2, which shows the lifetime prevalence of alcohol abuse disorder in individuals with selected psychiatric diagnoses and in the general population.

Most studies have found alcohol abuse disorder comorbidity is more frequent in bipolar patients than in those with any other mood disorder. The ECA study of alcohol abuse/dependence and psychiatric comorbidity (Helzer and Pryzbeck, 1988) found that mania was strongly associated with alcohol abuse/dependence (odds ratio = 6.2) but

TABLE 7-1. Lifetime Prevalence Rates for Alcohol and Drug Abuse/Dependence in Persons with Mood Disorders and in the General Population

Type of Abuse/Dependence	Bipolar-I (%)	Bipolar-II (%)	Major Depression (%)	General Population (%)
Alcohol	46	39	17	13.5
Abuse only	15	18	5	
Dependence	31	21	12	
Drug	41	21	18	6.2
Abuse only	13	9	7	
Dependence	28	12	11

that major depression was not (odds ratio=1.7); more highly recurrent or cyclic depressions were not analyzed separately. Bipolar-I was associated with a higher lifetime rate of alcohol abuse/dependence than bipolar-II (46 versus 39 percent) or unipolar depression (17 percent) (Regier et al., 1990).

A study of 267 patients enrolled in the Stanley Foundation Bipolar Network found that, as in the general population, more men (49 percent) than women (29 percent) with bipolar disorder met the criteria for lifetime alcohol abuse. Likewise, a recent study of 211 bipolar patients found that men had significantly higher rates of comorbid alcohol abuse/dependence (Kawa et al., 2005). However, having bipolar disorder raised a woman's risk of having an alcohol-related disorder to a much greater degree than it did for a man. Compared with nonbipolar patients, the odds ratio of having an alcohol-related disorder among those with bipolar disorder was 7.35 for women and 2.77 for men (Frye et al., 2003). Men and women with bipolar disorder also have different risk factors for comorbid alcohol-related diagnoses. In men, the risk appears to be more associated with a genetic predisposition. Specifically, men with bipolar disorder and comorbid alcohol abuse/dependence have a more extensive family history of both disorders compared with men with noncomorbid bipolar disorder. Women with bipolar disorder and alcohol-related disorders, on the other hand, do not have as great a family loading. Comorbid alcohol

abuse/dependence in women is associated more with a greater familial burden of depressive episodes and anxiety disorders (Frye et al., 2003).

Elderly bipolar patients are also at increased risk for alcohol abuse. A community survey compared 84 elderly (ages ≥ 65 years) bipolar respondents with 8,121 elderly respondents without bipolar disorder; those with bipolar illness had a significantly higher lifetime and 12-month prevalence of alcohol disorders ($p < .001$) (Goldstein et al., 2006).

In summary, many studies, using a wide variety of diagnostic criteria and patient populations and conducted over a period of more than 50 years, have been quite consistent in finding significantly elevated rates of alcohol abuse/dependence in manic depressive illness, particularly the bipolar form. Conversely, they have found a significantly increased proportion of patients with manic-depressive illness within populations of alcohol abusers.

Drug Abuse/Dependence

The data on rates of comorbid bipolar illness and drug abuse/dependence are much less extensive and consistent than those on comorbid alcohol-related disorders, in no small part because of the illegal nature of drug-related disorders. The ECA data for drug abuse/dependence in patients with mood disorders show strikingly high lifetime

prevalence rates of 18 percent in unipolar depressed patients and 41 percent in bipolar-I patients (Regier et al., 1990), nearly identical to the rates for alcohol-related disorders (see Table 7-1). In the general population, drug abuse/dependence is significantly less common than alcohol-related disorders (see also Table 7-2).

Determining the sequence of comorbid mood disorders and drug abuse/dependence presents the same methodological problems as those encountered in the case of alcohol-related diagnoses. The ECA data show that the affective disorder is 1.3 times more likely to occur before the drug abuse disorder (see the later discussion).

Cocaine

An interview study of patients voluntarily enrolled in a bipolar disorder case registry found that 3.4 percent met the diagnostic criteria for cocaine abuse, and 6.7 percent met the criteria for cocaine dependence (Chengappa et al., 2000). Consistent with other findings on drug abuse problems, more patients with bipolar-I than with bipolar-II abused cocaine.

Data of this sort cannot address the nature of the relationship between the mood and drug disorders. Clearly there are features of bipolar illness that can increase the likelihood of cocaine abuse, such as a desire to relieve the psychomotor retardation of bipolar depression and a desire to reinduce, prolong, or accelerate elevated mood and energy states. Weiss and Mirin (1986), for example, found

that the majority of their bipolar patients reported using cocaine more often when manic than when depressed. This finding is consistent with that of Estroff and colleagues (1985), who observed that 58 percent of their manic bipolar patients abused cocaine, compared with 30 percent of their depressed bipolar patients.¹

Opiates and Central Nervous System Depressants

In a study of 533 opiate and depressant abusers, 24 percent of the total subjects were diagnosed with major depressive disorder, and 5.4 percent were either bipolar-I or bipolar-II (Kosten and Rounsville, 1986). Mirin and colleagues (1984) found a similar rate of unipolar depression among opiate addicts, but twice the rate of bipolar illness among abusers of these central nervous system (CNS) depressants. They also found that nearly three times more female than male opiate addicts were diagnosed as bipolar (10.8 versus 3.7 percent). These rates of bipolar illness are substantially higher than those found in the general population. Estroff and colleagues (1985) examined drug abuse in bipolar patients in their drug treatment clinic and reported that 25 percent of their manic patients abused heroin, compared with 20 percent of their depressed bipolar patients. The small sample size of this study limits its generalizability, however. Miller and colleagues (1989), studying a larger sample, found that only 5 percent of their manic patients abused opiates.

TABLE 7-2. Rates of Drug Abuse/Dependence in the General Population

Study	Total Population (%)	Male (%)	Female (%)	Prevalence
Regier et al., 1988 (ECA)				
Drug abuse/dependence	5.9			Lifetime
	2.0			6-month
Kessler et al., 1994 (NCS)				
Drug abuse	4.4	5.4	3.5	Lifetime
	0.8	1.3	0.3	12-month
Drug dependence	7.5	9.4	5.9	Lifetime
	2.8	3.8	1.9	12-month
Narrow et al., 2002 (ECA and NCS)	1.3	1.8	0.7	1-month
Drug abuse disorder using "clinical significance" criteria	1.7			12-month

ECA = Epidemiological Catchment Area; NCS = National Comorbidity Survey.

Overall, the rates of bipolar illness in opiate abusers, although not as dramatically high as in cocaine abusers, are greater than those found in the general population, but not as high as the rates of unipolar depression among those with opiate dependence.

Marijuana

Marijuana (cannabis) is the most widely abused illicit drug in the United States. According to the 2000 National Household Survey on Drug Abuse, 6.3 percent of Americans aged 12 or older were current abusers; approximately 59 percent of them abused only marijuana, and another 17 percent abused another illicit drug as well (Office of Applied Studies, 2001). Marijuana abuse is more prevalent among patients with bipolar disorder than in the general population. A study of 3,536 patients from 14 European countries, for example, found that 12 percent of patients being treated for mania were current abusers of marijuana (Reed et al., 2005). Other studies have found a wide range of rates of marijuana abuse in bipolar disorder—from 15 to 65 percent—but all rates have been high.² Marijuana, which has both sedative and psychedelic properties, can cause a variety of mood-related effects. Acute intoxication is associated with euphoria, anxiety, agitation, and grandiosity. Chronic abuse can lead to low-grade lethargy and depression, sometimes accompanied by anxiety, paranoia, and memory loss. A recent study of 52 bipolar alcohol-dependent patients found that 48 percent reported marijuana abuse; those that did had significantly more psychiatric comorbidity, in addition to more severe alcohol and other drug abuse (Salloum et al., 2005).

Hypotheses about the Relationship between Bipolar Illness and Alcohol and Drug Abuse

Relationship of Alcohol and Drug Abuse to Phase of Illness

Although it is perhaps more intuitive to link increased alcohol consumption with the depressed phase of bipolar illness, evidence suggests that the link is as or more common with hypomania, mania, and mixed or transitional states. Indeed, bipolar patients who increase their alcohol consumption generally do so during the manic phase (Zisook and Schuckit, 1987). Table 7–3 summarizes six studies of the relationship between alcohol intake and phase of illness. Alcohol, to a point, does appear to provide some relief for the irritability, restlessness, and agitation associated with mania. In this sense, although its use is damaging overall, it is not surprising that alcohol consumption increases during mania.

There is some evidence that bipolar patients (38 percent) are more likely than unipolar patients (15 percent) to increase their drinking when in a depressive episode (Bernadt and Murray, 1986). The tendency for bipolar patients to drink more heavily when depressed may reflect the increased agitation and perturbation associated with coexisting transitional or mixed states. In an early study, Winokur and colleagues (1969) found that the percentage of bipolar patients increasing their alcohol consumption was higher during mixed and manic states (43 and 42 percent, respectively) than during bipolar depression (27 percent). Himmelhoch and colleagues (1976a) noted that the major differ-

^bDepressed phase approximated, excluding unipolar patients.

entiating feature between patients in mixed and nonmixed states was their rate of alcohol and drug abuse; the former patients were twice as likely to abuse these substances.

As noted earlier, findings of clinical research suggest that bipolar patients abuse cocaine when depressed, but are even more likely to do so while hypomanic or manic. Patients increased their cocaine abuse during the latter states not only to alleviate associated dysphoria, but also to bring about, sustain, or heighten the high-energy, euphoric state. These mood-altering uses of cocaine have been discussed by several investigators. The use of cocaine in hypomanic states was described by Khantzian (1985, p. 1263) as a means "to augment a hyperactive, restless lifestyle." Gawin and Kleber (1986, pp. 110–111) discussed the use of cocaine by cyclothymic individuals:

Cocaine use did not precipitate manic episodes, and it was initially well controlled. . . . Cocaine use early on reestablished hypomanic functioning during dysthymic cycles. However, cocaine use eventually was extended to continuously regulate mood state. When these subjects began to perceive that cocaine use was harmful, they successfully refrained from cocaine during dysthymic phases. Paradoxically, 80% described that when mood state improved toward hypomania, judgment of the seriousness of cocaine-related problems deteriorated, and cocaine use recurred.

The use of cocaine for control of both depressed and elated phases of bipolar illness was described by Weiss and Mirin (1984, pp. 49–50):

We were impressed by the perceived utility of [cocaine] in the regulation of both dysphoric and elated mood. Typically, depressed patients reported symptom relief at moderate doses but also noted the need to gradually increase the dose or the frequency of drug administration. . . . Bipolar and cyclothymic patients hospitalized for chronic cocaine use reported that they used the drug most frequently to enhance endogenously elevated mood in the manic phases of their illness.

Self-Medication Hypothesis

The hypothesis that alcohol and drug abuse/dependence occurs in an effort to self-medicate mood disorders has been suggested in various ways for more than a thousand years. In 1884, Freud recognized that cocaine, with its mood-elevating properties, could be used as a potent antidepressant. Later, Milkman and Frosch (1973; quoted in Khantzian, 1985, p. 1260) wrote:

[H]eroine addicts preferred the calming and dampening effects of opiates and seemed to use them to shore up tenuous defenses and reinforce a tendency toward withdrawal

and isolation, while amphetamine addicts used the stimulating action of amphetamines to support an inflated sense of self-worth and a defensive style involving active confrontation with their environment.

As we have seen, however, contrary to theories positing the use of stimulants to counter depressive states, most patients report using cocaine primarily when hypomanic or manic to enhance or induce euphoric moods associated with those states. Weiss and colleagues (1988), for example, found that the majority of their bipolar and cyclothymic patients abusing cocaine claimed that they were not self-medicating depression but lengthening and intensifying the euphoric effects of hypomania. These same authors had noted earlier (Weiss and Mirin, 1984, p. 50) that the manic phase of bipolar and cyclothymic cocaine abusers was characterized by euphoria, whereas "substance abusers who experienced dysphoria during mania or hypomania seemed to prefer to 'self-treat' their symptoms with opiates or other central nervous system depressants (including alcohol)."

This notion of using opiates to self-treat dysphoric feelings echoes similar results from Rounsville and colleagues (1982) and Castaneda and colleagues (1989) and, in part, those of Khantzian (1974) and of Wurmser (1974, p. 358), who suggested that the abuse of opiates was a mechanism for combating the "psychologically disorganized effects of overwhelming rage" (Weiss and Mirin, 1987). Evidence suggests, however, that alcohol and such drugs as heroin and PCP also may produce increased symptoms of dysphoria, irritability, and anxiety.

Why, then, do bipolar patients continue to abuse cocaine, even after they have alleviated the painful state from which they were trying to escape? Weiss and colleagues (1986) hypothesized that low to moderate doses of cocaine may make affectively ill patients feel better (as Post and colleagues, 1974b, found in depressed patients) by relieving anxious, agitated feelings, and that this effect promotes further drug use. Other factors then assume importance in maintaining drug-abusing behavior, and a chronic dependence often results (Castaneda et al., 1989). This may be true as well for opiate and alcohol abuse in manic and depressed patients who continue to drink or abuse drugs despite realizing the substances' adverse effects on mood (Weiss and Mirin, 1987).

Self-medication of affective illness by alcohol has been postulated, but it is less well supported by the evidence than such use of cocaine and opiates. Reich and colleagues (1974), like many other clinicians, observed that increased alcohol consumption appeared to be a type of self-medication, an attempt to slow down, relax, and take the edge off the dysphoria. They hypothesized that excessive alcohol use is a sign of more severe mania and represents an attempt to

control manic symptoms, especially sleep disturbance and hyperactivity. Noting that patients with mixed states are twice as likely as other patients to abuse drugs and alcohol, Himmelhoch and colleagues (1976a) suggested that the switch phase could be dysphoric and uncomfortable, and substance abuse could be used to self-medicate this dysphoria. Weiss and Mirin (1987) posited that, in addition to self-medication, the increased use of drugs and alcohol during manic episodes could be attributed to impulsiveness, recklessness, and poor judgment. Liskow and colleagues (1982) suggested that "drinking may simply be another manifestation of mania—manics tend to do more of everything" (p. 145) and noted that "the self-medication hypothesis relating alcoholism to affective disorder appears to be simplistic if not entirely erroneous" (p. 146).

The self-medication hypothesis in substance abuse among affectively ill patients is likely to be debated for some time before being resolved. The ECA data discussed earlier show a greatly increased rate of major depression preceding substance abuse, rather than substance abuse preceding depression. Recently, a study of 45 patients with bipolar disorder and substance dependence found that nearly all patients said they had initiated substance abuse because of symptoms of bipolar disorder; of these, most (78 percent) cited depression, followed by racing thoughts (58 percent). Two thirds (67 percent) of the patients reported improvement in at least one symptom as a result of the substance abuse (Weiss et al., 2004).

In summary, not all studies have supported the validity of the self-medication hypothesis. It is probable that a subgroup of bipolar patients abuses alcohol and other drugs to intensify elevated mood and energy states, while another subgroup abuses the same substances to ameliorate or self-medicate their manic, depressive, or mixed symptoms. Some do both.

Precipitation of Illness

An underlying bipolar illness may be precipitated by alcohol or drug abuse. For example, the first manic episode in a biologically vulnerable individual may be triggered by hallucinogen or stimulant abuse. Interactions among predisposed individuals, their substance abuse patterns, and the onset of abnormal mood episodes have been observed by many clinicians and investigators.

The most demonstrable drug-induced psychoses in manic-depressive patients are those resulting from hallucinogenic drugs such as LSD and PCP. The psychotic symptoms associated with the abuse of these drugs have been well documented by several authors (e.g., El-Guebaly, 1975; Bowers, 1977; Erard et al., 1980). Amphetamine abuse was noted by Ellinwood and Petrie (1979) to be a precipitant of psychosis. Many of the presenting symptoms (e.g., delusions of persecution and grandeur and visual and auditory hallucinations) are present in manic psychoses. Evidence from animal studies shows that cocaine is a potent inducer of a process analogous to kindling in the CNS (sensitization) (Post et al., 1984). The role of kindling—sensitization processes in the pathophysiology of manic-depressive illness is discussed in Chapter 14.

There may be important differences between patients who develop substance abuse after the emergence of manic-depressive illness and those who develop substance abuse first. Since the literature on the sequential relationships between major depression and substance abuse typically does not differentiate more recurrent from less recurrent forms of depression, our focus once again is on the bipolar subgroup. In a retrospective study of 188 patients, those with bipolar disorder who later developed a substance abuse disorder had a younger age at onset of mood symptoms (13.5) compared with bipolar patients who never developed such a disorder (22.7) (Feinman and Dunner, 1996). As noted earlier, Strakowski and colleagues (2005), in a 5-year follow-up study of 144 bipolar-I patients, found that those whose alcohol abuse disorder preceded the onset of bipolar disorder were older and tended to recover more quickly than those whose bipolar illness proceeded their alcohol abuse disorder. This later age at onset in the alcohol-first group was found in the 2001–2002 National Epidemiologic Survey on Alcohol and Related Conditions as well (Goldstein and Levitt, 2006). This may mean that an early onset predisposes bipolar patients to future substance abuse, or there may be a subpopulation at risk for both an early onset of bipolar disorder and substance abuse. Of particular note in the Feinman and Dunner study, patients whose drug abuse came first had a later onset of mood symptoms than those with primary bipolar disorder, and later even than that of patients with uncomplicated bipolar disorder (i.e., no substance abuse at all). One might speculate that these patients had a less active form of bipolar disorder, perhaps one that required triggering by substance abuse before symptoms of abnormal mood could emerge.

Differences between primary and secondary substance abuse disorders were examined in a 5-year prospective follow-up study of 70 patients with alcohol abuse and bipolar disorder (Winokur et al., 1995). In this study, as in that conducted by Feinman and Dunner (1996), bipolar disorder that developed after exposure to alcohol abuse appeared to be less severe than that which developed spontaneously. Patients with primary alcohol abuse had fewer episodes of abnormal mood during the 5-year follow-up period.

The concept of activation of a latent bipolar vulnerability by the abuse of mood-altering substances illustrates the challenges involved in studying comorbid populations. As

the two studies just discussed suggest, substance abuse may unmask a less severe form of bipolar disorder that might never have been expressed had the patient not been exposed to alcohol or drugs. Because these patients have an inherently less severe form of mood disorder, their inclusion in studies can lead to the occasional finding that comorbid patients have a more benign clinical course compared with non-drug-abusing patients with bipolar disorder. Alternatively, the indiscriminate blending of patients with secondary and primary bipolar disorder can lead to a washing out of potential differences between comorbid and noncomorbid groups. It appears to make a difference whether the substance abuse is a cause or a result of bipolar mood fluctuations. This methodological and diagnostic issue is one of many that complicate the study of the two illnesses.

From a clinical standpoint, if substance abuse is able to unmask a latent bipolar disorder, bipolar parents who pass along a genetic vulnerability to their children should be counseled on the importance of helping their children avoid substance abuse. Abuse of illicit drugs can cause significant morbidity and mortality in any child, but those who have a genetic predisposition toward development of a mood disorder are at particularly high risk of harm.

Modification of Course

Alcohol and drug abuse may modify the course and expression of manic-depressive illness. Substance abuse problems can lead to more severe psychopathology and less favorable outcomes in a number of ways, including higher rates of mixed states, rapid cycling, impulsivity, aggression, and destabilization of sleep patterns. They may also slow the time to recovery, increase the probability of treatment nonadherence, and decrease the effectiveness of prescribed medications. As reviewed in Chapter 8, the mortality associated with substance abuse and depressive disorders is cause for particular concern. More than 90 percent of suicides are associated with a psychiatric disorder (Institute of Medicine, 2002), but the association is stronger for some conditions than others. Two of the highest-risk conditions are bipolar disorder and substance abuse, and there appears to be an often dangerous interaction between the two. Harris and Barraclough (1997) examined the effect of comorbid substance abuse on suicide rates in 7,819 patients with bipolar disorder, unipolar depression, or schizophrenia. Substance abuse problems increased the lifetime risk of suicide in all of the patients, but the increase was greatest among those with bipolar disorder (recurrent unipolar patients were not identified separately).

Rapid-cycling bipolar disorder, defined by four or more mood episodes per year, tends to have a more treatment-resistant course, and a link between the risk of rapid cycling

and substance abuse has long been considered likely. In the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD), a multicenter project designed to evaluate the longitudinal outcome of patients with bipolar disorder, the first 500 patients were evaluated for clinical characteristics associated with rapid cycling (Schneck et al., 2004). The investigators found a correlation between substance abuse and rapid cycling but concluded that the direction of causality was unknown; that is, it was not clear whether the substance abuse destabilized the bipolar disorder and led to rapid cycling, or the more severe psychopathology associated with rapid cycling predisposed to substance abuse. The authors did find that among rapid cyclers, those with bipolar-I were more likely than those with bipolar-II to abuse substances.

Mixed states, like rapid cycling, are characterized by greater psychopathology and associated with less favorable treatment outcomes than bipolar illness uncomplicated by these states (see Chapter 1). The observation that alcohol and drug abuse is significantly higher in patients with mixed mania has been reported by several authors (Winokur et al., 1969; Himmelhoch et al., 1976a; Himmelhoch and Garfinkel, 1986). Other investigators, however, have not found a higher frequency of substance abuse disorders in patients with mixed states (Cassidy et al., 2001; Brieger, 2005). Himmelhoch and colleagues (1976a, p. 1065) noted that "drug abuse (particularly alcohol and sedatives) alters the clinical presentation of manic-depressive swings, and the impact of oversedation or withdrawal or both on a 'pure' affective state is to make it dysphoric and mixed." More recently, Goldberg and colleagues (1999) studied the long-term effects of substance abuse on the course of bipolar-I disorder. They found that in a sample of hospitalized patients, substance abuse was more common among those who had mixed states. Remission during hospitalization was less likely among those with mixed mania, current substance abuse, or even a past history of substance abuse in the absence of current substance abuse. This finding raises the possibility that early or nonchronic substance abuse can have long-term negative effects on the course of bipolar disorder.

Although substantial data support the contention that alcohol abuse has a deleterious effect on mood disorders, less is known about the impact of moderate alcohol use. For healthy males, moderate alcohol use can have health benefits through a reduction in mortality from cardiovascular disease (Gaziano et al., 2000), but for patients with mood disorders, the negative effects on mood may outweigh the benefits. A study of 84 adult outpatients with bipolar-I or -II disorder who did not have active substance abuse disorders examined the relationship of moderate alcohol use to symptoms of mania and depression. On average, these

patients consumed only 2.2 alcoholic beverages per week. Overall, beer consumption was not associated with mood symptoms; the consumption of distilled spirits, however, was associated with a lifetime number of manic episodes (Goldstein et al., 2005).

Comorbid substance abuse is reported to increase a bipolar patient's risk of experiencing a switch to mania when treated with an antidepressant (see Chapter 19). A recent controversial meta-analysis failed to find an increased risk of manic switch when the combination of a mood stabilizer³ and an antidepressant was used to treat bipolar depression; however, all of the trials reviewed excluded patients with substance abuse disorder (Gijsman et al., 2004), and were therefore not representative of patients seen in clinical practice.

A smaller, retrospective investigation that did include substance abusers studied 53 DSM-IV bipolar patients. Fully 60 percent of those with comorbid substance abuse had a history of antidepressant-induced mania or hypomania, compared with 18 percent of patients with no substance abuse history. None of the patients without a substance abuse history switched into mania if they were taking a concomitant mood stabilizer during periods of antidepressant treatment. In the subgroup with comorbid substance abuse, however, 29 percent of the patients taking both an antidepressant and a mood stabilizer experienced antidepressant-induced mania or hypomania (Goldberg and Whiteside, 2002).

The effect of marijuana on mood changes was examined in a group of 50 patients with new-onset bipolar disorder. (Strakowski et al., 2000). Patients were followed for a period that ranged from 16 to 104 weeks. During this period, on average, patients met the full criteria for marijuana dependence or abuse 13 percent of the time. Patients who experienced a longer duration of marijuana abuse/dependence also had longer periods of mania. It is not clear whether the drug contributed to the maintenance of the manic state, or manic patients were more likely to abuse it as a result of symptoms associated with their elevated mood. A recent study carried out in the Netherlands, however, found that while use of marijuana at baseline increased the risk for manic symptoms during follow-up, manic symptoms at baseline did not predict the onset of marijuana use during follow-up (Henquet et al., 2006).

Evidence generally points to a destabilizing effect of marijuana. Its effect on mood was evaluated in participants in the 1980 ECA study, who were then questioned in a follow-up investigation conducted between 1994 and 1996 (Bovasso, 2001). Marijuana abuse was associated with subsequent depressive symptoms in individuals who had had no depression at the beginning of the study. Specifically, participants with no baseline depressive symptoms

who had a diagnosis of marijuana abuse were four times more likely than those with no marijuana abuse to have depressive symptoms at the follow-up assessment. Suicidal ideation and anhedonia were both associated with abuse of the drug. Shedding light on causality, depressive symptoms at baseline did not predict later development of marijuana abuse, supporting the theory that the abuse of the drug led to the depression, rather than the reverse. An Australian study of 81 patients with recent-onset psychosis (bipolar disorder, schizophrenia, delusional disorder, substance-induced psychosis) found that a higher frequency of marijuana use was predictive of psychotic relapse, after controlling for medication adherence, other substance abuse, and duration of untreated psychosis (Hides et al., 2006). An increase in psychotic symptoms was also predictive of relapse to marijuana use.

Treatment nonadherence may be a mediator of poorer outcome among manic-depressive patients with substance abuse. Personality factors, attitudes toward medication, and the experience of side effects have all been associated with nonadherence (see Chapter 21); it is only more recently that attention has been given to the role of comorbid substance abuse (Haywood et al., 1995; Swartz et al., 1998; Perlick et al., 2004). Patients with substance abuse are likely to have poor insight into both their substance abuse and their mood disorder, and the denial of the need for medication is a common reason for nonadherence in this population, especially in the bipolar subgroup (Keck et al., 1997). Calabrese and Delucchi (1990) found that poor medication adherence associated with comorbid alcohol, marijuana, or cocaine abuse led to poor outcomes in rapid-cycling patients being treated with lithium or valproate. The efficacy of these medications was not affected by comorbid substance abuse in medication-adherent patients.

The disorganized lifestyle that accompanies substance abuse, difficulties in personal relationships and employment, and the experience of more adverse effects due to the interaction between medications and alcohol and drugs (e.g., fatigue, headache, irritability, destabilized sleep, neurocognitive side effects) also contribute to the poorer clinical outcomes seen in bipolar patients with substance abuse problems. (See Chapter 4 for further details on the relationship between substance abuse and the clinical course of bipolar disorder.)

ANXIETY DISORDERS

While comorbidity implies the presence of two separate disorders, individual symptoms of anxiety—agitation, accelerated thought processes, restlessness, social anxiety, irritability, and dysphoric mood—are common features of

depression, mixed states, and mania (Young et al., 1993; Gibb et al., 2005). In one study, 39 percent of a group of inpatients with bipolar disorder had symptoms of anxiety that were an integral part of their mood episodes (Cassidy et al., 1998). Thus it is not surprising that epidemiologic studies have found full-syndrome anxiety disorders to be common in bipolar populations. McElroy and colleagues (2001) observed a 42 percent rate of anxiety disorders in a group of 288 outpatients with bipolar-I or -II disorder, nearly the same rate noted earlier for anxiety *symptoms*. This rate was identical to the rate of substance abuse in the same clinical sample. The presence of at least one Axis I anxiety diagnosis was associated with a history of development of both cycle acceleration and more severe episodes over time. Table 7-4 summarizes the rates of comorbid anxiety disorders in this sample of bipolar patients.

In contrast to substance abuse, which is more common in bipolar-I than bipolar-II patients, comorbidity of anxiety disorders may be more common in patients with bipolar-II disorder (Judd et al., 2003a). In a recent Finnish study (Mantere et al., 2006), for example, rates of comorbid anxiety were similar in bipolar-II disorder and major depression (56.5 percent and 52.5 percent, respectively), but lower in bipolar-I patients (35.6 percent). This association may be related to the fact that bipolar-II patients have a more chronic course, more major and minor depressive episodes, and shorter well intervals between episodes.

Panic disorder and OCD are particularly common comorbidities in patients with bipolar disorder. In the ECA

study, 21.0 percent of patients with either bipolar-I or bipolar-II disorder met criteria for lifetime panic disorder, and 21.0 percent met criteria for lifetime OCD, compared with 0.8 and 2.6 percent, respectively, in the general population (Robins and Regier, 1991). Table 7-5 provides an overview of studies of the comorbidity of bipolar and anxiety disorders.

Sociodemographic risk factors associated with bipolar-anxiety comorbidity were derived from the Netherlands Mental Health Survey and Incidence Study, a prospective epidemiological study of 7,076 adults aged 18 to 64 years. Comorbid mood and anxiety disorders, but not pure mood disorders (depression, bipolar disorder, and dysthymia), were associated with female gender, younger age, lower educational level, and unemployment (de Graaf et al., 2002).

There appears to be an interaction between mood and anxiety disorders in that each illness can be triggered or worsened by the other. Bipolar patients with high anxiety scores are more likely than those with low anxiety to have made suicide attempts, to abuse alcohol, and to respond less favorably to lithium treatment (Young et al., 1993). An analysis of a cross-sectional sample from the STEP-BD project found that the presence of a comorbid anxiety disorder was associated with younger age at onset of bipolar disorder, decreased likelihood of recovery, poorer role functioning, and lower quality of life (Otto et al., 2006). Comorbid anxiety and bipolar disorders were also associated with substance abuse and a greater risk of suicide attempts in the STEP-BD data.

TABLE 7-4. Percent of 288 Bipolar Patients Who Also Met Criteria for Various Anxiety Disorders

Disorder	Lifetime %	Current %
Anxiety disorders	42	30
Panic disorder/agoraphobia	20	9
Social phobia	16	13
Simple phobia	10	8
Obsessive-compulsive disorder	9	8
Post-traumatic stress disorder	7	4
Generalized anxiety disorder	3	3
Other anxiety disorders	3	2

Source: Adapted from Freeman et al., 2002.

Not all studies of comorbid anxiety and bipolar disorders have found a less favorable outcome. In a French study that evaluated 318 consecutively hospitalized bipolar patients, comorbidity with anxiety disorders was not correlated with severity of bipolar illness, as defined by number of previous hospitalizations, psychotic features, abuse of alcohol and drugs, and violent and nonviolent suicide attempts (Henry et al., 2003). This study also differed from other investigations in finding that comorbid patients, compared with bipolar patients without anxiety, responded less well to anticonvulsants but equally well to lithium; other studies have found anticonvulsants to be more effective than lithium in this population (see Chapter 24). The authors noted that only 21 percent of the patients in the study had a history of substance abuse. This relatively low rate of substance abuse may explain why the comorbid anxiety disorders had less of a negative impact on the clinical course of the bipolar disorder and its treatment than has been found in other studies.

Determining the prevalence of comorbid anxiety disorders and elucidating the nature of their interaction with bipolar disorder is scientifically important as well as clinically useful. Some investigators have suggested that genetic heterogeneity of bipolar illnesses may be responsible for the comorbidity with anxiety disorders (MacKinnon et al., 2003). That is, different forms or subphenotypes of bipolar disorder appear to aggregate in families and may be associated with different combinations of susceptibility genes and comorbid presentations (see Chapter 13). Ultimately, genetic research will provide a more fundamental understanding of comorbidity.

Panic Disorder

Panic disorder is one of the most common comorbid anxiety disorders seen in bipolar patients (McElroy et al., 2001). Data from the ECA study found that the lifetime prevalence of panic disorder among individuals with

bipolar disorder was 21 percent, compared with 10 percent among those with unipolar depression and 0.8 percent of the general population (Chen and Dilsaver, 1995b). Conversely, patients with panic disorder have high rates of bipolar disorder, ranging from 6 to 23 percent (Savino et al., 1993; Bowen et al., 1994; Perugi et al., 1999).

Comorbid panic disorder can negatively affect the course of bipolar disorder. In a sample of 66 patients with bipolar-I disorder, comorbid panic symptoms were associated with more prior depressive episodes, higher levels of depressive symptoms, and greater suicidal ideation during the acute treatment phase. Patients who reported high lifetime scores on the panic-agoraphobia spectrum took 27 weeks longer for their depressive episodes to remit than those who reported low scores (44 versus 17 weeks) (Frank et al., 2002).

Not only is the bipolar disorder more severe in comorbid patients, but so, too, is the anxiety disorder. The NCS found that the co-occurrence of bipolar disorder and panic attacks was associated with earlier onset of panic attacks (age 17.1 versus 22.0 years) and, not surprisingly, with significantly greater panic symptomatology (Goodwin and Hoven, 2002). Comorbid substance dependence, specific phobia, and generalized anxiety disorder were each independent correlates of the co-occurrence of bipolar disorder and panic attacks.

Evidence suggests that panic disorder may be genetically related to bipolar disorder. The National Institute of Mental Health's (NIMH) Bipolar Genetics Initiative, which focused on family members of probands with bipolar disorder, found that panic disorder occurred in 17 percent of relatives who had a recurrent major affective disorder, compared with only 3 percent of those who did not (MacKinnon et al., 2002). Conversely, 90 percent of first-degree relatives with panic disorder also had a major affective disorder (MacKinnon et al., 1997).

It has been observed that some forms of rapid cycling and panic disorder are phenomenologically linked by sudden shifts in affect. Consequently, a logistic regression analysis of rapid mood switching as a function of familial risk for panic disorder was performed on data gathered from subjects in the NIMH Bipolar Genetics Initiative (MacKinnon et al., 2003). The analysis found that familial panic disorder increased the odds of rapid mood switching, suggesting that this comorbid presentation may stem from a genetically distinct subtype of bipolar disorder. Similarly, family clusters or specific susceptibility genes have been identified for bipolar disorder with psychotic features (Potash et al., 2001) and for suicidality in the context of alcohol abuse/dependence and bipolar disorder (Potash et al., 2001). A study of bipolar patients that focused on siblings found that those who did not suffer from a mood disorder had a low rate of panic disorder (3 percent) compared with those who had bipolar disorder (32 percent) (Doughty et al., 2004).

The pathophysiology underlying the close relationship between the two disorders is not fully understood. Dysregulation of the serotonin system probably plays a role in the overlap of mood and anxiety disorders, and the fact that SSRIs are first-line agents in the treatment of panic disorder suggests a role for serotonin in the pathophysiology of that disorder. SSRIs and postsynaptic serotonin receptor antagonists are also commonly used to treat mood disorders, but the role of serotonin in bipolar disorder is complex. As detailed in Chapter 14, some studies have found abnormalities in levels of 5-hydroxyindolacetic acid (5-HIAA) in patients with bipolar disorder (Young et al., 1994); however, this finding is not consistent across all studies (Berrettini et al., 1985). Patients with both bipolar disorder and panic disorder have been found to have noradrenergic hyperactivity. Increased plasma levels of the main norepinephrine metabolite, 3-methoxy-4-hydroxyphenylglycol (MHPG), have been found in patients with mania and depression (Swann et al., 1983). Several lines of evidence suggest that catecholamines, especially norepinephrine, are also implicated in the etiology and symptomatology of panic disorder. Significantly higher baseline levels of norepinephrine excretion are seen in patients with panic disorder compared with healthy controls (Bandelow et al., 1997).

As reviewed in Chapter 24, SSRIs and serotonin/norepinephrine reuptake inhibitors (SNRIs) may be used to treat comorbid anxiety in bipolar disorder. However, they carry the risk of inducing manic and mixed episodes, as well as longer-term cycle acceleration.

The efficacy of benzodiazepines in panic disorder suggests that dysregulation of the gamma-aminobutyric acid (GABA) system may also contribute to the etiology of this illness. Evidence for GABA abnormalities in bipolar

disorder, however, is uneven and conflicting. For example, effective mood stabilizers such as valproate have putative effects on the GABA system. Valproate increases functional levels of GABA in the brain, apparently by activating the biosynthetic enzyme glutamic acid decarboxylase and inhibiting the degradative enzyme GABA-transaminase. Other mood-stabilizing anticonvulsants also modulate the GABA system. However, the relevance of this neurotransmitter to unstable mood in bipolar disorder remains unknown. (See Chapter 14 for more information on the role of specific neurotransmitters in manic-depressive illness.)

Social Anxiety Disorder and Social Phobia

In the NCS, an epidemiologic study based on nonclinician assessments, nearly one-half of patients with bipolar disorder met criteria for a lifetime comorbid social anxiety disorder, compared with 13.3 percent of the general population (Kessler et al., 1994). However, data from the Stanley Foundation Bipolar Network, obtained by clinicians using structured diagnostic interviews with a clinical population, reveal social anxiety disorder in only 16 percent of bipolar patients (McElroy et al., 2001). As with panic disorder, there appears to be a mutual-risk interaction, such that patients with social anxiety disorder also have high rates of bipolar disorder. Symptoms of social anxiety tend to disappear during hypomanic episodes, when excessive social inhibition is replaced by disinhibition. There may be an underlying social behavior dysregulation connecting the two disorders (Perugi et al., 2001). A recent study of 57 patients with social anxiety disorder found that a subgroup improved while taking antidepressants, and indeed presented with clear hypomania. Without antidepressant therapy, the symptoms of social anxiety returned (Valengaet et al., 2005).

Although social anxiety disorder is a serious illness and is strongly associated with functional impairment, feelings of social isolation, and suicidal ideation (Olfson et al., 2000), it tends to go unrecognized and untreated (Weiller et al., 1996). Clinicians who treat patients with bipolar disorder should be particularly wary of failing to identify this potentially disabling disorder. However, just as with panic disorder, treatment decisions can be complex. For example, in a study of 32 patients with social anxiety disorder, 14 (78 percent) of 18 patients who responded to a monoamine oxidase inhibitor (MAOI) became hypomanic (Himmelhoch, 1998) (see Chapter 24).

Obsessive-Compulsive Disorder

Analysis of data from the ECA study showed a lifetime prevalence of OCD of 21.0 percent in patients with bipolar disorder; this was significantly higher than the rates of 12.2 percent in unipolar depression and 2.5 percent in the

general population (Chen and Dilsaver, 1995a). As with anxiety disorders in general, bipolar-II is more common than bipolar-I among patients with OCD (Perugi et al., 1997, 2002). Among patients with bipolar-I disorder, those with episodes of mixed mania may be more likely to have comorbid OCD than those with pure euphoric mania (McElroy et al., 1995). The presence of comorbid OCD leads to greater bipolar morbidity and possibly to greater mortality due to suicide (Krüger et al., 2000). Compared with bipolar patients without OCD, those with OCD have more severe symptomatology, including more lifetime suicidal ideation, suicide attempts, and comorbid panic disorder.

The phenomenology of comorbid OCD is somewhat different from that of "pure" OCD. The onset of the illness is more gradual, and the course tends to be episodic rather than continuous. There are higher rates of sexual and religious obsessions and a lower rate of checking rituals (Perugi et al., 1997, 2002). The episodic nature of OCD in bipolar patients may be related to the course of the mood disorder. In one study (Strakowski et al., 1998), the symptoms of both OCD and bipolar disorder cycled together in 7 of 16 patients. There were no cases of OCD that persisted in the absence of an affective syndrome. These data showing such a tight correlation between the symptom emergence of the two illnesses suggest the possibility that the two represent variability in the expression of a single underlying CNS dysfunction.

Post-Traumatic Stress Disorder

Although PTSD is a less common comorbidity than some of the other anxiety disorders, it is substantially more

common in bipolar patients than in the general population. A meta-analysis of eight studies representing a total of 1,214 bipolar patients found that the mean lifetime prevalence of PTSD in those patients was 16.0 percent, a rate roughly double that of the general population (Otto et al., 2004). Table 7-6 summarizes the seven studies.

Little is known about why there is a relatively high rate of comorbidity of the two disorders, but there are some characteristics of bipolar disorder that place a patient at risk for the development and exacerbation of PTSD and vice versa. Pretrauma psychiatric illness, including some symptoms of depression and hypomania, increase a patient's vulnerability to developing PTSD after trauma (Schnurr et al., 1993). Abnormal mood at the time of the trauma can reduce resilience. For example, unrealistic and exaggerated negative attitudes common in depression can aggravate a patient's response to stressful events.

The impulsivity and poor judgment associated with elevated mood states place patients at risk for the occurrence of traumatic events such as assault and motor vehicle accidents. In one study of the general population, 51 percent of women and 61 percent of men reported a history of exposure to trauma (Kessler et al., 1995), and while some studies have found no difference among bipolar patients (Neria et al., 2002), others have found rates as high as 98 percent (Mueser et al., 1998). The experience of psychosis, which may occur in the context of a manic or depressive episode, is often a highly traumatic event in itself. Psychosis fundamentally disrupts an individual's notion of self and expectations of the future. Psychosis as part of an abnormal mood episode occurs in the setting of a highly volatile

TABLE 7-6. Prevalence of Post-Traumatic Stress Disorder (PTSD) in Samples of Patients with Bipolar Disorder

Study	Sample Characteristics	Sample Size	Rate of PTSD (%)
Keck et al., 1995	BP patients admitted for mania or mixed mania	71	17
Kessler et al., 1997	National general population survey; respondents with BP-I characterized by euphoria, grandiosity, and excessive energy	29	39

emotional state that further diminishes a patient's capacity to adaptively tolerate this type of stress.

On the other hand, for some patients or situations, euphoria or an underlying hyperthymic temperament associated with bipolar disorder may increase resilience in the face of trauma. That is, some patients with bipolar disorder have temperamental features that protect them at least partially from the adverse psychological consequences of severe stress. Persistent optimism and self-confidence can enable an individual to avoid some of the emotional injury that occurs in the face of trauma and continue to function in an adaptive way in situations in which others would experience high levels of distress and functional impairment (Jamison, 2004). The tendency to shift focus rapidly, not always a positive attribute of a hyperthymic temperament, may be protective during periods of intense stress by allowing the individual to avoid ruminating and fixating on traumatic experiences. The hyperthymic individual is also future oriented, a trait that decreases the deleterious influence of past events.

Symptoms of PTSD can aggravate the course of bipolar disorder. Stress of any kind places bipolar patients at risk for the emergence of a mood episode. PTSD is commonly associated with chronic overarousal that occurs in addition to the acute overarousal experienced in response to environmental cues. One of the consequences of overarousal is sleep disturbance, which can have a direct impact on the course of bipolar disorder (see Chapter 16). Chronic symptoms of avoidance seen in patients with PTSD can lead to social isolation, which is associated with more depression and longer recovery times in bipolar patients (Johnson et al., 1999).

Like panic disorder and bipolar illness, PTSD has been associated with chronic noradrenergic hyperactivity (Kosten et al., 1987). One consequence of this abnormality is a decrease in the number and sensitivity of alpha-2-adrenergic receptors (Maes et al., 1999). The serotonin system is almost certainly involved as well. Large placebo-controlled trials have demonstrated the efficacy of SSRIs in the treatment of PTSD (see Chapter 24), supporting the view that pathology associated with the serotonin system plays an important role in the development and maintenance of the disorder.

The presence of comorbid PTSD increases the morbidity, mortality, and functional impairment associated with bipolar disorder. Data from the STEP-BD project reveal that patients with comorbid PTSD have a lower likelihood of being in remission from bipolar disorder, are more likely to abuse substances, have higher rates of suicide, and have lower role attainment and quality of life compared with bipolar patients without PTSD (Simon et al., 2004b).

OTHER PSYCHIATRIC ILLNESSES

Attention-Deficit Hyperactivity Disorder

The overlap of symptoms seen in bipolar disorder with those seen in attention-deficit hyperactivity disorder (ADHD) can make it difficult to separate the two illnesses. This is especially true in children, in whom mood disorders manifest somewhat differently than in adults, and who may have difficulty in accurately describing their internal affective states. Distractibility, physical hyperactivity, and pressured speech can be symptoms of either bipolar disorder or ADHD. See Chapter 6 for an extensive review of the comorbidity of ADHD and other disorders in children and adolescents. See also Chapter 9 for an in-depth discussion of the pervasive attentional deficits associated with bipolar illness, even when the illness is in remission.

The rate of comorbidity for ADHD is much lower in bipolar adults than in children. Most children aged 12 and younger with bipolar disorder meet the criteria for ADHD (Findling et al., 2001), whereas comorbid ADHD was found in just 9 percent of the first 1,000 adult patients enrolled in the STEP-BD project (aged 15 and older) (Kogan et al., 2004). Among adult patients with early-onset bipolar disorder (before age 13), the rate rose to 20 percent (Perlis et al., 2004). ADHD affects approximately 4 percent of adults in the general population (Kessler, 2004).

Data from a large claims database revealed that adults diagnosed with ADHD were significantly more likely to have a comorbid diagnosis of bipolar disorder or major depressive disorder than non-ADHD patients (Secnik et al., 2005). Adults diagnosed with ADHD had significantly higher outpatient, inpatient, and prescription drug costs than noncomorbid patients with a mood disorder. A study based on structured psychiatric interviews found that 88 percent of adults with comorbid ADHD and bipolar disorder had the bipolar-II subtype (Wilens et al., 2003). This is another example of a comorbidity that is chronic in nature, being associated with the more chronic form of bipolar disorder. Compared with patients with pure ADHD, those with both bipolar disorder and ADHD had more DSM-IV symptoms of ADHD (14.8 versus 11.4 percent), poorer global functioning, and more additional comorbid psychiatric disorders (3.7 versus 2.0 percent). Based on the outcome of their analysis, the authors concluded that the observed symptomatology in the comorbid group supported the construct of two separate disorders that were distinguishable clinically.

Eating Disorders

Only a few studies have assessed the co-occurrence of bipolar disorder and eating disorders in community sam-

ples. One study of 3,258 Canadian adults found no overlap between 22 individuals diagnosed with lifetime bipolar disorder and 4 individuals diagnosed with anorexia nervosa; other eating disorders were not assessed (Fogarty et al., 1994). More recent studies, which differed somewhat by including subthreshold hypomania and binge eating, did find associations. Among 891 randomly selected schoolgirls, approximately one-quarter of those with an eating disorder had subthreshold bipolar disorder, compared with 3.8 percent of those with no eating disorder (Lewinsohn et al., 2000). However, the rate of full-syndrome bipolar disorder was similar among the girls with and without an eating disorder. Binge eating has been found to be specifically associated with hypomania. A comparison of patients with a history of hypomania, patients with a history of depression, and a control group with no abnormal mood episodes found that the rate of binge eating was highest in the group with a history of hypomania (Angst, 1998).

Studies of clinical populations have also found connections between bipolar disorder and eating disorders. Data gathered from clinical populations may differ from community data, however, because subjects currently in treatment typically have higher levels of distress and comorbidity than do community samples.⁴ Consistent with this pattern, bipolar-II disorder was found to be common among hospitalized patients with eating disorders. An evaluation of a group of 15 bulimics and 7 anorexics found that 19 of the 22 had a major mood disorder; 1 had bipolar-I disorder, and 13 had bipolar-II (Simpson et al., 1992). In a larger sample, patients with bipolar disorder were found to have a lifetime prevalence of bulimia of 4 percent (bipolar-I, 3 percent and bipolar-II, 6 percent) and a lifetime prevalence of anorexia nervosa of 2 percent (bipolar-I, 2 percent and bipolar-II, 4 percent) (McElroy et al., 2001). Analysis of the first 500 patients in the STEP-BD investigation found that the rate of bulimia in bipolar women was relatively high (12 percent), as was true for the rate in bipolar men (2 percent) (Baldassano et al., 2005). In the only study assessing binge eating and bipolar disorder (Krüger et al., 1996), the rate found in the bipolar patient sample (13 percent) was significantly higher than that reported for the general population (5 percent) (Spitzer et al., 1993). In a comprehensive review of comorbid bipolar and eating disorders, McElroy and colleagues (2005) found a particularly strong association between bulimia nervosa and bipolar-II disorder. Their summary of eating disorders in patients with bipolar disorder is given in Table 7-7.

Axis II Disorders

Affective instability is a common feature of certain personality disorders, especially those found in cluster B. Because of the frequency with which these disorders are seen in

bipolar patients and the effect they have on clinical course, Chapter 10 focuses specifically on this topic.

MEDICAL ILLNESSES

In addition to psychiatric disorders, bipolar patients experience certain general medical conditions at a higher rate than the general public. Some of this excess morbidity is associated with adverse effects of medications used to treat bipolar disorder and some with lifestyle. In other cases, the etiology of the comorbidity is not fully understood. Because many patients with serious mental illnesses have difficulty obtaining adequate medical care, the treating psychiatrist may be the only physician caring for these patients on a regular basis, and therefore should screen them for common medical problems.

Cardiovascular Disease

Cardiovascular disease accounts for the majority of the mortality seen with metabolic syndrome (discussed later). Obesity, glucose dysregulation, and dyslipidemia are all risk factors for cardiovascular disease, and consequently patients with bipolar disorder experience cardiovascular mortality at elevated rates compared with the general population (Weeke, 1979; Sharma and Markar, 1994). The mortality ratio of bipolar patients versus the general population for cardiovascular disease is 3.0. Additionally, when all the symptoms of the metabolic syndrome are controlled for, bipolar disorder continues to be an independent risk factor for cardiovascular mortality (Norton and Whalley, 1984). Before the modern era of psychopharmacology, death from manic exhaustion was not uncommon; many such deaths were attributable to cardiac events (Derby, 1933; Cade, 1979). In a long-term study that followed a group of 406 patients for more than 30 years, mortality due to circulatory disorders was second only to suicide as a cause of death among patients with bipolar disorder (Angst et al., 2002). A large study of 15,386 patients hospitalized in Sweden for bipolar disorder between 1973 and 1995 found that the most frequent cause of death was cardiovascular disease, followed by suicide and cancer. The observed number of cardiovascular deaths among male patients was 1.9 times the expected number. Among females, the mortality rate was 2.6 times the expected number (Osby, 2001).

Increased platelet aggregation and low-grade systemic inflammation seen in depressed patients may be mechanisms by which a mood disorder is a significant and independent risk factor for ischemic heart disease (Musselman et al., 1996). Patients with bipolar disorder also are more likely to smoke and to have a history of hypertension (Yates and Wallace, 1987; Johannessen et al., 2006).

TABLE 7-7. Studies of Eating Disorders in Patients with Bipolar Disorder

Study	Study Population	Assessment Instrument; Diagnostic Criteria	Eating Disorder Findings
Strakowski et al., 1992	41 inpatients with BP and first-episode mania (25 women)	SCID; DSM-III-R	7.3% had BN; 12.0% of women and no men had BN
Strakowski et al., 1993	60 inpatients with BP-I and first-episode mania	SCID; DSM-III-R	6.6% had BN
McElroy et al., 1995	71 inpatients with BP-I and acute mania (39 women)	SCID; DSM-III-R	8.5% had AN or BN
Krüger et al., 1996	61 euthymic outpatients with BP-I ($n=43$) or BP-II ($n=18$) (38 women)	Semistructured Clinical Interview; DSM-IV	13.1% had BED; 37.7% had recurrent binge eating episodes
Schuckit et al., 1996	14 women with BP and 1,176 with other psychiatric disorder ^a	SAGA; DSM-III-R	Of women with BD, none had AN and 7.1% had BN, compared with 0.3% and 0.6%, respectively, of controls ($p<.01$ for BN)
Cassano et al., 1998	47 inpatients with BP-I with psychotic features	SCID; DSM-III-R	6.4% had AN or BN
Edmonds et al., 1998	64 persons with BP-I ($n=44$) or BP-II ($n=11$) from a BP registry	DIGS; DSM-IV	7.3% had a DSM-IV ED
Pini et al., 1999	125 patients with BP-I with psychotic features (69 women)	SCID; DSM-III-R	4.0% had BN and 2.4% had AN
McElroy et al., 2001	288 outpatients with BP-I or BP-II (162 women)	SCID; DSM-IV	5.9% had AN or BN
Vieta et al., 2001	129 outpatients with BP-I (76 women)	SCID; DSM-IV	2.3% had BN
MacQueen et al., 2003	139 outpatients with BP-I or BP-II (94 women)	SCID; DSM-IV	15% had an ED

AN = anorexia nervosa; BED = binge eating disorder; BN = bulimia nervosa; BP = bipolar disorder; DIGS = Diagnostic Interview for Genetic Studies; ED = eating disorder; SAGA = Semi-Structured Assessment for the Genetics of Alcoholism; SCID = Structured Clinical Interview for DSM.

Thyroid Dysfunction

Thyroid dysfunction associated with bipolar disorder is a significant problem. In addition to the medical morbidity associated with thyroid problems, mood states and affective stability are intimately connected to proper functioning of the hypothalamic–pituitary–thyroid axis (see Chapter 14). Patients with thyroid disease have higher rates of panic disorder, simple phobia, OCD, major depressive disorder, bipolar disorder, and cyclothymia than the general population (Placidi et al., 1998). Bipolar women have higher rates of comorbid thyroid disease than men; analysis of the first 500 STEP-BD participants, for example, found rates of 26.9 percent in females and 5.7 percent in males (Baldassano et al., 2005). Hypothyroidism is the

most frequent manifestation of thyroid dysfunction. The most common psychiatric symptoms related to hypothyroidism are depression and cognitive dysfunction. Fatigue, weight gain, dry skin, hair loss, intolerance to cold, and irritability are also seen. Abnormally elevated levels of thyroid hormone can cause dysphoria, anxiety, restlessness, and emotional lability (Trzepacz et al., 1988).

Problems with the hypothalamic–pituitary–thyroid axis are more prevalent in patients with mood disorders than in the general population; however, many studies have included large numbers of patients taking lithium or carbamazepine, which may account for some of the high prevalence found. (The association between mood stabilizers and thyroid function is discussed in Chapter 20.) Nevertheless, the effects of lithium and carbamazepine do not fully explain

the association between bipolar disorder and thyroid dysfunction. In a sample of bipolar patients who had never been treated with either lithium or carbamazepine, the rate of thyroid hypofunction was 9 percent (Valle et al., 1999). Hypofunction was determined on the basis of serum levels for total thyroxine (T_4), total triiodothyronine (T_3), and thyroid-stimulating hormone (TSH) levels. Bipolar-II patients showed significantly lower levels of thyroid functioning than those with bipolar-I disorder, as measured by higher TSH levels. Primary hypothyroidism was diagnosed in 3 percent of a general population sample (Flynn et al., 2004).

The relationship between thyroid hypofunctioning and rapid cycling is unclear. In the sample just described, no difference in thyroid parameters was observed between rapid-cycling and non-rapid-cycling bipolar patients. Other studies, however, have found hypothyroidism to be a risk factor for rapid cycling. For example, in a sample of 30 patients with rapid-cycling bipolar disorder, 60 percent also had hypothyroidism (Bauer et al., 1990). Subclinical hypothyroidism, in which thyroid hormone levels are low compared with controls but still fall within the broad normal range, has been found to be associated with rapid cycling (Kusalic, 1992), although more recently, doubt has been cast on this association (Post et al., 1997). Identifying subclinical hypothyroidism in bipolar patients may be almost as important as identifying overt dysfunction. In 1974, Wenzel and colleagues introduced a system for grading hypothyroidism. In this classification, grade 1 represents overt hypothyroidism, as defined by decreased serum T_4 . Grades 2 and 3 define subclinical hypothyroidism. Grade 2 is characterized by increased TSH with normal T_4 , and grade 3 by the presence of an isolated exaggeration of the TSH response to stimulation by thyroid-releasing hormone (TRH) (Wenzel et al., 1974).

Subclinical hypothyroidism can influence the outcome of mood disorders even in samples of patients with otherwise normal thyroid indices. Frye and colleagues (1999) assessed thyroid function prospectively in 52 outpatients with bipolar disorder. Even though their free thyroxine index (FTI) values were within the normal range, patients with lower mean FTI values had more affective episodes and more severe depressive symptoms. Cole and colleagues (2002) found less favorable treatment response in bipolar patients with low-normal FTI and high-normal TSH. Others have found subclinical hypothyroidism to be associated with an elevated lifetime prevalence of depression (Hagerty et al., 1993). The rate of subclinical hypothyroidism is particularly high (30 percent) in patients with refractory, treatment-resistant depression (Howland, 1993). The relationship between subclinical hypothyroidism and treatment response is discussed further in Chapter 19.

Hyperthyroidism has also been linked to depressive disorders in some studies (Kathol et al., 1986; Placidi et al., 1998), but not all (Fava et al., 1995; Engum et al., 2002; Thomsen and Kessing, 2005); it has also been linked to mania in a case series (Brownlie et al., 2000), but this finding was not confirmed in a controlled study (Cassidy et al., 2002). In a recent large historical cohort study of 133,570 patients with a clinical diagnosis of osteoarthritis, depressive disorder, or bipolar disorder (610 of whom had hyperthyroidism), patients with bipolar disorder had a hazard ratio for hyperthyroidism of 1.59 ($p < .052$) compared with the arthritis controls, and 1.86 ($p < .014$) compared with those with depression (Thomsen and Kessing, 2005).

Although the evidence for a link between mood disorders and decreased thyroid function is more consistent than that for a link to increased thyroid function, the hypothesis that some mood disorders may be linked to dysregulation of thyroid function is consistent with most of the data. Clearly, all patients with a mood disorder should be tested routinely for thyroid abnormalities, including abnormal levels of TSH and free T_4 . Even in the context of normal T_4 , elevated TSH should prompt a further workup and consideration of thyroid supplementation. The absence of abnormal TSH should not rule out hypothyroidism in a patient with clinical manifestations of the disease because many patients with both major depression and bipolar disorder fail to mount a TSH response to a TRH challenge (Gold et al., 1977). Evaluation of thyroid abnormalities is particularly appropriate in rapid-cycling and treatment-resistant patients.

Overweight and Obesity

Obesity is a leading cause of preventable death in the United States, and the prevalence of overweight and obesity is increasing. A survey of 4,115 adult men and women conducted in 1999 and 2000 as part of the National Health and Nutrition Examination Survey found that 64.5 percent of the U.S. population is overweight (body mass index [BMI] ≥ 25), and 30.5 percent is obese (BMI ≥ 30) (Flegal et al., 2002). A separate, smaller study of 50 bipolar patients, which used the same BMI standard, found an obesity rate that was only slightly higher (32 percent). The number of previous depressive episodes was correlated with the likelihood of being overweight or obese. Most of the weight gain occurred during acute rather than maintenance treatment, and the increase in BMI was related to the severity of the depressive episode, as measured by the patient's score on the Hamilton Rating Scale for Depression (Fagiolini et al., 2002). Although several studies have found significant obesity in bipolar patients (Elmslie et al., 2000, 2001; Fagiolini et al., 2002; McElroy et al., 2002), it is difficult to ascertain the degree to which the obesity is

secondary to medications used to treat bipolar disorder or to the illness per se (see review by Toalson et al., 2004).

Longitudinal studies of children and adolescents have found a positive association of major depressive disorder with adult BMI. This association persisted even after controlling for age, gender, substance abuse, social class, pregnancy, and medication exposure (Pine et al., 2001). An important implication of the last of these factors (medication exposure) is that there is a baseline risk for elevated BMI that is independent of the weight gain associated with psychotropic medication. Yet despite the multiple etiologic factors that link mood disorders with obesity, of greatest concern to the clinician is the fact that mood-stabilizing medications frequently cause weight gain (see Chapter 20). Evidence for this conclusion comes from the Stanley Foundation Bipolar Network. Both current weight and the BMI of patients in this study were correlated with the number of weight gain–associated psychotropics to which patients had been exposed (McElroy et al., 2002). Atypical antipsychotic medications are associated specifically with central obesity, which occurs when the main deposits of body fat are localized around the abdomen. Accumulating evidence suggests that central deposition of body fat is a risk factor independent of overall obesity for mortality due to cardiovascular disease, hypertension, and type II diabetes (Donahue et al., 1987).

Other medications used to treat bipolar disorder, including lithium, valproate, and some antidepressants, have also been associated with weight gain. Thus far, there has been less concern regarding the development of metabolic syndrome with these drugs than with the atypical antipsychotics.

Beyond weight gain caused by medications, symptoms of bipolar disorder itself can lead to obesity. Depressed mood leads to lower levels of activity. Atypical features such as hyperphagia, hypersomnia, “leaden paralysis,” and carbohydrate craving are seen more commonly in bipolar depression than in major depressive disorder and are more liable to lead to weight gain. It should be noted that manic syndromes are associated with loss of appetite, hypophagia, hyperactivity, and weight loss. In the majority of bipolar patients, however, depressive symptoms are far more frequent than manic symptoms (Judd et al., 2003b). Depression is often accompanied by hypercortisolism, which is also associated with central obesity. Even in the context of normal body weight, hypercortisolism has been associated with excess visceral fat deposition as measured by computed tomography (CT) scan (Weber-Hamann et al., 2002).

Overweight and obesity, in addition to being a result of bipolar disorder, can worsen the disorder by exacerbating depression. The Western emphasis on being thin as a desirable physical trait can lead to negative body-image problems

among overweight individuals. Overweight and obese individuals may also be targets of discrimination. The socio-economic effects of excess weight were studied in a group of 10,039 randomly selected young people, who were evaluated for weight and BMI and then followed-up 7 years later. Women who had been overweight had completed fewer years of school, were less likely to be married, and had lower household incomes than those who had not been overweight; these findings were independent of baseline socioeconomic status. Men who had been overweight also were less likely to be married. In contrast, people with other chronic health conditions did not differ in these ways from the nonoverweight subjects (Gortmaker et al., 1993).

Among individuals seeking weight loss treatments, rates of mood disorders have ranged from a low of 8 percent (Wise and Fernandez, 1979) to a high of 60 percent (Hudson et al., 1988). Although there can be an overrepresentation of psychopathology among treatment-seeking patients, studies using community samples have yielded similar results. A national survey of 40,086 adults examined the relationship between body weight and clinical depression, suicidal ideation, and suicide attempts. Among women, increased body weight was associated with major depression and suicidal ideation; in men, there was also an association with suicide attempts (Carpenter et al., 2000).

Diabetes

Because overweight and obesity are associated with diabetes, many of the risk factors that have been linked to weight gain apply also to the development of diabetes. The prevalence of reported diabetes mellitus was found to be approximately three times higher in a sample of 345 hospitalized bipolar patients (9.9 percent) than in the general population (3.4 percent) (Cassidy et al., 1999). Patients in this sample also had a more severe course of their mood disorder and significantly more lifetime psychiatric hospitalizations than the nondiabetic subjects. Age at first hospitalization and duration of psychiatric disorder were similar in the two groups. Patients with bipolar disorder and comorbid diabetes have also been reported to be more likely to experience rapid cycling and to have a chronic rather than an episodic course of illness (Ruzickova et al., 2003). A comparison of 26 diabetic and 196 nondiabetic subjects from a community-based project carried out in Canada found that the disability rates for bipolar disorder were significantly different (Ruzickova et al., 2003); 81 percent of comorbid patients were receiving disability compensation payments for bipolar disorder, compared with only 30 percent of bipolar patients without diabetes.

When patients with diabetes are being treated, lithium should be used with care. Patients with juvenile-onset insulin-dependent diabetes are susceptible to diabetic

nephropathy, and the risk is increased by the presence of hypertension. On the other hand, there is evidence that when lithium is combined with an oral hypoglycemic medication or insulin, it has an assisting hypoglycemic effect in diabetic patients (Hu et al., 1997). Fasting blood glucose levels were found to be decreased in patients taking lithium combined with other therapy, but not in those being treated with a hypoglycemic agent alone. A possible explanation for this finding is that lithium increases the sensitivity of glucose transport to insulin in skeletal muscle and adipocytes (Tabata et al., 1994). The authors of this study noted that the effects of lithium on glucose transport and metabolism in skeletal muscle were strikingly similar to the effects of exercise.

Dysregulation of the hypothalamic–pituitary–adrenocortical axis occurs frequently in patients with mood disorders. Hypercortisolemia, associated with depressive states, can lead to insulin resistance. Conversely, diabetic vascular CNS lesions may contribute to mania. Weber-Hamann and colleagues (2002) found that postmenopausal women who had depression also had significantly higher levels of free cortisol than age-matched controls. Elevated levels of cortisol can lead to decreased insulin receptor sensitivity through currently unknown mechanisms (Perry et al., 2003).

A more hypothetical link between bipolar disorder and diabetes relates to intracellular signal transduction involving the enzyme glycogen synthase kinase-3 β (GSK-3 β). Alterations in GSK-3 β functioning play a role in insulin resistance. Insulin inhibits GSK-3 β , which results in enhanced glucose transport into skeletal muscle. Insulin-mediated inhibition of GSK-3 β leads as well to increased glucose utilization and the production of glycogen (Orena et al., 2000). GSK-3 β is also one of the targets for lithium action. Lithium significantly inhibits brain GSK-3 β at concentrations relevant for the treatment of bipolar disorder (Gould et al., 2004). In addition to its role in glucose regulation, active GSK-3 β facilitates apoptosis in neurons, while inhibition of GSK-3 β attenuates cellular apoptosis, resulting in a neuroprotective effect (Hetman et al., 2000). Disturbances in the GSK-3 β signal transduction pathway associated with diabetes may affect the viability of neurons that play a role in mood stabilization. Diminished insulin-mediated inhibition of GSK-3 β may have an effect opposite to that of lithium and may ultimately lead to an accentuation of psychiatric symptoms related to bipolar disorder. For a more detailed discussion of the neuroprotective role of lithium and its putative significance for lithium's mood-stabilizing effects, see Chapter 14.

Migraine Headaches

The lifetime prevalence of migraine is markedly higher among individuals with mood disorders (Swartz et al.,

2000; Fasmer, 2001; Odegaard and Fasmer, 2005) than in the general population. Bipolar women especially are more likely to suffer from migraines (Blehar et al., 1998; Calabrese et al., 2002). The Canadian Community Health Survey ($N=36,984$) found that individuals with bipolar disorder had a higher prevalence of migraine than the general population (24.8 versus 10.3 percent; $p <.05$); the sex-specific prevalence of comorbid migraine in bipolar disorder was 14.9 percent for males and 34.7 percent for females. Bipolar males with comorbid migraine reported an earlier age at onset of bipolar illness ($p <.05$) and a higher lifetime prevalence of comorbid anxiety disorders ($p <.05$) than bipolar males without migraine. Bipolar females with comorbid migraine had more additional comorbid medical disorders ($p <.05$) than bipolar females who did not have migraines (McIntyre et al., 2006). Most strikingly, bipolar-II patients are far more likely to suffer from migraines than bipolar-I patients (77 and 14 percent, respectively), leading Fasmer (2001, p. 894) to suggest that bipolar-I and bipolar-II are “biologically separate disorders [which points] to the possibility of using the association of bipolar II disorder with migraine to study both the pathophysiology and the genetics of this affective disorder.”

The comorbidity of migraine in women with bipolar-I disorder may be mediated by shared hormonal mechanisms that influence the timing of recurrence or complicate treatment. Both clinical and community studies using standardized diagnostic criteria have provided evidence of this comorbidity, independently of which illness caused the patient to seek treatment (Angst and Merikangas, 1992). In another study (Merikangas and Angst, 1992), bipolar-II disorder in probands was associated with an increased risk of migraine in relatives.

CONCLUSIONS

The scientific principle of parsimony holds that one should not increase, beyond what is necessary, the number of entities required to explain an observed phenomenon. In many cases, attributing all of a patient's symptoms to a single diagnostic entity is an appealing strategy. Symptoms that might be caused by a comorbid illness—such as excessive worry (generalized anxiety disorder), social avoidance (social anxiety disorder), distractibility (ADHD), and low energy and fatigue (diabetes)—are consistent with a diagnosis of affective disorder. Nevertheless, a large body of evidence derived from rigorously conducted studies unambiguously supports the presence of extensive comorbidity in bipolar illness, although with what frequency and which diagnosis subtype is open to debate (while substance abuse is more common in bipolar-I than in bipolar-II patients, the opposite is true for anxiety and eating disorders). It is

probably appropriate, therefore, to begin by assuming that symptoms such as those cited above are not part of the core bipolar or unipolar presentation, and then to evaluate the patient systematically for the presence or absence of suspected comorbid illnesses. At the very least, all bipolar patients should be screened routinely for both psychiatric and medical comorbidities.

This type of comprehensive evaluation is time-consuming. Complicating the clinician's task, one of the most common comorbidities—substance abuse—is likely to be actively concealed by a patient during psychiatric consultation. Self-report screening questionnaires are useful when well-validated instruments are available. If the patient fills out such a questionnaire before seeing the clinician, less time need be devoted to ruling out comorbid diagnoses. Additionally, as a clinician works with a patient over time, a deeper understanding of the patient's symptoms and level of functioning develops, increasing the likelihood of uncovering additional disorders or problems.

As with other psychiatric illnesses, patients with recurrent affective disorders often fail to experience a complete remission of symptoms and a return to premorbid levels of functioning. The widespread prevalence of comorbidities, often missed by the diagnosing clinician, offers an opportunity to improve outcomes substantially by identifying and

treating such problems as substance abuse, thyroid dysfunction, and anxiety. Patients who fail to respond adequately to multiple trials of medication should not be considered treatment resistant until a comprehensive assessment for untreated comorbidities has been undertaken. (See Chapter 24 for a discussion of the treatment of comorbid conditions.)

NOTES

1. These percentages are substantially higher than noted in the bipolar case registry (Chengappa et al., 2000), because in the Estroff et al. (1985) study, cocaine abuse was observed during an active episode of either mania or depression.
2. Estroff et al., 1985; Winokur et al., 1998; Goldberg et al., 1999; Cassidy et al., 2001.
3. Nearly 70 percent of all of the patients included in the analysis were participants in a study in which the concomitant mood stabilizer was olanzapine, which was considered placebo for purposes of the analysis. A smaller, well-designed study of lithium with antidepressants versus placebo did find a higher switch rate in the antidepressant plus lithium group, but in the meta-analysis this study was overwhelmed by the huge olanzapine study. See Chapter 19 for additional discussion of this study.
4. As noted in the introduction to this chapter, however, there are biases that operate in the other direction, namely the tendency of nonclinician interviewers to overdiagnose when using symptom checklists.

This page intentionally left blank

The patients . . . often try to starve themselves, to hang themselves, to cut their arteries; they beg that they may be burned, buried alive, driven out into the woods and there allowed to die . . . One of my patients struck his neck so often on the edge of a chisel fixed on the ground that all the soft parts were cut through to the vertebrae.

—Emil Kraepelin (1921, p. 25)

Patients with depressive and manic-depressive illness are far more likely to commit suicide than those with other psychiatric or medical illnesses. An analysis of nearly 250 studies, reported over a 30-year period, found that mood disorders carry the highest risk of suicide (Fig. 8–1; see also Juurlink et al., 2004). Yet despite this high risk, the lethality of manic-depressive illness is often underemphasized. We believe suicide is far too common in untreated, inadequately treated, or treatment-resistant manic-depressive illness. Suicide is often preventable if a correct diagnosis is made, if acute and chronic suicide risk factors are recognized and acted upon, and if appropriate treatment is provided (see Chapter 25).

We begin the chapter with a look at diagnostic and methodological issues related to the study of suicide in bipolar and unipolar depressed patients. Next, we present findings on suicide rates. We then address causes of suicide, including the contributions of genetic, family, biological, and psychosocial factors. Finally, we review psychiatric and medical comorbidities and other clinical correlates of suicidal states.

DIAGNOSTIC AND METHODOLOGICAL ISSUES

It has long been recognized that suicidal thinking and behavior are associated with both bipolar and unipolar major depressive disorders (see Chapter 2). More recently, the *Diagnostic and Statistical Manual*, 4th edition (DSM-IV) incorporated into its diagnostic criteria for major depression a specific criterion for suicidal potential: “Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide” (p. 327).

Studies of suicide have used several outcome measures—ideation, suicide attempts, and completed suicide. Over the

years, researchers have recognized that these end points reflect a wide range of thoughts and behaviors. Today, the focus is on the use of more nuanced measures, such as the type (e.g., violent versus nonviolent) and the severity (e.g., Beck Scale of Suicidal Ideation, Schedule for Affective Disorders and Schizophrenia [SADS] suicide subscale) of the attempt. Suicidal ideation without particular information about plans or means is common in manic-depressive illness. Yet it is neither a sensitive nor a specific predictor of suicide, at least over the long term (see Chapter 25), and scales for rating suicidal ideation and intent therefore lead to high false-positive and false-negative rates (Jacobs et al., 2003). This chapter thus places greater emphasis on actual suicide attempts, especially those of high lethality (although, unfortunately, most studies of suicide attempts do not rate lethality), and completed suicide.

The approaches taken in research on suicide have generally ignored the presence of two distinct populations. The first comprises those individuals who commit suicide who have never been diagnosed with a psychiatric disorder. This group accounts for approximately 50 percent of all suicides, even though retrospective studies have found that a psychiatric diagnosis could be established in more than 90 percent of such cases (Henriksson et al., 1993; Cheng et al., 2000). This finding was the basis for *The Surgeon General’s Call to Action to Prevent Suicide* (U.S. Public Health Service, 1999), which cited stigma, lack of public education about psychiatric disorders, and insufficient financial resources as barriers to diagnosis and treatment for those at risk of committing suicide. It also addressed the need to train physicians to recognize and treat conditions, such as depression or bipolar disorder, that can lead to increased suicide risk.

The other group of concern encompasses the remaining 50 percent of individuals who commit suicide despite

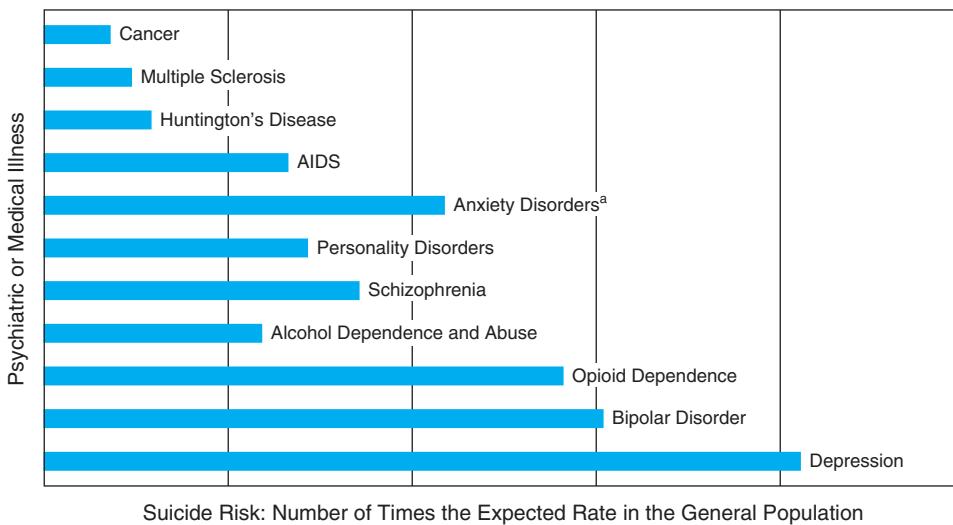

Figure 8–1. Suicide risk in psychiatric or medical illness: number of times the expected rate in the general population. ^aObsessive-compulsive disorder and panic disorder. (Source: Adapted from Harris and Barraclough, 1997. Reprinted with permission from the *American Journal of Psychiatry*, copyright 2001, American Psychiatric Association.)

having been in recent contact with a clinician or diagnosed with or treated for a psychiatric disorder. Robins (1981) reported that 50 percent of his sample of suicides had seen a physician within 1 month of committing the act. Likewise, Barraclough (1970) found that 70 percent of those who had committed suicide had been in touch with a physician within 1 month, and nearly 50 percent within 1 week, of their death. And upon reviewing 40 published studies over the next decade, Luoma and colleagues (2002) concluded that 45 percent of those who had committed suicide had had contact with their primary care physician within 1 month of their death; 20 percent had been in contact with mental health services. Moreover, it has been reported that 6 to 10 percent of suicides occur in hospitals each year (Robins, 1981). Thus, despite ongoing treatment or health care contact, a significant number of patients are not being identified as being at acute risk for suicide. Others do not receive adequate treatment or fail to adhere to clinical recommendations (see Chapter 21). Many deaths could be prevented if physicians in both primary and specialty care settings became more alert to acute risk factors for suicide (see Chapter 25).

Other methodological problems limit interpretation of the findings of suicide studies. Diagnostic criteria often are unclear, and bipolar and unipolar distinctions only recently became standard in the literature. It is important to keep in mind that the definition of manic-depressive illness changed with the adoption of DSM-III in 1980 (see Chapter 3). The DSM-III nomenclature replaced the diagnosis manic-depressive disorder with that

of bipolar disorder. Prior to this, a diagnosis of manic-depressive disorder had required a history or presence of recurrent depression *or* an episode of mania, thus encompassing the broader group of patients that is the focus of this volume (see Chapter 1). The narrower bipolar diagnosis required the presence or history of an episode of mania or hypomania; patients with recurrent depression were subsumed under the unipolar depression diagnosis, and recurrent unipolar was broadened to include anyone with more than one episode. This shift in diagnostic practice has made it more difficult to interpret secular trends. In this chapter, we employ the diagnostic terms relevant to particular studies, but otherwise (as throughout the volume) use “manic-depressive illness” to refer to the broader concept of recurrent major affective disorder; we use “bipolar disorder” to refer to the bipolar spectrum.

Particularly critical is the enormous range across studies in the length of follow-up periods; this broad range necessarily results in variable periods of risk for suicide. Moreover, when studies include only patients who have been hospitalized, suicide rates are likely to be higher, reflecting a greater severity of illness. Most early studies of suicide in manic-depressive illness were of hospitalized patients; many more recent studies are of outpatients or combinations of outpatients and inpatients. Because suicide risk is one of the most decisive criteria for admission to a psychiatric hospital, studies of hospitalized patients are necessarily skewed toward a greater likelihood of suicide.

SUICIDE RATES

In this section, we begin by reviewing suicide rates among the general population and among bipolar and unipolar depressed patients. We then present specific rates according to diagnosis (bipolar versus unipolar; bipolar-I versus bipolar-II), gender, and seasonality.

Rates in the General Population

In the United States in 2002, there were 31,655 deaths recorded as suicide.¹ This figure represents an overall suicide rate of 10.99 per 100,000 population (National Center for Injury Prevention and Control [NCIPC], 2005). Worldwide, an estimated 900,000 suicide deaths occur each year (World Health Organization [WHO], 2001); a figure of 1.5 million is projected for 2020 (Bertolote and Fleischmann, 2002). The estimated global suicide rate is 17.7 per 100,000 for males and 10.7 per 100,000 for females (Mathers et al., 2006). Many cultural factors, including religion and the adequacy of public health reporting systems, result in a wide range in the reporting and occurrence of suicide—from a low in Islamic countries to a high in Eastern Europe (the rates of suicide per 100,000 population are, for example, 33.1 in Hungary, 35.5 in the Russian Federation, and 41.9 in Lithuania [World Health Organization, 2001]).

Rates in Manic-Depressive Illness

Early studies documented a strikingly high lifetime rate of suicide, 15 percent, among patients with manic-depressive illness. The estimated rate today has dropped by about one half, except for patients early in the course of illness. The higher rates in most early studies (published before the mid-1980s) almost certainly reflect poorer clinical outcomes before the widespread use of lithium and other mood stabilizers, tricyclic antidepressants, and selective serotonin reuptake inhibitors (SSRIs). The figure of 15 percent lifetime risk also reflects suicide risk in clinical populations with severe, untreated manic-depressive illness.

Guze and Robins (1970) were the first to document systematically the extent of suicide risk in manic-depressive illness. They reviewed 14 follow-up studies, 2 population surveys, and 1 family study and found that at least 12 percent of all deaths among manic-depressive patients had been the result of suicide (in these early studies, patients with recurrent depressions were diagnosed as manic-depressive). In 9 of the studies, 12 to 19 percent of deaths had been due to suicide, and in the other 8 studies, the suicide rate ranged from 35 to 60 percent. The authors concluded that by the time all the patients in these studies had died, about 15 percent would have committed suicide, a rate at least 30 times that found in the general population.

Subsequent analyses buttressed these early findings. Our own review of 30 studies of completed suicide (1937–1988), presented in the first edition of this text, found a mean lifetime rate of 19 percent in patients with severe manic-depressive illness (range 9 to 60 percent). In 13 of the 30 studies, the figure was in the 10 to 30 percent range. In one fifth of the studies, at least half of the manic-depressive patients had died because of suicide. Similarly, a study of nearly 500 bipolar patients (mostly untreated or inadequately treated) over a 17-year period (1970–1987) found a suicide rate of 15 percent (Sharma and Markar, 1994).

The high suicide rate in manic-depressive illness is also documented by comparison with suicide rates in the general population. Harris and Barraclough (1997) calculated standardized mortality ratios (SMRs) in a meta-analysis of 14 studies reported from 1945 to 1992 ($N=3,700$ bipolar patients). They found that the SMR for suicide in bipolar disorder was about 15 times higher than expected (see Fig. 8–1). Increased risk was associated with recent hospital discharge, a suicide attempt within the previous 5 years, and current alcohol abuse. The authors found a somewhat higher SMR, 20.4, for suicide in patients with major depression.

More recent studies, however, have found significantly lower rates of suicide (in the range of 5 percent lifetime risk) among never-hospitalized patients with bipolar disorder of moderate severity (see Tondo et al., 2003, for a review). But these lower suicide rates do not apply early in the course of illness. A study from the United Kingdom found a lifetime suicide rate of 6 percent for patients with affective disorders (depression and bipolar disorder), but the rate increased to 23 to 26 percent early in the course of bipolar illness (Inskip et al., 1998) (see later discussion).

There are several possible explanations for this marked decrease over time in reported suicide rates in bipolar disorder. A major reason, alluded to earlier, is most likely the increased use of lithium and other medications in the treatment of manic-depressive illness since 1980 (see Chapter 25). Other reasons for the decline are probably methodological. The findings of newer studies, which often have focused on outpatient populations or mixed inpatient and outpatient populations, reflect suicide rates in less severely ill patients. In their review, Tondo and colleagues (2003) suggested that reported rates are lower because most of the patients among whom the rates were ascertained were never hospitalized. They also pointed out that more recent studies, by reflecting the milder range of illness severity, underestimate the risk in more severely ill patients. They noted as well that, compared with a general population of patients, there is a lower ratio of attempts to fatalities in patients with major mood disorders. In their view, this finding suggests a high

lethality and intent in affectively ill patients. The SMR for bipolar patients, based on a review of 28 studies from 1945 to 2000, was 22.1. Rates of suicide averaged about 0.376 percent per year.

Bostwick and Pankratz (2000) directly calculated the rates of suicide in hospitalized affectively ill patients versus other groups. In their meta-analysis, they reanalyzed both the Guze and Robins (1970) study and our own analysis of 30 studies (cited earlier), in addition to more recent studies (up to 1998). Using a different metric (case-fatality prevalence) they found lifetime suicide rates of 8.6 percent for patients hospitalized for suicide risk, 4.0 percent for those not hospitalized, and 2.2 percent for mixed inpatient/outpatient populations; the rate was less than 0.5 percent for the non-affectively ill population. The authors did not separate the risk for bipolar and unipolar disorders.

Bipolar–Unipolar Differences

Most studies have tended to find somewhat higher suicide rates in unipolar depression than in bipolar disorder (e.g., Harris and Barraclough, 1997; Osby et al., 2001; Angst et al., 2002). Others, however, have found either no bipolar–unipolar difference² or higher rates among patients with bipolar disorder (e.g., Rihmer and Pestal, 1999; Bottlender et al., 2000). The reason for these disparate findings, in our view, lies largely in the heterogeneity of the unipolar population and the underdiagnosis of mixed states and other forms of bipolarity.

The broad definition of unipolar depression in today's nomenclature simply means that the diagnosis is not bipolar; that is, a unipolar diagnosis encompasses patients with all degrees of recurrence, ranging from single-episode depression to highly recurrent or cyclic depression (see Chapter 2). Yet the research literature rarely has distinguished among unipolar patients on the basis of differences in their patterns of recurrence, which may in turn reflect different suicide risks depending on comorbidities, course of illness, and other clinical factors noted throughout this chapter. We believe that patients with recurrent unipolar depression may be likely to have suicide rates as high as or higher than those with bipolar disorder, whereas patients with less recurrent forms of unipolar depression are likely to have lower rates. Because the majority of unipolar patients have at least some recurrence, their inclusion could be expected to skew the unipolar category to higher rates. This might explain why Harris and Barraclough's meta-analysis (see Fig. 8–1) and other studies have found somewhat higher rates in unipolar depression than in bipolar disorder. A compounding problem is that, as we have seen (see Chapter 19), a substantial percentage of patients with major depression eventually convert to bipolar

illness. Finnish researchers have found that these patients form a subgroup that is particularly prone to suicide (Sokero et al., 2005).

What also may contribute to the apparently higher suicide rates in unipolar illness is the tendency to misdiagnose bipolar-II disorder as unipolar depression. Rihmer and Kiss (2002) argued that patients with bipolar-II disorder are often misdiagnosed and then included as unipolar patients. The unipolar category would thereby be erroneously elevated because the suicide rate in bipolar-II is higher than that in unipolar depression (Rihmer and Kiss, 2002) (Table 8–1). A final problem is that some patients diagnosed as having "agitated depression" may in fact have mixed states associated with bipolar disorder. This, too, would falsely raise the suicide rate in unipolar depression, particularly because mixed states carry a relatively higher suicide risk (see later discussion). If suicide occurs early in the course of affective illness, it may well be that patients who otherwise might have gone on to have a recurrent or bipolar course will have been diagnosed as having had a single episode of depression, again spuriously elevating the rate in unipolar illness.

The search for bipolar–unipolar differences, while important, may obscure the more significant point that all studies show greatly elevated suicide rates in both unipolar and bipolar groups in comparison with other medical and psychiatric populations (Sharma and Markar, 1994; Harris and Barraclough, 1997; Juurlink et al., 2004). The most prudent approach is to assume a high suicide risk in both bipolar and unipolar patients.

Bipolar-I versus Bipolar-II Disorder

Identifying diagnostic subgroups with an increased incidence of suicide or suicide attempts is one of the first steps toward identifying individual bipolar patients who are at particularly high risk. Several investigations over the last three decades have found that patients with bipolar-II disorder have a higher risk of suicide attempts than those with bipolar-I. These studies were reviewed by Rihmer and Kiss (2002) (see Table 8–1).

In addition, Bulik and colleagues (1990) studied 67 patients with a history of recurrent depression and suicide attempts. In comparison with 163 patients with recurrent major depression and no suicide attempts, they found that attempters were distinguished by a history of bipolar-II depression. The findings of these studies suggest that bipolar-II depression confers a particularly high risk of suicide in patients presenting with major depression. A recent retrospective study of 90 bipolar-I and 10 bipolar-II patients, however, did not find a significant difference in rates of suicide attempts between the two groups (Valtonen et al., 2006).

TABLE 8–1. History of Prior Suicide Attempts in Patients with Unipolar Major Depression and Bipolar-I and Bipolar-II Disorder

Study	Patients with Unipolar Depression Rate (%)	Patients with Bipolar-I Disorder Rate (%)	Patients with Bipolar-II Disorder Rate (%)
Dunner et al., 1976	2/23 (9)	11/29 (38)	9/16 (56)
Endicott et al., 1985	26/204 (13)	30/122 (25)	15/56 (27)
Coryell et al., 1987	31/303 (10)	7/29 (24)	7/40 (18)
Cassano et al., 1992	60/558 (11)	9/35 (26)	17/94 (18)
Vieta et al., 1997	—	12/38 (32)	6/22 (27)
Tondo et al., 1999	24/126 (19)	34/353 (10)	7/25 (28)
TOTAL	143/1234 (12)	103/606 (17)	68/253 (24)

Note: Bipolar-I + bipolar-II versus unipolar: $X^2=21.32$, degrees of freedom (df) = 1, $p < .001$; bipolar-I versus unipolar: $X^2=9.41$, $df=1$, $p < .01$; bipolar-II versus unipolar: $X^2=26.59$, $df=1$, $p < 0.001$; bipolar-II versus bipolar-I: $X^2=5.85$, $df=1$, $p < .02$.

In their review, MacQueen and Young (2001) noted a particularly high liability for comorbidity with personality disorders, substance abuse disorders, and anxiety disorders in bipolar-II patients with an elevated risk of suicide (see Chapter 7). Bipolar-II patients, who have higher rates of comorbid substance abuse and personality disorders than bipolar-I patients, may be at increased risk in large part because of the comorbidity. Rihmer and Kiss (2002) found that when lifetime prevalence in the general population is the comparator, bipolar-II patients have the highest prevalence of attempted and completed suicides. The evidence strongly suggests that bipolar-II patients have—relative to the general population and to those with bipolar-I or unipolar depression—the highest rate of suicide.

Differences by Gender

In the general population of the United States, approximately three times as many women as men attempt suicide; however, four times as many men actually kill themselves (NCIPC, 2005). The patterns of suicidal behavior among women and men with manic-depressive illness show both similarities to and differences from this pattern.

Like the general female population, bipolar women attempt suicide more often than bipolar men. In contrast to the general population, however, there is no clear predominance of males among bipolar patients who actually commit suicide; the completed suicide rate for males is generally equivalent to or lower than that for females.

Reviewing 28 studies conducted from 1945 to 2001, Tondo and colleagues (2003) found that among bipolar patients, the average SMR for suicide was 14.9 for males and 21.1 for females. And a recent Swedish study of mortality outcomes in 15,386 bipolar patients found very similar SMRs for suicide—15.0 for men and 22.4 for women (Osby et al., 2005). It may be that the risk of suicide associated with manic-depressive illness is so powerful that it overrides the male–female differences in the general population. With regard to suicide attempts, Tondo and colleagues (2003) found that the rate among females within the bipolar subgroup (15 to 48 percent) was about double that for men (4 to 27 percent). Evidence of differences by gender among suicide attempters may be distorted by reporting biases, however. When patients are asked about past suicidal behavior, women may be more likely than men to admit to or remember attempts; men, on the other hand, may be more prone to suicidal equivalents, such as extreme risk taking, involvement in car accidents, and substance abuse. These behaviors are less often explored in surveys.

In summary, women with manic-depressive illness attempt suicide more often than men. In contrast to the general population, the suicide rate in women with manic-depressive illness is higher than or equivalent to that in men.

Seasonality

Seasonality affects the timing of manic and depressive affective episodes (see Chapter 16). It also has a profound

effect on suicide. There is a robust literature on suicide and seasonality, in part because it is easier to date a suicide than the onset of an affective episode accurately and precisely. Most of the literature reviewed here does not specify diagnosis, but at the end of the section we discuss studies that deal expressly with bipolar disorder and seasonal suicide patterns related to mood states.

We reviewed dozens of seasonality studies for the first edition of this text. Since that time, many more such studies have been published. Taken as a whole, this literature affirms a striking peak incidence of suicide in late spring–early summer. Many studies have also found a smaller peak in October, generally for women rather than men. Both peaks, however, have lessened in amplitude over time (Fig. 8–2). Findings of more recent studies add considerably more nuance to the overall pattern of a spring-to-summer peak in suicides.

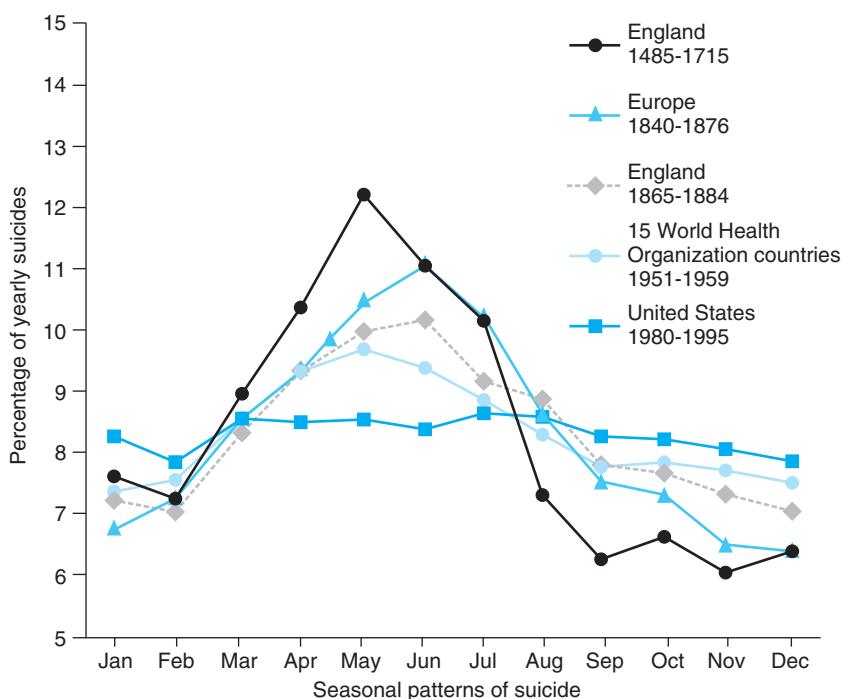

Seasonality and Suicide Rates

Granberg and Westerberg (1999) analyzed suicide data from Sweden (1911–1993) and New Zealand (1975–1995) and found that suicides peaked in the spring months—May in Sweden and November in New Zealand. In other studies, carried out in the southern hemisphere (Takahashi, 1964; Parker and Walter, 1982), the seasonality of suicide was consistent with the pattern seen in the northern hemisphere (i.e., peaks in the spring), although for New

South Wales, Parker and Walter (1982) found two peak suicide periods (in May and November) among women rather than one. Chew and McCleary (1995), using time-series and cross-sectional data for 28 countries and employing bivariate plots and simple correlation techniques, found a sizable spring peak in suicide only in the temperate zones. More recently, Lee and colleagues (2006), utilizing the nationwide mortality database in Taiwan 1997–2003, found that suicides peaked in spring, regardless of gender or age. Ambient temperature was positively associated with suicide after adjustment for seasonality.

Fisher and colleagues (1997), studying 16,389 nationally registered suicide deaths between 1980 and 1989, found a peak in the spring in South Africa. Retamal and Humphreys (1998), reviewing 5,386 suicides in Chile for the period 1979–1994, found the highest rates in the “warm months” (i.e., the southern hemisphere’s spring and summer), particularly December, and the lowest rates in the colder months, particularly June. Morken and colleagues (2002) studied all admissions in Norway for mania and depression during 1992–1996 ($N=4,341$) and all 14,503 suicides in the years 1969–1996. They observed a significant peak in depression for women in November, with a secondary peak in April, and a peak for men in admissions for both depression and mania in April. Both genders showed a trough in admissions in July. Among men, the monthly occurrence of suicides correlated with the rate of admissions

Figure 8–2. Seasonal patterns of suicide. (Source: Jamison, 1999, *Night Falls Fast*. Reprinted with permission.)

for depression and mania (a spring peak); no such correlation was found in women. It may be that women were admitted earlier in the course of their depressive episode and that the peak severity occurred later; men may have been more severely depressed at the time of their admission. This issue has not been studied systematically.

Maes and colleagues (1993a) found significant spring seasonality for violent suicides but not for nonviolent suicides in Belgium. They also noted seasonality in the severity of depressive symptomatology as measured by the Zung self-rating scale, with greater severity reported in the spring months. Preti and colleagues (1998, 2000), examining violent suicide attempts in Italy, found a peak in the spring months, but only for violent suicide attempts in males. No seasonal trend was observed in nonviolent suicides among males or females during 1984–1995.

Findings reported by Maes and colleagues (1994) and Linkowski and colleagues (1992) suggest that violent suicides and perhaps violent attempts may be more common in sunny weather or higher temperatures. It is known that violent suicides and attempts are much more common in males than in females, a fact that is consistent with the greater occurrence of seasonality patterns in males.

Rasanen and colleagues (2002) investigated the seasonal distribution of the specific suicide method for both genders ($N=20,234$) in Finland for the years 1980–1995. In summer, significant peaks occurred in suicides by drowning, jumping, and gassing among males. In autumn, there were peaks in female suicides by poisoning and drowning. Traffic suicides showed substantial winter troughs for both genders. The results demonstrated that specific violent and nonviolent methods for suicide formed their traditional clusters on the basis of seasonality, except for suicides by gassing and shooting.

Gender differences in seasonal patterns of suicide in Italy were examined by Micciolo and colleagues (1989). They found cyclic fluctuations in the number of suicides in both sexes, but only one significant peak per year for men and two for women. The most significant peak for both men and women was in May; women had a second peak in October and November. Hakko and colleagues (1998) studied seasonal patterns of suicide in Finland using a database of 21,279 suicides and found a peak for males from April to July; the distribution for females was bimodal, with peaks in May and October. In the elderly, they found a significant excess of suicides in autumn. Violent suicides showed a single spring peak, whereas nonviolent suicides displayed a bimodal distribution. Marion and colleagues (1999) found that in British Columbia, suicides among the young were associated with a spring–summer peak, whereas those among the elderly appeared to be related to deviations from expected temperatures for the

time of year. Salib (1997), studying suicide in an elderly population of 40,000 in Cheshire, England, over a 5-year period, found a positive relationship of suicide with hours of sunshine and humidity, rather than with extreme weather conditions. The findings of more recent studies have raised the question of whether the elderly may be affected more by rapid shifts in weather conditions than by seasonal effects. These findings raise the possibility that studies of seasonality should take into account age as well as violent versus nonviolent suicide methods, rather than simply merging groups of suicide cases.

There have also been suggestions that seasonal variation is greatest in rural as opposed to urban areas (e.g., Micciolo et al., 1991); one possible explanation for this difference is that urban living conditions, such as less direct exposure to natural light and more exposure to artificial light, may somehow reduce the seasonal effect. In their analysis of seasonal patterns of suicide in farmers and nonfarmers, Simkin and colleagues (2003) observed no significant seasonal patterns in violent suicides among nonfarmers.

The often-raised possibility of the effect of lunar cycles on suicide was addressed in a review of 20 studies by Martin and colleagues (1992), who found no evidence to support such a relationship. Likewise, Maldonado and Kraus (1991) found no effect of lunar phase in 4,190 suicides occurring between 1925 and 1983 among residents of Sacramento County, California. They did find that suicide occurred most frequently on Monday for both genders across age groups, and least frequently between the hours of 4:00 and 8:00 AM.

In short, it appears that seasonal variation in suicide applies most consistently to males, to the use of violent methods, and to those living in temperate zones. Seasonality may not be as much of a factor for females and males using nonviolent methods.

As noted earlier, a significant weakening of the association between seasonality and suicide over time has been observed in a number of studies. Rihmer and colleagues (1998), for example, found a link with seasonality in a (relatively small) sample of suicides from 1981–1986, but no such link in a sample from 1990–1996. Likewise, Hakko and colleagues (1998) found a decreasing frequency of seasonality in suicides in Finland after 1990. A reevaluation of seasonal variation in suicide in Australia and New Zealand led Yip and colleagues (1998) to conclude that seasonality was less of a determining factor than it had been. Tietjen and Kripke (1994) found no seasonal peaks in suicide in California's Los Angeles and Sacramento counties. Rock and colleagues (2003), on the other hand, found that seasonal amplitude had increased over time in Australia, contrasting this finding with those of contemporary European reports showing a decrease in seasonal amplitude over

time. A recent study of suicides and seasonality in the Austrian prison system ($N=412$), conducted over a 53-year period by Fruehwald and colleagues (2001), found no seasonal fluctuation in suicide rates. Parker and colleagues (2001) found no seasonal variation in 2,013 male and 1,382 female suicides in the equatorial region of Singapore.

Given the strength and breadth of the early findings of a strong seasonal component to suicide, an obvious question is why the seasonal effect has abated. In a review of the international literature on the seasonal incidence of suicide, Aschoff (1981) proposed that environmental factors play a role in the seasonal patterns observed. He found that during the nineteenth century, seasonal variation in suicide rates was greatest in the least industrialized nations and declined with greater industrialization. It is likely that certain aspects of industrialization (e.g., artificial light, central heating) may partially insulate patients from environmental risk factors for affective episodes. Seasonal variation in suicide rates, as we have seen, is greatest in the temperate latitudes as opposed to the north, with its extremes of light and temperature. Seasonal variation also is most correlated with hours of clear sunshine (not day length per se). Petridou and colleagues (2002), evaluating the traditional peak occurrence of suicide in June in the northern hemisphere and in December in the southern hemisphere, found an association between the seasonal amplitude of suicide and total sunshine. They suggested that suicide may be triggered by sunlight, perhaps through seasonally determined hormones such as melatonin (see later discussion). Papadopoulos and colleagues (2005) studied Greek suicide patterns and solar radiance data for a 10-year period and found that the solar radiance on the day preceding suicide was positively correlated with suicide risk, as was average solar radiance during the 4 days preceding that. They hypothesized that “sunshine acts as a natural antidepressant, which first improves motivation, then only later improves mood, thereby creating a potential short-term increased risk of suicide initially upon its application” (pp. 287–288).

Another likely explanation for the trend toward diminishing amplitude of the spring-to-summer peak in suicide rates is the greater use of mood-stabilizing medications. Rihmer and colleagues (1998) hypothesized that the link between seasonality and suicide has been weakened by the widespread use of lithium and antidepressants. Likewise, Oraveez and colleagues (2006) attributed the decrease in the seasonality of suicides in Slovenia to improvements in access to and effectiveness of psychiatric treatment following the 1991 war. Because major depression has such a strong seasonal component, the investigators argued that the decrease in the seasonality of suicide occurred as a result of improved treatment.

Neurobiological Factors in Seasonality

Clearly, profound biological changes occur in response to seasonal variations in light and temperature. Many neurobiological systems of relevance to mood disorders and suicide—including neurotransmitters, sleep and temperature regulators, melatonin, cholesterol, testosterone, estrogen, and thyroid hormone (summarized in Jamison, 1999; Institute of Medicine [IOM], 2002)—show pronounced seasonal fluctuation in their levels.³

A number of measures of serotonin function (see the later discussion of serotonin and suicide) have been reported to be correlated with the seasons.⁴ This correlation may reflect a biological variable related to violent suicides, the effect of which may be diminished by older age, as well as urban living and perhaps even antidepressant treatment (see earlier discussion). Relating seasonal patterns in suicide to seasonal changes in various biological systems could thus yield greater insight into biological factors in susceptibility to suicide.

Timonen and colleagues (2004), studying 1,296 males and 289 females during the years 1988–2000, found the proportion of suicides in atopic (allergic) patients to be significantly higher than that in nonatopic patients. They further found that 72 percent of suicides in atopic patients occurred during the first 6 months of the year, and 28 percent during the second 6 months. By contrast, the distribution across the two periods was even in nonatopic patients. De Vries and colleagues (2004) found a correlation between monthly variations in levels of the n-3 polyunsaturated fatty acids arachidonic acid and eicosapentaenoic acid and the mean weekly number of violent (but not nonviolent) suicides. A seasonal effect on factors likely to change levels of omega-3 essential fatty acids—such as fluctuating availability of foods and increased intake of fat-rich foods during the winter months—has been suggested by Hibbeln (1998, personal correspondence, 1999).

Seasonality in Bipolar Disorder

The seasonal pattern of suicide appears to run counter to that of bipolar depression, which is more likely to occur in the winter months in the temperate zones. (See Chapter 16 for extensive discussion of the seasonal patterns of mania and depression.) It may be that the increased activation associated with longer periods of light in the late spring months brings to a suicidal climax depressive episodes that begin in the winter months, particularly among those bipolar patients who are prone to developing dysphoric manic states. Cassidy and Carroll (2002a) analyzed the seasonal occurrence of 304 hospital admissions for mixed or manic bipolar states. They found that the frequency of all admissions for mania peaked in early spring, with a nadir in late

fall. Admissions for mixed mania had a significantly different pattern, with a peak in late summer and a nadir in late November. Whitney and colleagues (1999) likewise found that mixed-state admissions in Canada peaked in the summer, but they did not find a seasonal pattern for mania and depression. D'Mello and colleagues (1995), studying the admissions of 377 bipolar patients in Michigan over a 6-year period, observed that women had a bimodal seasonal distribution, with peak admission rates in the spring and fall. They found that aggressive behavior peaked in the spring for both men and women. Several other investigators (Parker and Walter, 1982, in New South Wales; Mulder et al., 1990, in New Zealand; and Takei et al., 1992, in London) found a peak in admissions for mania in spring and summer.

These findings suggest a seasonal pattern in activation levels in bipolar disorder. Wehr (1992) observed that the risk for depression peaked at two opposite times of the year—spring/early summer and fall/early winter. These two periods are associated with opposite vegetative symptoms: sleep and appetite increases in winter depressions and decreases in spring/summer depressions. Maes and colleagues (1993b) observed that the severity of depression as measured by the Zung Self-Rating Depression (ZD) and Anxiety (ZA) scales showed a significant increase in the spring (April–May), with lows occurring in August–September; up to 31 percent of the variance in the weekly average of ZA scores could be explained by a circannual rhythm. In a subsequent study, Maes and colleagues (1995) noted a correlation between seasonal variations in serum L-tryptophan and suicide. Taken together, the studies reviewed here suggest an activation of manic-depressive illness (including mixed states, as well as unipolar recurrent depression) in the spring/summer months that roughly parallels the seasonal increase in suicides reported in the temperate zones, especially in males.

The second suicide peak in October may reflect an increase not only in unipolar depressive episodes, but also in suicidal depressions following the pronounced increase in manic episodes among bipolar patients during the summer months. That is, this second peak may represent suicidal postmanic depressions. It also may reflect the impact of mixed, transitional mood states. As patients recover from summer or autumn hypomania or mania, or as they switch from hypomania or mania into depression, mixed states are not uncommon. A recent study of depressed patients with mixed states found that the depressive episodes peaked in autumn (Sato et al., 2006). In vulnerable individuals, this may lead to periods of an acute, agitated suicidal state.

CAUSES OF SUICIDE

In this section, we review what is known about the biological, psychological, and social factors associated with suicide

in bipolar illness. This growing body of research is focused on determining what role these factors play—as underlying causes, risk factors, or protective factors—and on ascertaining whether they can be modified through treatment. To date, while it is clear that suicide is caused by a potent combination of biological and psychosocial risk factors, research has not yet reached the point where any particular combination of factors can be identified as predictive of suicide.⁵

Genetic and Family Transmission

The tendency for suicides to run in families has been noted in writings dating back many hundreds, if not thousands, of years. Using modern methods, researchers have shown that suicidal behavior does indeed have heritable contributions. This has been demonstrated through three lines of inquiry: family studies, studies of suicide in monozygotic (MZ) versus dizygotic (DZ) twins, and studies of adoptees (for reviews see Roy et al., 1999; Baldessarini and Hennen, 2004). These types of studies allow us to draw inferences about heritability and genetic contributions to suicide. Yet while they help narrow the search for genes that may be implicated, they cannot, by design, be used to identify particular genes (candidate gene identification is discussed in the next section).

Family studies compare the risk of suicidal behavior (i.e., suicides or suicide attempts) in close relatives of index cases versus the risk in close relatives of nonsuicidal cases or normal controls. Tsuang (1977, 1983) was among the first of modern scientists to report clustering of suicide in families. Since the 1970s, dozens of such investigations have been undertaken. In a recent meta-analysis of 22 studies, Baldessarini and Hennen (2004) found a nearly three-fold higher risk of suicidal acts among relatives of index cases compared with controls (Fig. 8–3). The investigators used random-effects regression modeling with weighting for study size and interstudy variances.

In the original studies on which the meta-analysis was based, the index suicide cases were not limited to a particular psychiatric diagnosis; a few studies were limited to major depression, but only one to bipolar illness (with comorbid alcoholism) (Potash, 2000). This latter study found bipolar disorder, alcoholism, and attempted suicide to be clustered in some families. Among subjects with bipolar disorder, 38 percent of those with comorbid alcoholism had made a suicide attempt; 22 percent of those without alcoholism had attempted suicide ($p < .005$).

Family transmission of suicidal behavior is not necessarily tantamount to genetic transmission, for any linkage between suicide and families also could be through learned behaviors or shared environment (e.g., parenting, physical or sexual abuse). Identifying genetic transmission requires piecing together of additional evidence, such as studies of

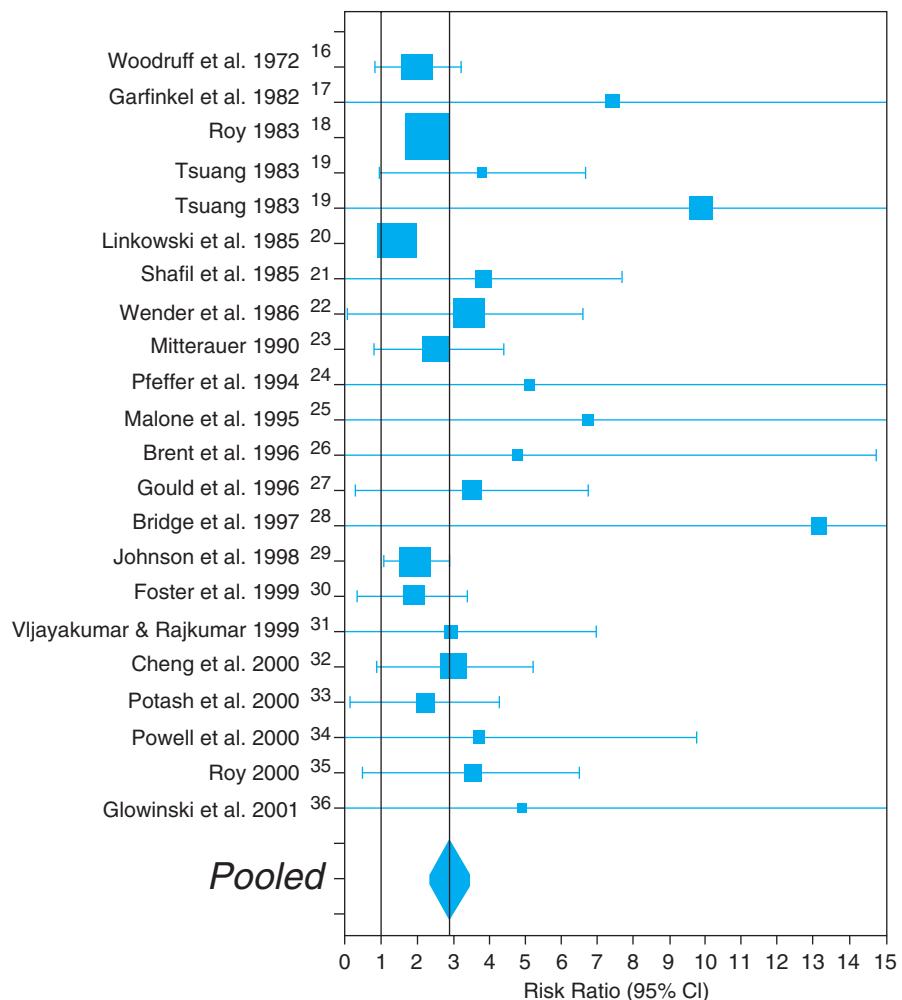

Figure 8–3. Meta-analysis of 22 studies of familial risk of suicide behavior based on random effects of modeling of relative risk (size of shaded squares reflects approximate weighting by sample size and variance measures) among families of suicidal probands versus controls and their 95% confidence intervals (CI; horizontal bars), with a pooled risk ratio and its CI (diamond). All 22 studies found increased familial risk associated with suicidal probands. The pooled risk ratio (vertical line with diamond) is 2.86 (CI, 2.32–3.53), which is highly significantly ($p<.0001$) greater than the null of 1.0 (vertical line). (Source: Baldessarini and Hennen, 2004.)

concordance rates in twins and adoptees, biological markers, and genetic polymorphisms, as well as linkage analysis.

Twin studies are designed to separate genetic from environmental contributions by comparing risks in MZ and DZ twins. Roy and colleagues (1999) compared concordance rates in 176 twin pairs with a suicide and found a greatly elevated rate among MZ (13.2 percent) versus DZ (0.7 percent) twins. His review examined only completed suicides, not attempts. In an analysis pooling seven twin studies, the rate of suicide or suicide attempts in MZ twin pairs (23 percent) was found to be much higher than that in DZ (0.1 percent) twin pairs (Table 8–2) (Baldessarini and Hennen, 2004). These rates yielded a relative risk of 175, but the investigators considered this figure to be unreliablely high because the 0.1 percent rate in DZ pairs was cal-

culated from only 2 suicides among more than 1,000 pairs. The investigators concluded that case ascertainment was likely to have been incomplete because the rate among DZ twins should have been comparable to that found among siblings, which typically runs about 9 percent in most family studies. Substituting this expected rate of 9 percent for the actual rate of 0.1 percent among DZ twins, they found a more modest relative risk of 2.6 in MZ compared with DZ twins. The increased risk is similar in magnitude to that found in a large study of 3,416 female adolescent twins (relative risk [RR] = 1.9) (Glowinski et al., 2001).

Adoption studies compare the risk of suicidal behavior in biological versus adoptive relatives of index cases of suicide. This design gives adoption studies the advantage of controlling for shared environmental factors. Three adoption

TABLE 8–2. Summary of Twin Studies of Suicidal Risk

Study	REPORTED CO-TWIN SUICIDAL RATES		
	Identical (MZ)	Fraternal (DZ)	Risk Ratio
Kallman and Anastasio, 1947 ^a	0/11	0/8	Not estimable
Haberlandt, 1967 ^b	14/51	0/98	>27
Juel-Nielson and Videbach, 1970 ^a	4/15	0/58	>15
Zair, 1981 ^a	1/1	Not reported	Not estimable
Roy et al., 1991 ^a	7/62	2/114	6.41 (95% CI, 1.38–30.0)
Statham et al., 1998 ^c	365/1,538	0/1,199	>285
Roy et al., 1999 ^c	10/26	0/9	>133
Total (7 studies)	401/1,704	2/1,486	174.8 (95% CI, 43.6–700.5)
Twin rates	23.5%	0.135%	175 ^d
Family risk	Not applicable	8.98% ^e	2.62

Notes: The estimated risk (concordance) among DZ co-twins (0.135%) is 67 times lower than the average rate (8.98%) among the combined pool of first- and second-degree relatives in family studies summarized in Table 1 of Baldessarini and Hennen (2004), suggesting a more-plausible estimate of the MZ/DZ risk ratio of 2.62 (23.5%/8.98%; $\chi^2 [1 df] = 276$; $p < .0001$). Even with DZ and family rates pooled, the MZ/DZ risk ratio would be 23.5%/7.40%, or 3.18. For most studies, CIs are not provided because zero values appear in several numerators.

^aBased on rate of suicides.

^bBased on rate of suicides plus attempts.

^cBased on rate of attempts only.

^dOverall, Fisher's exact $p < .0001$ for the 7 studies.

^eBased on raw data pooled from Table 1, column 3 (612/6811, or 8.98%), in Baldessarini and Hennen (2004).

CI = confidence interval; DZ = dizygotic; MZ = monozygotic.

studies have been undertaken, all of which used the same register of 5,483 adoptions in greater Copenhagen from 1924 to 1947 (Kety et al., 1968; Schulsinger et al., 1979; Wender et al., 1986). Pooling the data from these studies, Baldessarini and Hennen (2004) found that biological relatives of suicide cases are nearly five times more likely than adoptive relatives to commit suicide (risk ratio of 4.8) (Table 8–3).

What is being transmitted in the subjects of family, twin, and adoption studies? Is it the genes for a particular psychiatric disorder or some other factor (e.g., impulsivity, aggression) that may act independently of, or in an overlapping, additive, or catalytic manner with, a psychiatric disorder? For there to be overlap, some traits (and the genes underlying those traits) might be hypothesized to confer vulnerability to affective disorder as well as to suicidal behavior. Most of the research addressing the latter questions has not focused specifically on manic-depressive illness, however.

Several family studies have found that a higher risk of suicidal behavior holds true even after controlling for the effects of psychiatric disorders.⁶ One of the largest and most recent studies was reported by Qin and colleagues (2002), who conducted a nested case-control study of 4,262 people who committed suicide between the ages of 9 and 45 during 1981–1997 and 80,238 population-based controls (matched for age, sex, and date of suicide). They found that a family history of suicide and psychiatric illness significantly and independently increased the suicide risk ratio by 2.58 and 1.31, respectively. This and the preceding studies are widely interpreted to suggest that there is an independent contributor to suicide risk beyond psychiatric illness.

In comprehensive reviews, Roy and colleagues (1999) and Mann (1998, 1999) and their colleagues proposed a stress–diathesis model of suicide in which an independent genetic/biologic factor predisposes to suicide risk only in

TABLE 8–3. Summary of Adoption Studies of Suicide Risk

Groups	REPORTED SUICIDE RATES IN RELATIVES		
	Biological	Adoptive	Risk Ratio (95% CI)
A. Kety et al., 1968 ^a			
Suicides	5/156 (3.20%)	1/83 (1.20%)	2.67 (0.32–22.4) ^b
B. Schulsinger et al., 1979 ^c			
Suicides	12/269 (4.46%)	0/148 (0.00%)	4.46 ^d
C. Wender et al., 1986 ^e			
Suicides + attempts	28/387 (7.24%)	8/180 (4.44%)	1.63 (0.76–3.50)
Suicides	15/387 (3.88%)	1/180 (0.56%)	6.93 (0.93–52.4)
Attempts	13/387 (3.36%)	7/180 (3.89%)	0.86 (0.32–2.13)
D. Pooled data from studies A and C	20/543 (3.68%)	2/263 (0.76%)	4.84 (1.14–20.6)

Notes: All three studies are based on a single Danish database. Study A data are for rates of suicides or attempts in biological or adoptive first-degree relatives of early-adopted probands who were diagnosed with schizophrenia-like disorders ($n=33$), committed suicide ($n=57$), or were diagnosed with an affective disorder (definite or probable DSM-III major depression or bipolar disorder; $n=71$), compared with early-adopted controls matched for number, gender, socioeconomic class of adoptive parents, age at adoption, current age compared with proband age at suicide, and time living with biological mother. Study B data (involving suicidal adopted probands), although complementary to other analyses, are probably not independent and are therefore not included in D (pooled data from studies A and C).

^aSchizophrenia-like probands.

^bFisher's exact $p=0.0056$.

association with psychiatric disorders or major life stressors. Psychiatric disorders and major life stressors, in other words, may trigger the genetic susceptibility to suicidal behavior.

Kety (1987) was among the first to hypothesize that a genetically influenced inability to control impulsive behavior might be a specific and independent susceptibility factor. Several family studies have lent support to the hypothesis that impulsive aggression, independently of psychiatric illness, increases suicide risk.⁷ Impulsive aggression has been linked to low serotonin function (see reviews by Linnoila and Virkkunen, 1992; Oquendo and Mann, 2000), which is a biological marker of suicidal behavior (see later discussion).

Aggressiveness/impulsivity was one of a number of potential suicide risk factors studied by Oquendo and colleagues (2004). They tested the stress-diathesis model for suicidal behavior in a prospective investigation of 308 patients with major depressive or bipolar disorder. They found that the three strongest predictors of future suicidal

acts were a history of suicide attempt(s), severe depression (according to subjective self-reports), and, for unknown reasons, cigarette smoking (although the National Comorbidity Survey—Replication [2001–2003] found no causal effect of smoking on suicidal behavior). Each of these factors posed an additive risk. The authors also determined that the tendency toward pessimism, as well as the presence of aggressive/impulsive traits, heightened future suicide risk in an additive manner. Swann and colleagues (2005) found that a history of severe suicidal behavior in 48 patients with bipolar disorder was associated with impulsivity, manifested as a tendency toward rapid, unplanned responses (as measured by impulsive errors on an immediate memory task and shorter response latencies).

Diathesis-stress models of suicide often assume that a predisposition to impulsive behavior provides the "diathesis" and the acute depressive or manic symptoms the "stress" that result in suicide.⁸ However, there are virtually no longitudinal data on measures of impulsivity or aggression in

bipolar disorder, and at the clinical level, rather than being invariant, impulsivity would be expected to be accentuated during manic and mixed states. Further, characterization of the essential deficit as being in the domain of impulsivity or aggressivity may be too narrow. An especially comprehensive neuropsychological study recently contrasted the profiles of medication-free depressed patients who had a history of a high-lethality suicide attempt, a low-lethality suicide attempt, or no suicide attempt with the profiles of healthy controls (Oquendo et al., 2003). The cognitive domains sampled included general intellectual functioning, motor functioning, attention, memory, and executive functioning. A discriminant analysis indicated that separate dimensions distinguished the total depressed sample from the healthy controls and the high-lethality attempters from the other patient groups. Impairment in attention and memory segregated the patients from controls, highlighting that a basic attentional disturbance may be a key factor in determining the cognitive sequelae of mood disorders, both unipolar and bipolar (see Chapter 9). Impaired executive function distinguished high-lethality attempters, with the executive function measures not restricted to indices of impulsivity. This work raised the possibility that a more broad-based deficit in executive function, perhaps related to self-monitoring functions, was disturbed in individuals with a history of a high-lethality suicide attempt.

In summary, there are strong genetic influences on suicidal behavior according to the findings of family, twin, and adoption studies. The findings of these studies also suggest that a family history of suicide and impulsivity/aggressiveness may increase the risk of suicide independently of transmission of psychiatric disorders. The possibility of independent risk factors should motivate clinicians, during their assessment of suicidal patients, to ask about family history of suicide, impulsivity, and aggression (see Chapter 25).

Neurobiological Factors

Serotonin Hypofunction

Many studies conducted over several decades have found an association between suicide and serotonin hypofunction. The first investigators to observe the association were Asberg and colleagues (1972), who found, in particularly violent suicide cases, low levels of 5-hydroxyindolacetic acid (5-HIAA)—the principal serotonin metabolite—in cerebrospinal fluid (CSF). A meta-analysis of 20 studies involving 1,002 psychiatric patients found that those with a history of attempted suicide, particularly violent attempts, had lower levels of 5-HIAA in CSF than did psychiatric controls (Lester, 1995). Lower serotonergic activity has

been localized to the prefrontal cortex in imaging studies of high-lethality suicide attempters (Oquendo et al., 2003). A recent prospective study of 27 bipolar depressed patients found that six subjects made suicide attempts during the 2-year follow-up period. These patients had higher aggression and hostility scores than the patients who did not make an attempt; CSF 5-HIAA, homovanillic acid (HVA), and MHPG levels were negatively correlated with the maximum lethality of the suicide attempts (Sher et al., 2006).

The robust finding of serotonin hypofunction, combined with the research discussed earlier pointing to genetic contributions to suicide, led to a search for candidate genes whose products control serotonin biosynthesis, degradation, or reuptake. Studies have sought to link higher prevalence of polymorphisms in serotonin-related genes to suicidal behavior.

Although serotonin hypofunction remains an important finding, studies of candidate genes have produced conflicting results and are beset by methodological problems (for reviews see Mann, 1998, 2002; Baldessarini and Hennen, 2004); moreover, few studies have focused specifically on bipolar patients. Consequently, a complete review of this subject is beyond the scope of this chapter. The recent studies highlighted here are illustrative of the complex range of findings regarding the enzyme tryptophan hydrolyase (TPH; the rate-limiting enzyme in serotonin synthesis), serotonin receptor subtypes, and the promoter region of the serotonin transporter. The serotonin transporter gene is responsible for reuptake of serotonin into the presynaptic neuron.

One explanation for finding low serotonin metabolites in individuals who have committed suicide is that less serotonin is being produced as a result of genetic defects affecting serotonin synthesis. Studying TPH, Turecki and colleagues (2001) found that one haplotype for the gene was significantly more prevalent among suicides involving violent methods than among living controls. Pooley and colleagues (2003) also found that a variation in the TPH gene was associated with deliberate self-harm. Other investigators, however, found no association between several TPH polymorphisms and suicidal behavior (Kunugi et al., 1999; Ono et al., 2000).

One of the earliest findings in autopsy studies was the higher number of serotonin 5-HT_{1A} receptors, particularly in the prefrontal cortex, in suicide cases (Arango et al., 1995). Pandey and colleagues (2002) found an increase in another receptor subtype, the 5-HT_{2A} receptor, in the prefrontal cortex and hippocampus of teenage suicide victims. In another study, one of the few with a distinct subgroup of bipolar patients, a polymorphism in the 5-HT_{2A} receptor was found in this subgroup to be associated with a

lower risk of suicidal behavior (Bonnier et al., 2002). On the other hand, Turecki and colleagues (2003), studying genes for seven serotonin receptor subtypes, found no differences in allelic or genotypic distributions. Schmauss (2003) found evidence of altered transcripts of the 5-HT_{2C} gene in the brains of depressed suicide victims and hypothesized that the alteration reflects defects in regulation of ribonucleic acid (RNA) editing by synaptic serotonin.

The promoter region of the serotonin transporter gene has been found to be altered in several studies of suicidal behavior or violent suicides. Bondy and colleagues (2000) found increased frequency among suicide victims (with unknown diagnoses) of one or two short alleles of the serotonin transporter gene promoter (5-HTTLPR). The short allele, as compared with the long allele, has been linked to lower transcriptional efficacy (Lesch et al., 1996). In prior studies, the alleles were found to be associated with anxiety-related personality traits, affective disorders, or severe alcohol dependence. In a meta-analysis, Lin and Tsai (2004) also found a significant relationship between the short allele of 5-HTTLPR and suicidal behavior, especially violent suicide. But many studies have not found a relationship between the serotonin transporter polymorphism and completed suicide (Mann et al., 2000; Fitch et al., 2001) or suicide attempts (Geijer et al., 2000; Baca-Garcia et al., 2004) or in suicidal inpatients (Russ et al., 2000).

Two key studies sought to determine the predictive value of possessing the homozygous short (S/S) allele. Courtet and colleagues (2004) followed 133 patients hospitalized for a suicide attempt after first genotyping them for both A218C TPH and the functional S/L 5-HTTLPR polymorphism. Of the 76 patients they followed for 1 year, 20 reattempted suicide. The frequencies of the S or S/S allele were higher in those who had reattempted suicide, with elevated odds ratios (in comparison with the homozygous long [L/L] allele group) of 2.8 and 6.5, respectively. Impulsivity scores on the Baratt Impulsivity Scale (BIS) were significantly higher in patients carrying the S/S genotype than in those carrying the S/L genotype ($p=.026$). No differences were found in the TPH gene. The authors concluded that the SS genotype is a risk factor for future suicide attempts among those who have made a previous attempt.

A related study by Caspi and colleagues (2003) prospectively followed a cohort to test whether genetic vulnerability, as manifested by the short allele of 5-HTTLPR, would lead to depression or suicidality in individuals exposed to serious life stressors. Their hypothesis was supported by the finding that individuals with one or two copies of the short allele displayed, after exposure to stressful life events, more depressive symptoms, diagnosable depression, and

suicidal ideation or attempts compared with individuals homozygous for the long allele. This study provides evidence of a gene–environment interaction, insofar as an individual's response to stressful life events is moderated by a particular aspect of his or her genetic makeup (in this case, the short allele of the promoter region of the serotonin transporter gene). It is noteworthy that the study found a relationship of genotype not only with depressive symptoms, but also with suicidal ideation or attempts.

While few studies of candidate genes have looked at possible gender differences, Baca-Garcia and colleagues (2003) published pilot data suggesting that females with the L/L allele are less likely to make suicide attempts than those with the S/S or S/L alleles. This protection may be lost, however, during life phases characterized by lower estradiol, such as menses or menopause.

The brain's serotonin system is highly complex. Although the findings of studies reviewed here point to genetic alterations in the serotonin system as having a relationship to suicidal behavior, the findings with respect to manic-depressive illness and suicide remain inconclusive.

Low Cholesterol

A number of studies have suggested a possible relationship between low cholesterol and impulsive aggression, including higher death rates from suicide. The link is hypothesized to occur through cholesterol's effect on serotonin activity (Mann, 1998). The findings of these studies, however, which include both large epidemiologic surveys and studies of suicidal individuals, have been mixed.⁹ In some cases, an association was found only in violent suicide attempters (Alvarez et al., 2000). (See reviews by Boston et al., 1996; Hillbrand and Spitz, 1997.)

In those studies looking specifically at bipolar patients, the findings have again been mixed. Bocchetta and colleagues (2001) studied 783 consecutive patients admitted to a lithium clinic. They found that the proportion of men with a lifetime history of suicide attempts or a history of a suicide by a first-degree relative was significantly higher in the group with low cholesterol levels (in the lowest 25th percentile) than in those with higher levels. Cassidy and Carroll (2002a) found low fasting cholesterol in manic patients, particularly during mixed manic episodes, and hypothesized that this condition is secondary to immune activation. On the other hand, Tsai and colleagues (2002), studying 43 bipolar patients who died by suicide in Taiwan between 1985 and 1996, found no difference in cholesterol levels compared with controls, who were bipolar patients still living.

In summary, if there is a relationship between low cholesterol and suicide, it is likely to apply to violent suicide attempts and completed suicides. However, lowering cho-

lesterol with statin medications does not appear to have increased suicide risk in the large samples studied (Manfredini et al., 2000; Muldoon et al., 2001), and it is unclear whether the association between low cholesterol and suicide risk will hold true in bipolar patients.

Hypothalamic–Pituitary–Adrenal Axis Hyperactivity

Hyperactivity of the hypothalamic–pituitary–adrenal (HPA) axis has long been hypothesized as a biochemical marker of suicide. The HPA axis is the preeminent modulator of the relationship between acute stress exposure and physiological activation. In studies dating back to the 1960s, researchers observed that, within days before suicide, patients with major affective disorders had elevated levels of urinary 17-hydroxycorticosteroid and serum cortisol.¹⁰ Not all studies of suicide found these elevations, however (Levy and Hansen, 1969).

In a related finding, individuals who died from suicide had enlarged adrenal glands compared with controls who died from accidents (Dorovini-Zis and Zis, 1987; Szigethy et al., 1994). Findings of increased levels of corticotropin-releasing factor (CRF) in the CSF of suicide victims (Arato et al., 1989; Brunner and Bronisch, 1999), as well as evidence of downregulation of CRF receptors in the frontal cortex (Nemeroff et al., 1988), suggested increased CRF release prior to suicide. Hucks and colleagues (1997) found no decrease in CRF receptors, even when they compared those taking and not taking antidepressants before suicide. More recently, Hiroi and colleagues (2001) found a shift in the ratio of corticotropin-releasing hormone receptor 1 (CRH-R1) to corticotropin-releasing hormone receptor 2 (CRH-R2) in the pituitary gland of suicide victims.

Another measure of HPA hyperactivity studied in relation to suicide is the dexamethasone suppression test (DST), which shows a failure of exogenous dexamethasone to suppress levels of cortisol secreted by the adrenal glands. Most studies have found a relationship between DST non-suppression and suicide completion, but the relationship to suicide attempts is not as strong.

Studying 65 patients with major depression, Brown and colleagues (1986) found no relationship between DST non-suppression and suicide attempts. In contrast, Coryell (1990) observed that 76 depressed inpatients who were nonsuppressors at inpatient admission were more likely over a 5-year follow-up period to develop mania or hypomania and to make serious suicide attempts. Studying depressed inpatients, Norman and colleagues (1990) matched 13 patients who had committed suicide with depressed inpatients who had made suicide attempts before admission ($n=25$) and those who had not made attempts ($n=28$). More than half of the patients committing suicide were nonsuppressors, compared with lower proportions of

suicide attempters and nonattempters. Likewise, a meta-analysis found that DST non-suppression was predictive of completed suicide (Lester, 1992).

Findings of a more recent study strengthened the relationship between non-suppression and completed suicide. Coryell and Schlesser (2001) found that nearly half of 78 inpatients with affective disorders were DST nonsuppressors at admission. After being followed for 15 years, 26.8 percent of nonsuppressors eventually died by suicide, compared with only 2.9 percent of DST suppressors. Within this sample, a comparatively small number of bipolar patients had received a DST because most had been admitted in a manic state, which made cooperation in taking the DST more difficult. Data from studies of abused children and patients with post-traumatic stress disorder also suggest that these overwhelming stressors can persistently alter the responses of the HPA axis (Heim and Nemeroff, 1999, 2002).

Norepinephrine Function

Several studies have identified alterations in norepinephrine transmission in relation to suicide. Ordway (1997) and others (Arango et al., 1997; Gonzalez-Maeso et al., 2002) found reductions in norepinephrine levels in the locus caeruleus (LC) of suicide victims, as well as increased levels of tyrosine hydroxylase and supersensitivity of alpha-2 adrenoceptors. Ordway characterized the changes he found in suicide victims as being similar to those found in rats after LC activation. He hypothesized that suicide victims experience chronic activation of the LC, leading to depletion of norepinephrine and other compensatory changes. Recently, Ono and colleagues (2004) found evidence suggesting that a Val/Val polymorphism for the catecholamine-metabolizing enzyme, catechol-O-methyltransferase, may be protective against suicide.

Psychological Traits and Temperament

A passive sense of hopelessness is a chronic risk factor for suicide. This conclusion is supported by the findings of a 20-year prospective study (Beck et al., 1999; Brown et al., 2000); another large-scale prospective investigation, the National Institute of Mental Health's (NIMH) Collaborative Program on the Psychobiology of Depression-Clinical Studies, which studied 954 patients with affective disorders, including more than 300 with bipolar illness (Fawcett et al., 1990); and a meta-analysis of case-control, cohort, and cross-sectional investigations of attempted suicides (23 studies) or completed suicides (13 studies) in bipolar patients (Hawton et al., 2005). While hopelessness has generally been conceptualized as a symptom specific to depression, the NIMH study found baseline hopelessness to

be trait-like (Young et al., 1996). The study also found that baseline hopelessness predicted a suicide attempt. In the 20-year prospective study, researchers found that severity of suicidal ideation at its worst point is predictive of suicide. The patients who scored in the high-severity category on this measure were far more likely to ultimately kill themselves than those in the lower-severity group (odds ratio [OR] = 13.8) (Beck et al., 1999). We are unaware of any studies concerning familial transmission of hopelessness. Hostility, which in an acute way is often associated with mixed states, is also associated with increased rates of attempted and completed suicide (so, too, relatedly, are impulsivity and aggression) (Michaelis et al., 2004; Rutter and Behrendt, 2004; Galfalvy et al., 2006).

Certain temperaments, such as novelty seeking and harm avoidance, have been hypothesized to show familial or genetic transmission. Such temperaments may also be related to suicide risk. According to Cloninger and colleagues (1993, 2000), novelty seeking is related to impulsiveness, while harm avoidance tends to be related to anxiety and anhedonia. Studying 758 sibling pairs from 177 nuclear families of alcoholics, Cloninger and colleagues (1998) demonstrated significant heritability for proneness to anxiety and harm avoidance. Likewise, the capacity for pleasure in an individual may be trait-like and connected to temperament (Clark, 1991). A strong harm avoidance trait could be related to both vulnerability to anhedonia and comorbid anxiety disorders. Engstrom and colleagues (2003) measured personality characteristics of bipolar patients with the Temperament and Character Inventory (TCI) and found that patients with early-onset bipolar illness scored significantly higher on harm avoidance than those with late onset. Suicide attempts also were significantly more common among patients with early onset. Bondy and colleagues (2000), as noted earlier, observed that the presence of one or two short alleles of the serotonin transporter gene was associated with anxiety-related personality traits as well as affective disorder. Caspi and colleagues (2003) found that individuals with one or two copies of the short allele exhibited more diagnosable depression and suicidality in response to stressful life events. Their study yielded evidence of a gene–environment interaction, in which the individual's response to major life stresses is mediated by his or her genetic makeup. As more evidence becomes available, vulnerability to suicide may be manifest in detectable familial–genetic traits associated with other biological markers that are triggered by psychiatric illness and major life stresses.

Social Factors

The impact of social factors, such as losing an important relationship or a job or facing legal or criminal proceed-

ings, can be devastating to anyone; this is particularly true, however, for those with a major psychiatric illness such as bipolar disorder. Although rarely sufficient by themselves to cause suicide, social stressors can precipitate or determine the timing of the act. In this way, they act as risk factors that increase the likelihood of suicide. They may trigger suicide in individuals with certain biological vulnerabilities and psychological traits (e.g., Caspi et al., 2003, discussed earlier), but most studies have not teased apart their precise role in manic-depressive illness. Social stressors may also precipitate sleeplessness; this, in turn, has been shown in bipolar patients to increase the risk of an affective relapse.

Social factors not only can increase risk, but also may buffer individuals from suicide. For example, supportive families and friends and religious beliefs may, to a point, deter suicide by acting as protective factors (IOM, 2002). Religious beliefs and devotion—as opposed to practice and affiliation—have been shown to be protective for African-American women (Neeleman et al., 1998; Greening and Stoppelbein, 2002; Kaslow et al., 2004), the ethnic group with the lowest suicide rate in the United States (Kaslow, 2000). The potentially protective role of religious belief and practice has not been studied in relation to individuals with bipolar illness, however.

Social and cultural factors also shape an individual's willingness to seek help, styles of coping with adversity, and social support structures. On a societal level, social and cultural factors influence laws, regulations, and health policies that dictate the availability of resources for treatment and prevention (U.S. Department of Health and Human Services, 2000; IOM, 2002). Indeed, awareness of the potency of cultural and social factors prompted the U.S. Surgeon General, Dr. David Satcher, to mobilize clinicians, public health professionals, communities, families, and the media as part of a comprehensive strategy for suicide prevention (U.S. Public Health Service, 1999).

CLINICAL CORRELATES OF SUICIDE

In this section, we review research findings on correlations between suicide and various features of bipolar disorder: mixed states, depression, rapid cycling, and severe anxiety or agitation. We then examine suicide in bipolar disorder in relation to comorbid personality disorders, substance abuse, psychosis, and course of illness.

History of Suicide Attempts

There is an extensive literature documenting the strong correlation between a history of suicide attempts and subsequent completed suicide (see, for example, Nordstrom et al., 1995a,b; Tsai et al., 2002; Joiner et al., 2005). Harris and

Barraclough, in their extensive meta-analysis, found that a suicide attempt created a 37-fold risk for completed suicide; several large prospective studies also demonstrated a substantial increased risk for suicide in those who had previously attempted it (Jawcett et al., 1990; Marangell et al., 2006). In their meta-analysis of 13 studies of completed suicide and 23 studies of attempted suicide, Hawton and colleagues (2005) found that past suicide attempts were the factor most predictive of future suicidal behavior. In the Finnish Jorvi Bipolar Study, 191 bipolar patients were followed for 18 months, during which time 20 percent attempted suicide (Valtonen et al., 2006). Baseline previous suicide attempts were the most significant predictor (odds ratio [OR] = 3.8; 95 percent confidence interval [CI] = 1.7–8.8; $p = 0.001$) of a subsequent attempt.

During a 2-year follow-up period, 12 of 64 bipolar patients studied at Columbia University made at least one suicide attempt. All attempters had a history of past suicide attempts; none of the previously nonattempters made an attempt (Galfalvy et al., 2006).

Mixed States

Mixed states are a significant risk factor for suicide. Among the first to study the relationship between agitated, dysphoric states and suicide was Jameison (1936), who concluded that mixed states were the most dangerous clinical phase of illness for suicide risk.¹¹ In his investigation of 100 suicides (half with manic-depressive psychosis), he noted that the combination of depressive symptoms, mental alertness, and tense, apprehensive, and restless behavior was particularly lethal. Mixed states represent a potentially deadly combination of depressive affect and cognition, linked to dysphoric state, heightened energy level, and increased impulsiveness. Jameison's clinical account of mixed states and their association with suicide remains apt, as does his observation that those patients who were both tense and restless were at the greatest risk for suicide:

Finally there are the patients with mixed manic-depressive states. The majority of these show the usual depression, numerous self-accusations, ideas of guilt and punishment and a varying degree of hypochondriasis. At the same time there is a mental alertness, associated with tense, apprehensive and restless behavior. The retardation of thought and action that paralyzes the acting out of the wish for death in the average depressed patient is entirely absent in these persons. They are, therefore, the most dangerous types of patients with mental disease, so far as suicide is concerned. The records of the fifteen patients in the group emphasize this strikingly. Three of these patients committed suicide twenty-four hours after leaving the hospital, two within forty-eight hours, another

within a week and still another within two weeks. The patient who was longest outside the hospital lived two months, and the average period for this group was fifteen days! (Jameison, 1936, p. 4)

Winokur and colleagues (1969) found that suicidal thoughts or attempts occurred in 13 percent of depressive episodes following mania and in a strikingly high proportion of mixed states (43 percent), although the latter finding applied only to women. Kotin and Goodwin (1972) also described the coexistence of suicidal behavior and mixed states, as did Kraepelin (1921) in his original clinical monograph.

In a series of studies, Dilsaver and colleagues (1994, 1997; Dilsaver and Chen, 2003) found that, compared with patients with pure mania, patients with depressive mania had significantly higher rates of suicidality. Suicidality was defined as a severity level of 3 to 7 on the suicide subscale of the SADS, which ranges from mild suicidality (frequent ideation, but without a specific method or plan) to suicide attempts. More recently, Dilsaver and colleagues (2005) studied suicidality in adolescents and determined that mixed states increased the probability of attempting suicide for girls only, in whom the increased risk was four-fold. In a study of 100 bipolar-I manic patients, Goldberg and colleagues (1998, 1999) found a significant relationship between dysphoric mania and suicidal ideation. They also noted that multiple suicide attempts were associated with nonremission of mixed mania. Sato and colleagues (2004), using the criteria for dysphoric mania developed by McElroy and colleagues (1992, 1995) and Strakowski and colleagues (1996), studied 576 patients hospitalized with acute mania. They found that mixed mania was strongly associated with suicidality.

Depression

It has long been known that depression is strongly correlated with suicide and suicide attempts (Jameison and Wall, 1933; Barraclough et al., 1974; Weeke, 1979). More recent findings strengthen the early clinical observations. Isometsa and colleagues (1994) studied a sample of 31 bipolar patients who committed suicide in Finland within a 12-month period, 74 percent of whom had been receiving psychiatric care at the time of their suicide. Among these patients, 79 percent were depressed at the time of death, 11 percent were in a mixed state, and 11 percent died during or immediately after remission of psychotic mania. Dilsaver and colleagues (1997) found bipolar depression to have been associated with suicidality somewhat more frequently than were mixed states, although both conditions were associated with greater suicidality than was pure mania. Grunbaum and colleagues (2004) compared suicide attempts among 347 patients with melancholic versus nonmelancholic major depression. They found

that melancholic features during depression were correlated with more serious past attempts and the probability of suicide at follow-up.

The severity of depression is a factor as well (Arato et al., 1988; Henriksson et al., 1993; Isometsä et al., 1994). Swedish researchers psychiatrically assessed an entire rural population and then kept track of its mental health for the next 15 to 25 years (Hagnell et al., 1981). Virtually all of the men who committed suicide during the follow-up period had been diagnosed during their initial evaluations as having depressive illness. The suicide rate for men with no psychiatric diagnosis at all was 8.3 per 100,000, but for those with depression it escalated to 650. No one with mild depression committed suicide, but the rate rose to 220 per 100,000 for those who had been diagnosed with moderate depression and to 3,900 per 100,000 for those with severe depressive illnesses.

Weeke (1979) found that at the time of death, 58 percent of manic-depressive patients who committed suicide had been in a constant or worsening depressive state. Fully 30 percent of the patients, however, had been classified as "depressive state, recovering." Keith-Spiegel and Spiegel (1967) compared the clinician-rated mood states of 61 psychiatric patients immediately preceding their suicides with those of 51 matched control patients of comparable age and diagnoses who had not committed suicide or had no history of a suicide attempt. Those who killed themselves had histories of more frequent and more severe depressions, as well as more suicide attempts, threats, and suicidal ideation. Of particular significance, however, was that just before death, those who committed suicide had been assessed by their clinician as being calmer and in better spirits than members of the control group. An apparently unwarranted mood shift had been observed in those who killed themselves.

These findings add weight to the clinical observation, dating back hundreds of years, that improvement in depression is associated with an increased risk for suicide.¹² Several factors may account for this counterintuitive observation. The improvement may reflect a sense of calm once the decision has been made to die, a genuine calm before the storm brought about by biological changes, or a transition from one phase of the illness to another (e.g., from depression to hypomania, mania, or a mixed state). It also may reflect true clinical improvement, with a concomitant level of frustration when symptoms recur. In some instances, an improved clinical state enables a previously indecisive and lethargic patient to become more able to make an unambivalently lethal decision and to act on that decision. Finally, "improvement" may in fact be a patient's deliberate deception of physicians, hospital staff, and family so a suicide plan can be carried out. Problems

in assessing clinical improvement were described decades ago by Jameison (1936, p. 4):

It is only when the depression is lifting, often some weeks before the morbid and self-accusatory ideas have disappeared, that the possibility of suicide is less remote. Unfortunately, at this time a tendency to project the inner distress on the environment leads to complaints and pleadings, so that relatives, noting the improvement, agree with the patient that the hospital restrictions are prolonging the illness. The patient is then removed at a time when he is potentially more suicidal than at any time before.

Rapid Cycling

Rapid cycling increases the risk of suicide and suicidal behavior. One of the first large studies to examine the relationship between suicide and rapid cycling was NIMH's Collaborative Study on the Psychobiology of Depression-Clinical Studies (Fawcett et al., 1987). Of the study's 954 patients, 569 had unipolar depression,¹³ 185 had bipolar-I, 114 had bipolar-II, and the remaining 80 had schizoaffective disorder. The incidence of suicide over the 4-year study period was 3 percent. The rate did not differ by diagnosis. What did distinguish patients who died by suicide from those who did not was mood cycling during the index episode ($p <.002$). Mood cycling in this study meant that the patient had been admitted in one mood state, such as mania, and cycled into the other before recovery. While this is not synonymous with the classic definition of rapid cycling (i.e., four or more affective episodes in 1 year), there is overlap between the two groups. The authors of the study concluded that mood cycling, which is a feature of bipolar or schizoaffective disorder, is associated with suicide, particularly in men.

In a 5-year prospective study of 345 patients with bipolar-I or -II disorder, 89 patients were identified, using DSM-IV criteria, as having a pattern of rapid cycling for 1 year or more (Table 8-4; Coryell et al., 2003). The rapid-cycling patients were significantly more likely than the rest of the patients to have had onset of illness before age 17 and were twice as likely to attempt, but not to complete, suicide.¹⁴ The differences between the groups were most pronounced for attempts rated as being of high lethality.

Brodersen and colleagues (2000) conducted a 16-year follow-up study of 133 patients with major affective disorders (defined as having two to three affective episodes in a 5-year period) treated with lithium. Most of the 11 suicides occurred among the "atypical" patients (those with schizoaffective disorder, bipolar-II disorder, mixed episodes, and/or rapid cycling). MacKinnon and colleagues (2005), in a study of 1,574 family members with bipolar disorder, also found that a history of rapid mood switching was

TABLE 8–4. Relationship between Rapid Cycling, Suicide, and Suicide Attempts before Intake and during Follow-Up

	Any Rapid Cycling (n=89)	No Rapid Cycling (n=256)
Before Intake, No. (%)		
Any attempt	51 (57.3) ^a	85 (33.2)
Any attempt of high intent	31 (34.8) ^a	38 (14.8)
Any attempt of high lethality	36 (40.4) ^a	35 (13.7)
After Intake, No. (%)		
Completed suicide	3 (3.4)	11 (4.3)
Any attempt	46 (51.7) ^a	70 (27.3)
Any attempt of high intent	27 (30.3) ^a	33 (12.9)

associated with increased suicidality. Two other studies found trends for suicidal behavior and rapid cycling (Bauer et al., 1994; Maj et al., 1994). On the other hand, using retrospective chart reviews of 100 rapid-cycling and 120 non-rapid-cycling outpatients, Wu and Dunner (1993) found no association between suicide attempts and rapid cycling. Still, most studies have found that rapid cycling increases the risk of suicide and suicidal behaviors.

Anxiety and Agitation

Studies have shown high rates of comorbid anxiety disorder in bipolar patients, often reaching at least 40 percent (McElroy et al., 2001; Simon et al., 2004). The high incidence of comorbid anxiety disorders in both bipolar-I and bipolar-II patients calls for special attention to severe symptoms of anxiety in the assessment and management of suicide risk in bipolar patients (see Chapter 25).

Anxiety figured prominently in a major study of time-related risk factors for suicide. In their prospective study of 955 bipolar and unipolar patients, Fawcett and colleagues (1990) delineated a cluster of risk factors that were better predictors of suicide over the short term (acute risk factors) and others that were better over the long term (chronic risk factors). They found that anxiety symptoms were predictive both acutely (within 1 year of study entry) and chronically (after the first year of study entry). Among the 14 patients who committed suicide within 1 year of assess-

ment, suicide was related to symptoms of severe psychic anxiety, panic attacks, anhedonia, and moderate alcohol abuse; the abuse of alcohol with another drug was a significant risk factor, especially in males (see later discussion). No difference was found between bipolar and unipolar depressed patients with regard to severe psychic anxiety, panic attacks, and suicide. Over the next 4 years, another 13 patients killed themselves. These later suicides were most commonly associated with severe hopelessness, somatic anxiety, suicidal ideation, and a history of one or more suicide attempts. These findings underscore the importance of assessing patients in terms of acute versus long-term suicide risk (see Chapter 25).

The identification of time-related factors helps address the difficult problem of predicting a relatively infrequent behavior in the midst of subtle and fluctuating mood states. This point is illustrated by the predictive role of past suicide attempts. While attempts carry a high chronic risk for suicide—with an SMR of 37, according to Harris and Barraclough (1997)—they do not confer a significant acute risk.

Numerous other studies underscore the role of comorbid anxiety/agitation in relation to suicide. Among a sample of 209 outpatients who had attempted suicide or been identified as being at high risk for continued suicidal behavior or eventual suicide, Rudd and colleagues (1993) noted a statistically significant incidence of comorbid panic disorder and post-traumatic stress disorder among

suicidal bipolar patients. Likewise, MacKinnon and colleagues (2005) found that comorbid panic disorder increased the risk of suicidality in individuals with bipolar disorder. Among patients with major depression, Reich (1998) found that suicide attempts were correlated with higher levels of comorbid anxiety. Hall and colleagues (1999) found that severe anxiety was present in 90 percent and panic attacks in 80 percent of suicide attempters. Schnyder and colleagues (1999) reported similar findings showing the presence of severe anxiety in a study of 30 consecutive emergency room suicide attempters who were later admitted to a psychiatric inpatient unit (diagnoses not specified in the study). Likewise, Angst and colleagues (1998) found the presence of anxiety to be a suicide risk factor in a 5-year follow-up sample of 186 patients with unipolar and 220 patients with bipolar depression. And in an analysis of 76 inpatient suicides, Busch and colleagues (2003) found that 79 percent of patients had chart notes indicating severe anxiety/agitation within 1 week of their suicide.

One study attempted to ascertain what features of bipolar illness, including panic disorder, are related to suicidality. Dilsaver and colleagues (1997) divided their sample of 125 bipolar patients into three groups—those with bipolar depression, those with depressive mania, and those with pure mania. They examined the incidence of suicidality (rated using the SADS), psychosis, and intra-episode panic disorder (IEPD). IEPD was highly prevalent in the bipolar depression (79 percent) and depressive mania groups (56 percent) but rare (2.3 percent) in the pure mania group. Overall, the findings suggest a high degree of overlap among suicidality, IEPD, and bipolar depression or depressive mania, as opposed to pure mania.

Taken together, these studies argue for the assessment of severe anxiety or agitation and for aggressive anxiolytic treatment in the management of suicide risk in affective disorders (see Chapter 25).

Insomnia and excessive concern about sleep disturbances have been noted as correlates of increased potential for suicide,¹⁵ as has pervasive hopelessness (see earlier discussion). The body of evidence has led to widespread acceptance that insomnia and hopelessness are risk factors for suicide. Global insomnia is considered an acute risk factor because it was found, in a prospective study, to be associated with suicide within the first year of study entry (Fawcett et al., 1990).

Comorbidity and Axis II Disorders

Suicide among individuals with comorbid psychiatric conditions is so prevalent that it is the norm rather than the exception. This point is best illustrated by a population-based study from Finland, which found that a small fraction—only 12 percent—of all 229 suicide vic-

tims had only one Axis I diagnosis with no comorbidity (Henriksson et al., 1993). Comorbid conditions and certain behavioral states dramatically increase the risk of suicide. Most of the studies reviewed here, however, did not study bipolar disorder separately. This may be an important limitation on the conclusions that can be drawn about the role of comorbid conditions in suicide among bipolar patients.

In a psychological autopsy study of 117 suicides, Foster and colleagues (1999) found that, in comparison with deceased community controls without a mental disorder, the risks were extraordinarily high for two groups of patients: those with comorbidity (an Axis I and Axis II disorder; OR=346.0) and those with a single Axis I disorder (OR=52.4). Kim and colleagues (2003), studying the records of 115 male suicides, found that the most common comorbidities in suicide completers were depressive disorders plus cluster B disorders¹⁶ and substance dependence plus cluster B disorders (27.8 percent). In this study, those who committed suicide, compared with controls, were 22 times more likely to have three or more diagnoses (OR=22.38, $p < .0000001$). Heikkinen and colleagues (1997) compared 56 suicides who had both Axis I disorders (most commonly major depression) and comorbid personality disorders with an equal number who had no comorbidity. The patients with personality disorders, cluster B type, had experienced multiple life events preceding their suicide compared with the noncomorbid patients who had died by suicide. It appears clear from these studies that comorbidity of Axis I and Axis II disorders strikingly increases the risk of suicide.

Substance Abuse

Comorbid substance abuse is another risk factor for suicide in both bipolar and unipolar patients, particularly in the young (Fawcett et al., 1987; Murphy, 1988). In their large, prospective study, Fawcett and colleagues (1987) found a significant increase in long-term risk with so-called “double abuse” (alcohol plus any other abused substance). They also found recent, moderate alcohol abuse to be a short-term (acute) risk factor (see Chapter 25).

Like Fawcett and colleagues, others have noted an association between alcohol abuse and suicide. Barracough and colleagues (1974) found that as the number of suicide attempts increased, so did the chances that the attempter was alcohol dependent. In a study of 204 suicides, Rich and colleagues (1988) noted substance abuse and affective disorders to be the most frequent diagnoses for men and women. Morrison (1975) found that bipolar patients who were also alcohol dependent had a higher rate of suicide in their family histories than did nondependent bipolar patients. In a study of suicide among adolescents and young

adults, Runeson (1989) observed a 47 percent rate of comorbid substance abuse with any Axis I or II diagnoses. Depressive disorders were diagnosed in 64 percent of those who committed suicide (major depressive disorder = 41 percent).

Tondo and colleagues (1999) found an association between substance abuse disorders and suicide attempts in hospitalized patients, with substance abuse raising the suicide risk more than two-fold regardless of the disorder. In a study of 307 male veterans, Waller and colleagues (1999) noted that comorbidity of alcohol abuse and bipolar-I or unipolar depressive disorder was always associated with an increased risk of suicidality.

Pini and colleagues (1999) found that among 125 bipolar patients with psychotic features, the subgroup having substance abuse associated with other Axis I comorbidities had an earlier age at onset of their bipolar disorder, more frequent onset with a mixed state, and a higher risk of suicide. Oquendo and Mann (2001) observed that bipolar patients who attempted suicide had higher levels of aggression and comorbid substance abuse than nonattempters. Vieta and colleagues (2000) noted that among 40 patients with bipolar-II disorder, 21 percent had substance abuse comorbidity, and this group had significantly higher rates of suicidal ideation and attempts. Vieta and colleagues (2001) studied 129 bipolar outpatients in remission, finding comorbidity in 31 percent; these patients also had higher rates of mixed states, depressive episodes, and suicide attempts. Cornelius and colleagues (1995) found that suicidality was disproportionately higher among patients with comorbid depression and substance abuse than among those with either disorder alone.

The connection between suicide and substance abuse may be attributable to increased impulsivity or aggressiveness, impaired sleep, or destabilization of illness. As we have seen, low levels of the serotonin metabolite 5-HIAA are correlated with aggression and impulsivity, and it has been shown that patients making the most violent and impulsive suicide attempts have low 5-HIAA levels (see also Chapter 14). It is of interest that Rosenthal and colleagues (1980) found significantly lower levels of 5-HIAA among depressed patients with a family history of alcoholism than among those without such a family history. Low 5-HIAA levels also have been found in alcoholics after recovery (Ballenger et al., 1979; Linnoila and Virkkunen, 1992; Virkkunen and Linnoila, 1993). Therefore, not only do substance abusers have impaired judgment and decreased inhibition from the drugs themselves, but they may also bear a biological risk for suicide. Bipolar patients who are impulsive or more temperamentally prone to agitated states may be more inclined to use alcohol and other drugs than those who are not. Swann and colleagues (2004)

compared scores on a measure of impulsiveness (the BIS) in interepisode bipolar patients with and without substance abuse. Trait impulsivity was increased in interepisode bipolar disorder only in the case of current substance abuse.

Psychosis

The relationship between psychosis and suicide in mood disorders is unclear. An early, often-cited retrospective analysis of patients with unipolar depression hospitalized at the New York State Psychiatric Institute between 1955 and 1980 found an unusually high rate of delusions among those who committed suicide (Roose et al., 1983). Bipolar patients were not considered separately in this study, but the findings were suggestive of symptom patterns associated with a high risk of suicide. The authors noted that depressed inpatients who were delusional were five times more likely than those who were nondelusional to commit suicide, and that delusional males were particularly vulnerable. Two recent studies found that bipolar children and adolescents with a history of psychotic features were more likely to be suicidal than those who did not have such a history (Papolos et al., 2005; Caetano et al., 2006). The recent study from the Juvenile Bipolar Research Foundation (Papolos et al., 2005) also found that bipolar children and adolescents who threatened to commit suicide were far more likely to report having hallucinations than those who did not threaten suicide.

On the other hand, several studies suggest no such relationship. A study of 1,593 affectively ill patients revealed no increased risk of suicide among the 27.8 percent who had been psychotic at the time of their index hospitalization (Black et al., 1988). Likewise, Fawcett and colleagues (1987) found that psychotic patients diagnosed with affective illness did not have higher prospective rates of suicide over a 10-year follow-up. Dilsaver and colleagues (1997) found no association between the presence of psychosis and mild suicidality; a subsequent study found no association between psychotic features and suicidality in adolescents (Dilsaver et al., 2005). Similarly, Coryell and Tsuang (1982) and Frangos and colleagues (1983) found no increased risk of suicide in patients with delusional depression.

Course of Illness

There is consistent evidence of an increased risk of suicide and suicide attempts early in or just after the first episode of affective illness,¹⁷ as well as in bipolar disorder more specifically. Among the first to study the time course of suicide attempts in bipolar patients were Johnson and Hunt (1979). They found in their very small sample that 30 percent of suicide attempts (90 percent of which warranted hospitalization) occurred at the onset of the illness or

during the first episode of depression. Half of the serious suicide attempts occurred within 5 years of the onset of illness. In a related finding, Balazs and colleagues (2003), studying 100 suicide attempters in Hungary, observed that 60 percent were experiencing their first depressive episode. (Of this group, 35 percent had had mania or hypomania symptoms in the past.) In the largest study, Osby and colleagues (2001) documented suicide rates among all hospitalized patients in Sweden from 1973 to 1995, including more than 15,000 with bipolar disorder. The SMR was found to be especially high in patients whose age at first admission was less than 30 (81.6 for males and 71.7 for females) (Table 8–5).

Recent discharge from a hospital also carries a higher risk (Geddes and Juszczak, 1995, 1997; Appleby et al., 1999). A study was conducted of all suicides ($N=481$) among discharged patients who had been receiving care in 128 Veterans Affairs hospitals in the United States from 1994 to 1998 (Desai et al., 2005). The patients had been diagnosed as

having depression, bipolar disorder, schizophrenia, or post-traumatic stress disorder. The study found suicide deaths to be concentrated in the first 6 months after discharge, with almost 50 percent occurring within 3 months after discharge. Bipolar and unipolar rates were similarly high. A comprehensive investigation of all suicides committed in Denmark from January 1, 1981, to December 31, 1997 ($N=21,169$) found that there were two sharp peaks of risk for suicide in relation to psychiatric hospitalization (Qin and Nordentoft, 2005). The highest peak, which was strikingly elevated in those patients with affective illness, was in the week immediately following discharge from the hospital. The second peak was in the week following admission to the hospital. Suicide was substantially more likely in patients who had shorter hospitalizations.

Several studies have examined suicide risk in relation to age at onset. Perlis and colleagues (2004) studied 983 subjects diagnosed with bipolar disorder on entry into the multicenter Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD). For patients whose age at onset could be determined, the authors found that earlier onset of illness was associated with a greater likelihood of suicide attempts (Table 8–6). Based on multiple regression, the risk of making at least one suicide attempt was 2.85 times greater for those diagnosed with very early onset (before age 13) relative to those diagnosed after age 18. Early onset (ages 13 to 18) was also associated with higher rates of comorbid anxiety disorders and substance abuse, themselves risk factors for suicide (see earlier discussion). Grunebaum and colleagues (2006) found that suicide attempts in 96 patients with bipolar illness correlated with an earlier age at onset.

Engstrom and colleagues (2003) studied patients with bipolar-I and -II disorders and reported that in early-onset patients, treatment response was significantly lower ($p=.005$), and suicide attempts were more common

TABLE 8–6. Comorbid Conditions and Suicide Attempts in Bipolar Disorder by Age at Onset (percent)

	Onset Age <13 yr ($n=272$)	Onset Age 13–18 yr ($n=370$)	Onset Age >18 yr ($n=341$)	Wald X ² (2 df)	p Value

($p=.001$). Leverich and colleagues (2002, 2003) showed that a history of childhood sexual or physical abuse was associated with earlier age at onset; increased Axis I, II, and III comorbid disorders; more rapid cycling; and a higher rate and greater severity of suicide attempts (see Chapter 6). Similarly, Goldberg and Ernst (2004) found that a history of poor adjustment in childhood and adolescence was associated with both substance abuse and dependence and increased suicide attempts in adult patients with bipolar disorder.

The course of affective illness may have different effects on men and women. Johnson and Hunt (1979), in a very small but intriguing study, found that more men than women attempted suicide at the onset of manic-depressive illness (42 versus 17 percent), but that this gender difference later disappeared. Attempts by women were distributed more evenly across time. Although all attempts by women occurred within approximately 15 years after the onset of illness, those by men were distributed more extremely and bimodally: 60 percent of men who attempted suicide did so within 2 years after the onset of illness, and the other 40 percent 23 years or more after onset.

These findings underscore the importance of early recognition of bipolar disorder, accurate diagnosis, and aggressive treatment. They also highlight the need for ongoing reappraisal of suicidal risk (see Chapter 25).

CONCLUSIONS

Suicide is still far too common in manic-depressive illness. Patients diagnosed today face a lifetime suicide risk of at least 5 percent. While this figure is lower than in previous eras—a result in part of better treatments and in part of the inclusion of less severely ill patients in outcome studies—several groups of patients continue to bear a disproportionately high risk burden, including those who are hospitalized or recently discharged and those who are untreated, inadequately treated, or treatment resistant. Further, the suicide rate remains strikingly high early in the course of illness.

The precise causes of suicide remain elusive, although they most certainly entail an interaction between the underlying affective illness and additional biological and psychosocial risk factors. But research has not yet found any particular combination of risk factors to be sensitive or sufficient enough to predict a suicide. Salient risk factors include rapid cycling, mixed states, and severe depressive episodes. A significant advance has come with the identification of which of many risk factors operate in the short term (e.g., agitation, severe hopelessness, global insomnia) versus the long term (e.g., past suicide attempt, various comorbidities). Risk factors and their identification,

moreover, while far from perfect predictors of suicide, can serve as guideposts for clinicians confronting a complex clinical picture of an illness that encompasses the extremes of human emotions.

NOTES

1. National statistics tend to underestimate suicide deaths because of the difficulty of establishing suicidal intent in single-car accidents and other “accidental” deaths and because of cultural, financial, and religious disincentives to label a death as a suicide.
2. For example, Fawcett et al., 1987, 1990; Black et al., 1988; Angst et al., 1999.

PART III

PSYCHOLOGICAL STUDIES

This page intentionally left blank

I seem to be in perpetual fog and darkness. I cannot get my mind to work; instead of associations “clicking into place” everything is an inextricable jumble; instead of seeming to grasp a whole, it seems to remain tied to the actual consciousness of the moment. . . . I could not feel more ignorant, undecided or inefficient. It is appallingly difficult to concentrate.

—John Custance (1952, p. 62)

In this chapter, we examine what can be learned from studies of the neuropsychology of manic-depressive illness. Two streams of neuropsychological investigation can be distinguished. One uses a battery of objective measures, focusing largely on the sensorimotor and cognitive functions, to characterize profiles of strength and weakness in the various phases of bipolar or recurrent unipolar illness. The other generates hypotheses about how affective states, normal and abnormal, are represented in the brain and what factors mediate their expression. We consider the contributions of this second stream of investigation after reviewing what has been learned from the first, the evaluation of sensorimotor and cognitive function in manic-depressive illness, with an emphasis on the bipolar form. In the final section, we assess the overall contribution of neuropsychology to the conceptualization of mood disorders.

CONTRIBUTIONS OF NEUROPSYCHOLOGICAL EVALUATION

The contributions of traditional neuropsychological testing to our understanding of manic-depressive illness pertain to four issues. Such investigation can (1) provide an empirical basis for and clarification of clinical phenomenological concepts; (2) determine which abnormalities are state dependent and which are state independent; (3) characterize the neuropsychological functions that appear to be most persistently impaired, providing a clue to pathophysiology; and (4) determine the burden of the illness and its treatments with respect to cognitive functioning in terms of both cross-sectional and longitudinal outcomes.

Objectifying Clinical Constructs

First, neuropsychological investigation can identify the constituent processes impaired in some of the classic symptoms of the disorder. For example, psychomotor disturbance is common in major depression and bipolar disorder, and depressed bipolar patients may be especially likely to manifest psychomotor retardation (Sobin and Sackeim, 1997). In turn, this motor disturbance is viewed by some as having special prognostic significance with respect to treatment outcome (Hickie et al., 1990a, 1996; Parker and Hadzi-Pavlovic, 1993). However, the term “psychomotor retardation” is itself an amalgam, and the slowness of movement seen in depressed patients may reflect slowing in any of a variety of cognitive or motor processes. Indeed, some success has been achieved in using objective measures to dissect the constituent processes of such retardation and to identify those disturbed in affective disorders (Sobin and Sackeim, 1997). Thus in principle, neuropsychological evaluation can determine just what is slowed in psychomotor retardation and quantify the extent of abnormality.

Similarly, disturbances in attention are rife in mood disorders, yet they can pertain to distinct cognitive processes such as vigilance or sustained attention, freedom from distraction, divided attention, and capacity to shift set.¹ Neuropsychological investigation can clarify the nature of what is typically referred to as impaired concentration.

Identifying State-Related and State-Independent Abnormalities

The above contribution involves clarifying and quantifying deficits described more generally by clinical characterization of key features of the disorder. However, neuropsychological

evaluation also yields information on strengths and weaknesses that go beyond clinical phenomenology. For the past 40 years, there has been an unresolved debate about whether the bipolar subgroup of manic-depressive illness is overrepresented in individuals with higher levels of intelligence and/or creativity (Richards et al., 1983; Andreasen, 1987; Jamison, 1993) (see Chapter 12). This issue can be addressed by determining whether premorbid intelligence in individuals with bipolar disorder exceeds population norms, and whether such individuals exceed normative values on indicators of creativity, such as those assessed by measures of cognitive flexibility and idiosyncratic thought. In turn, findings in this area may be helpful in considering sociobiological questions, such as why the genes for bipolar disorder have been preserved.

More generally, through comparison of individuals in remission and in the depressed or manic state of bipolar disorder, neuropsychological investigation can provide new information on the sensorimotor and cognitive abnormalities that fluctuate with affective state or are invariant across the disorder. As noted above, the state of depression or mania can introduce serious confounds in neuropsychological evaluation. Therefore, a number of recent investigations have placed special emphasis on detailing the deficits characteristic of bipolar patients in remission,² of children at risk for the disorder (Decina et al., 1983; Dickstein et al., 2004; Meyer et al., 2004), and of other first-degree relatives (Sobczak et al., 2002; Ferrier et al., 2004; Zalla et al., 2004), including discordant monozygotic twins (Gourovitch et al., 1999). Indeed, the identification of abnormalities that persist across the phases of the illness or that precede its first expression as a mood disorder may provide markers of disease vulnerability and suggest neurobiological abnormalities responsible for disease expression.

Establishing Differential Deficits of Relevance to Pathoetiology

Perhaps the most common goal of neuropsychological evaluation is to identify the sensorimotor or cognitive processes that are most disturbed in patients with bipolar disorder, in contrast to either normative values or individuals with other neuropsychiatric disorders. The peaks and especially the nadirs of neuropsychological profiles are taken as evidence that certain neuropsychological processes are particularly disturbed, and therefore of particular relevance when considering pathoetiology.

The methods needed to establish such “differential deficits” were reviewed by Chapman and Chapman (1973) in the context of determining what aspect of information processing is most relevant in accounting for thought disorder in schizophrenia. Although there is intuitive appeal to a focus on abnormalities of greatest magnitude, what appears

to be most broken is not necessarily that which is in greatest need of repair. For example, intermittent dysfunction of the electrical system in a car may short out the radio, but the broken radio is not the fundamental problem. Other conceptual reservations concern the fact that cognitive processes are interdependent. Attention has a widespread impact on neuropsychological function. When one cannot attend adequately to information, encoding, learning, and memory are all impaired and, depending on other factors, perhaps more so than the attentional measures themselves. At a methodological level, the validity of comparisons across tests depends on the equivalence of the tests with regard to psychometric properties, particularly internal reliability (the extent to which one dimension is assessed) and difficulty level (overall performance level in the sample). These properties are partly intrinsic to a test and partly a function of the sample being assessed. Thus while it is common to view findings of differential deficit as indicating that one process is more impaired than another, such findings are commonly a psychometric artifact due to the fact that tests with greater power to discriminate among individuals detect larger differences. Thus, it can be argued that the prevalence of particular neuropsychological deficits, their persistence, and/or the extent to which particular deficits account for symptom severity may be as or more important than a gauge of the absolute level of deficit.

Documenting Neuropsychological Burden

Finally, neuropsychological evaluations have practical value in documenting the burden of the illness. Here as well, multiple approaches can be taken. Current theorizing suggests that states of depression and mania, especially when untreated, result in a destructive, atrophic process in the hippocampus due to excessive release of glucocorticoids (Brown et al., 1999; Lupien et al., 1999; MacQueen et al., 2003) (see Chapter 14). In turn, this progressive structural abnormality should be expressed in progressive deficits in declarative, episodic memory, the neuropsychological functions that are especially tied to hippocampal integrity. Indeed, it has been reported that, independently of age, hippocampal volume in euthymic unipolar women covaries with duration of lifetime exposure to the depressed state, as well as with verbal memory performance (Sheline et al., 1996, 1999).

Episode frequency is higher in bipolar than in most unipolar samples, and bipolar patients tend to express the most virulent forms of affective disturbance (e.g., psychotic depression). Thus it is possible that the neuropsychological consequences of manic-depressive illness are especially severe in bipolar relative to recurrent unipolar patients. In a recent study, performance on five tests of learning and memory was compared in young and elderly depressed unipolar and bipolar inpatients (Burt et al., 2000). Unipolar

and bipolar patients within each age group had equivalent scores on the verbal and performance intelligence indices of the Wechsler Adult Intelligence Scale-Revised (WAIS-R) (Wechsler, 1981) and on the modified Mini-Mental State (mMMS) exam (Stern et al., 1987). All patients were tested during a major depressive episode, and symptom severity was found to be similar across the groups. The elderly bipolar patients were distinguished by a higher number of prior affective episodes and psychiatric hospitalizations compared with the other three groups. There was a tendency for the young bipolar group to outperform the young unipolar group on several memory measures. As illustrated by the findings obtained with the Complex Figure Test (Fig. 9-1), elderly bipolar patients decidedly showed the most marked deficits on four of the five tests.

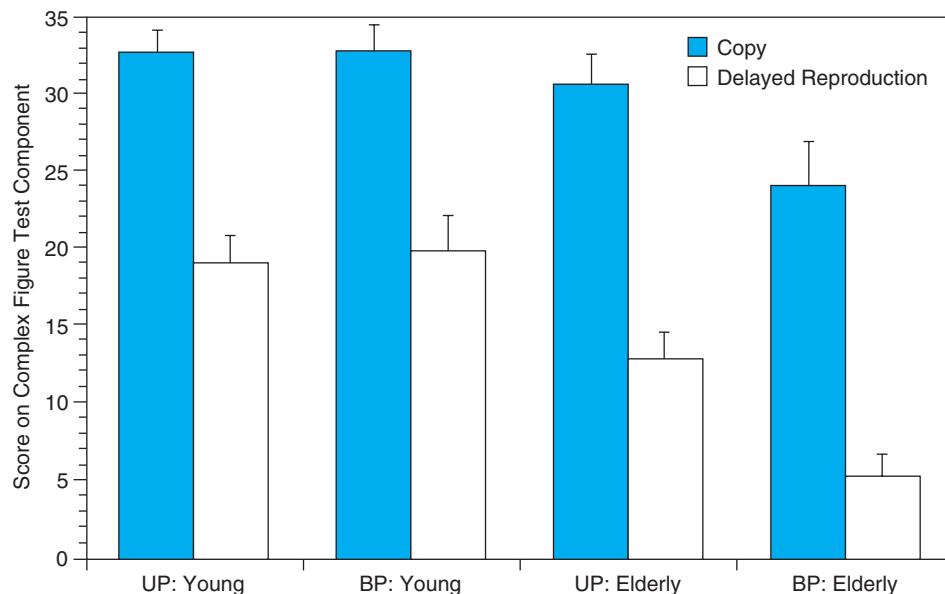

While limited by a cross-sectional design, these findings suggest that deterioration in memory function may be a more prominent characteristic of bipolar than unipolar illness, broadly defined. It would be interesting to know whether there would be unipolar–bipolar differences in memory measures if the two groups were matched on total number of episodes. Given the neuroprotective effects posited for lithium (Manji et al., 2000a,b; Moore et al., 2000) and possibly other mood stabilizers (see Chapter 18), it becomes especially important to determine the impact of treatment on these putative longitudinal effects.

Neuropsychological burden not only results from disease expression and progression, but may also be an inadvertent outcome of treatment (as may neuroprotection). An especially frequent complaint of patients treated with lithium is that, in concert with a dampening of the peaks and valleys of mood fluctuation, creative processes are inhibited. Some individuals report that they are not as original or forward thinking when treated with lithium, or are less quick to see connections and less spontaneous (see Chapter 12). These claims have been tested in neuropsychological investigations, whose results have revealed adverse cognitive effects of lithium that are dose dependent and appear to reverse shortly after discontinuation of the drug (Shaw et al., 1986, 1987).

META-ANALYSIS OF FINDINGS ON NEUROPSYCHOLOGICAL DEFICITS IN MOOD DISORDERS

In the following sections, we present a critical evaluation of what has been learned from neuropsychological evaluations of samples of manic-depressive patients. Much of the literature on neuropsychological function in mood disorders, especially in the depressed phase, has failed to distinguish between bipolar and unipolar subgroups. Necessarily, some of the discussion of neuropsychological deficits in depression

Figure 9-1. Findings obtained with Complex Figure Test. Unmedicated unipolar (UP) and bipolar (BP) patients in an episode of major depression were divided into young and elderly groups. Across multiple measures of memory, the elderly BP patients were greatly impaired, while the young BP patients tended to have the best performance. Shown are scores for copying a complex figure and also for later reproduction of the figure from memory. The delayed reproduction scores show the special deficit in the bipolar elderly. (Source: Burt et al., 2000. Reprinted with permission from Lippincott Williams & Wilkins.)

may not be specific to bipolar disorder, but to the extent that recurrent unipolar patients are included, these studies address the broader concept of manic-depressive illness. However, the major focus here is on those neuropsychological abnormalities that are consistent across manic, depressed, and euthymic phases of the bipolar form of the illness.

For the purposes of this chapter, we conducted a new meta-analysis of studies comparing neuropsychological functions in bipolar and healthy comparison samples. We identified 74 studies published since 1975 that entailed neuropsychological evaluations in a bipolar sample as compared with a healthy control or a psychiatric comparison sample (e.g., schizophrenia), and that met high methodological standards. For a study to be included, patients in the bipolar sample had to be described as predominantly in a depressed or manic state or in remission, and sufficient quantitative values had to be reported so that effect size could be computed. In addition, studies were labeled "mixed" if the bipolar sample included patients with a mix of manic, depressed, or euthymic states; did not specify the affective state; or provided no clear classification of state. Nonetheless, few of the studies classified as "mixed" actually focused on patients in a mixed state, and it is fair to assume that the bulk of patients in these studies were in a depressed state. The 74 studies thus identified yielded 1,216 statistical comparisons of a bipolar sample with another group on neuropsychological outcome measures. These comparisons pertained to multiple neuropsychological domains, sometimes with multiple tests sampling the same domain, and often with multiple outcome measures within a test.

The comparisons reported here concern only the performance of bipolar patients relative to normal control participants, and statistical comparisons were used in the meta-analysis only if they pertained to a major cognitive domain, such as attention. This filter reduced the number of studies examined to 52, and the number of neuropsychological comparisons to 614.³ For each test, all outcome measures were examined so that the effect size assigned a test was the average of these measures. In our meta-analysis, effect sizes for different tests representing the same domain within any study (e.g., attention) were also averaged.⁴

Global Intellectual Functioning

Several key questions have been posed about general intellectual functioning in manic-depressive illness, a literature that focuses primarily on the bipolar subgroup. Most of the research in this area has centered on whether intelligence or global neuropsychological status is invariant across symptomatic states and remission, or the state of depression or mania is associated with deficits or enhancements. There has also been considerable interest in whether premorbid

levels of intelligence, or surrogate measures such as occupational achievement, differ from population norms.

Figure 9-2 presents a meta-analysis of recent studies contrasting the full-scale intelligence quotient (IQ) scores of bipolar patients and healthy volunteers obtained with the WAIS-R. Despite the relatively small number of studies, significant deficits were observed in the remitted, manic, and mixed samples relative to controls. (Only one study [Deptula et al., 1991] was classified as exclusively examining bipolar depressed patients.) Thus, preliminary evidence indicates that intelligence, as assessed by a well-validated measure, is reduced in bipolar illness in both the remitted and manic states. This conclusion is supported by a variety of early studies that found evidence for general intellectual impairment in symptomatic bipolar patients.

The above findings do not imply that variations in state have no impact on intelligence scores. Cross-sectional comparison with control samples can establish whether each state manifests abnormality, but can give only a rough indication of the magnitude of changes that may occur within the same individuals in different states. Indeed, there is evidence that some patients have higher intellectual functioning when hypomanic than when depressed (Donnelly et al., 1982). Furthermore, a variety of longitudinal studies have found the remitted state to be associated with higher IQ than the depressed state.⁵ While such findings have been interpreted as indicating a state-dependent deterioration in IQ (Miller, 1975), much of this work was subject to the same confound: repeat IQ testing generally results in a modest increase in scores attributable to practice effects (Matarazzo et al., 1980). Most studies tested patients in a depressed or manic state, with later retesting during euthymia. Such an invariant order would bias results toward higher scores in the euthymic or remitted state relative to depression or mania.

The firmest conclusion that can be drawn from this literature is that samples of bipolar patients, whether remitted or not, show modest global cognitive impairment as reflected by diminished IQ scores. This conclusion is strengthened by findings obtained using broad-based clinical neuropsychological batteries, such as the Halstead-Reitan or Luria-Nebraska. Summary impairment scores on these batteries correlate highly with IQ scores. Several studies have found gross impairment, on a level comparable to that in schizophrenia, in manic samples, and moderate-to-severe impairment in unipolar and/or bipolar depressed samples.⁶

Interpretation of a global intellectual deficit in bipolar disorder is highly contingent on beliefs about the level of premorbid functioning. For example, an IQ deficit in the remitted state may reflect an impairment that preceded the expression of bipolar disorder, or may represent a form of deterioration resulting from the disorder or its treatments. On the other hand, it has been suggested that bipolar patients

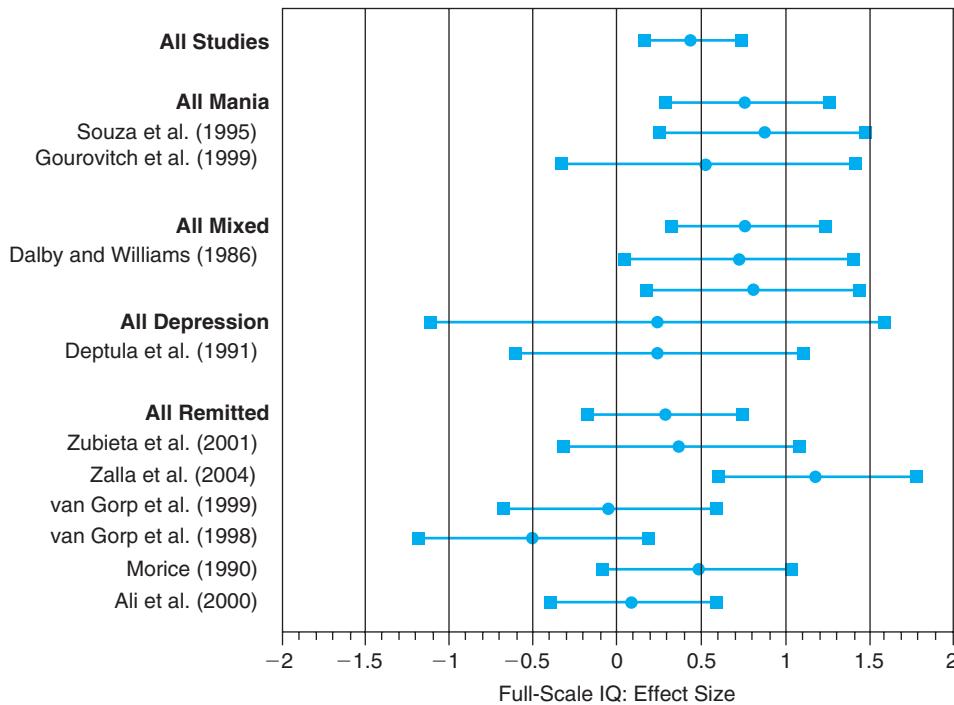

Figure 9-2. Meta-analysis of full-scale intelligence quotient (IQ) scores obtained with the Wechsler Adult Intelligence Scale-Revised (WAIS-R). Effect sizes (Hedges' G) are presented for individual study comparisons of a bipolar sample with healthy controls, as well as for samples of bipolar patients in remission, depression, mixed state, or mania and across all studies. Squares = confidence interval; circles = mean.

may be premorbidly advantaged; that is, their level of intelligence prior to disease expression tends to be above average. Were this the case, it would indicate that the deficits observed in comparisons with healthy volunteers underestimate the deterioration from premorbid values.

Unfortunately, while often discussed, this issue has received limited research attention. Mason (1956) contrasted the prerecruitment IQs of Army veterans hospitalized for schizophrenia and what was termed manic-depressive illness, which no doubt included some patients with recurrent unipolar depression. The schizophrenia sample had premorbid IQs below control values, whereas the IQs of mood disorder patients were significantly better than those of healthy subjects. Woodruff and colleagues (1968, 1971) found that bipolar patients and their brothers had higher levels of occupational and educational achievement than unipolar patients and their brothers, with the latter group not differing from healthy volunteers. Other work has similarly indicated that the families of individuals with bipolar disorder have an advantage relative to population norms for educational and occupational achievement (Petterson, 1977; Waters et al., 1981), as well as creativity (see Chapter 12). Indeed, limited research with children of bipolar probands before the first manifestation of frank mood disorder supports the possibility of an IQ elevation in the premorbid state (Decina et al., 1983).

This possibility of an elevation in premorbid intellectual abilities relative to population norms is reinforced by the literature on the relationship between social class and bipolar disorder. A number of studies, starting at the beginning of the twentieth century, have generally found that bipolar disorder is overrepresented in individuals with middle and high income levels and among business and other professionals. It is possible that these associations reflect an ascertainment bias. Individuals of a higher socioeconomic level may be especially likely to be diagnosed with a mood disorder instead of schizophrenia or schizoaffective disorder, with the reverse pertaining to those of lower socioeconomic levels. However, the fact that these associations are also observed among the family members of bipolar probands undercuts this hypothesis (Woodruff et al., 1971; Monnelly et al., 1974; Eisemann, 1986; Coryell et al., 1989).

Thus there is reason to suspect that as a group, individuals with bipolar disorder are endowed with general intellectual abilities superior to the distribution in the general population and may be more likely to have backgrounds of middle and upper socioeconomic levels. Yet it also appears that bipolar disorder is characterized by poorer general intelligence across all phases of illness. If both of these views are correct, it would suggest that the disorder is associated

with significant deterioration in general intellectual abilities or that there are compensatory cognitive advantages in a subgroup of individuals with bipolar illness (see Chapter 12). Studies contrasting patient samples with healthy volunteers likely underestimate the extent of deterioration because they do not account for the premorbid baseline.

Contexts in which a group differs in premorbid intellectual abilities present significant problems in interpreting comparisons with patients with other disorders or healthy volunteers. Neuropsychological tests differ in their sensitivity to the generalized effects of brain insult. For example, vocabulary and comprehension subtests of the WAIS-R are traditionally viewed as "hold" scales because of their relative immutability in providing an indication of premorbid ability in the face of brain damage. However, samples of patients with bipolar disorder have usually been matched to comparison groups on the basis of current demographic and neuropsychological features (e.g., age, sex, current IQ). This design may entail, therefore, that the two groups are mismatched with respect to premorbid levels. Thus patterns of apparently specific deficits seen in remitted or symptomatic states may be reflecting only the varying sensitivity of tests to a generalized destructive process.

Verbal and Performance IQ

The full-scale IQ score of the WAIS-R encompasses two composite scores: one for verbal IQ (VIQ) and one for performance (nonverbal) IQ (PIQ). It is well established that patients with mood disorders have a pattern of higher VIQ than PIQ. For example, a review by Kluger and Goldberg (1990) compared the VIQ–PIQ discrepancy in patients with bipolar disorder, right-hemisphere damage, left-hemisphere damage, and bilateral damage and healthy volunteers. Lower PIQ than VIQ was found in 19 of 22 studies of mood disorder patients (14 studies of bipolar and unipolar depressed patients, 4 of manic patients, and 4 of mixed groups), in 20 of 20 studies of patients with right-hemisphere lesions, and in 28 of 30 studies of patients with bilateral injuries. In contrast, PIQ exceeded VIQ in 15 of 20 studies of patients with left-hemisphere lesions. (See also our review of 25 studies in the first edition of this text.)

These effects were examined in the studies of bipolar samples included in our meta-analysis. Figure 9–3a presents the findings for VIQ and Figure 9–3b those for PIQ. Across studies and within studies grouped by state examined (mania, depression, mixed, remission), bipolar patients and normal controls evidenced no difference in VIQ. In contrast, across all studies ($z=3.36$, $p<.001$) and within studies grouped by state, bipolar samples showed a marked deficit in PIQ; the effect size (Hedges' G) across studies for PIQ was 0.71 (standard error [SE]=0.21), near the threshold for a strong effect. Specifically, the three studies of

bipolar patients in remission produced an effect size of 0.56 (SE=0.25).

The nature of the VIQ–PIQ discrepancy was closely examined in a study by Sackeim and colleagues (1992). They administered the full WAIS-R to 100 inpatients who were experiencing an episode of major depressive disorder and had been referred for electroconvulsive therapy (ECT), along with 50 matched healthy volunteers. In addition to age, gender, and race, the groups in this study were matched on indicators of premorbid function, specifically education and highest lifetime occupational level (sustained for 2 years). Based on an algorithm developed by Barona and colleagues (1984), estimates of premorbid full-scale IQ, VIQ, and PIQ were computed for all participants. A subset of patients was readministered the WAIS-R within 1 week ($n=26$) or 8 weeks after termination of ECT ($n=33$). Of the 100 patients, 25 were diagnosed with bipolar disorder, and 75 were unipolar. According to the Research Diagnostic Criteria (RDC) (Spitzer et al., 1978), 36 percent of the patient sample were psychotically depressed, 46 percent were of the retarded subtype, and all were of the endogenous subtype. Using a cap of 10, the bipolar patients averaged 5.3 (standard deviation [SD]=3.2) prior affective episodes and 3.1 (SD=2.7) prior hospitalizations. In contrast, the unipolar patients averaged 3.3 (SD=3.4) prior affective episodes and 1.8 (SD=2.6) prior psychiatric hospitalizations. Of the unipolar patients, 79 percent had recurrent illness.

Figure 9–4 presents the estimated premorbid IQ scores and IQ scores obtained with the WAIS-R for the total patient and healthy volunteer samples. The two groups did not differ in any of the three premorbid estimates. There was no consistent difference between estimated premorbid VIQ and PIQ in either group. In contrast, analyses of obtained IQ scores indicated that the patient group had significantly lower full-scale IQ. This result was attributable to low PIQ scores: the two groups did not differ in VIQ, but showed a marked difference in PIQ.⁷ While the VIQ scores of the healthy comparison group averaged 4.7 points higher than their PIQ scores, the comparable figure in the patient sample was 12.7 points. The obtained VIQ among patients was less than 4 points lower than the premorbid estimate, while the obtained PIQ was more than 15 points lower than the premorbid estimate.

These effects pertained to patients with both unipolar and bipolar depression. Figure 9–5 plots the cumulative distribution of VIQ–PIQ discrepancy scores for the healthy control and bipolar and unipolar subgroups. Throughout the range of discrepancy scores, the two patient groups were generally shifted to the right of healthy controls by approximately 10 points. The only indication of a difference between unipolar and bipolar patients was a higher

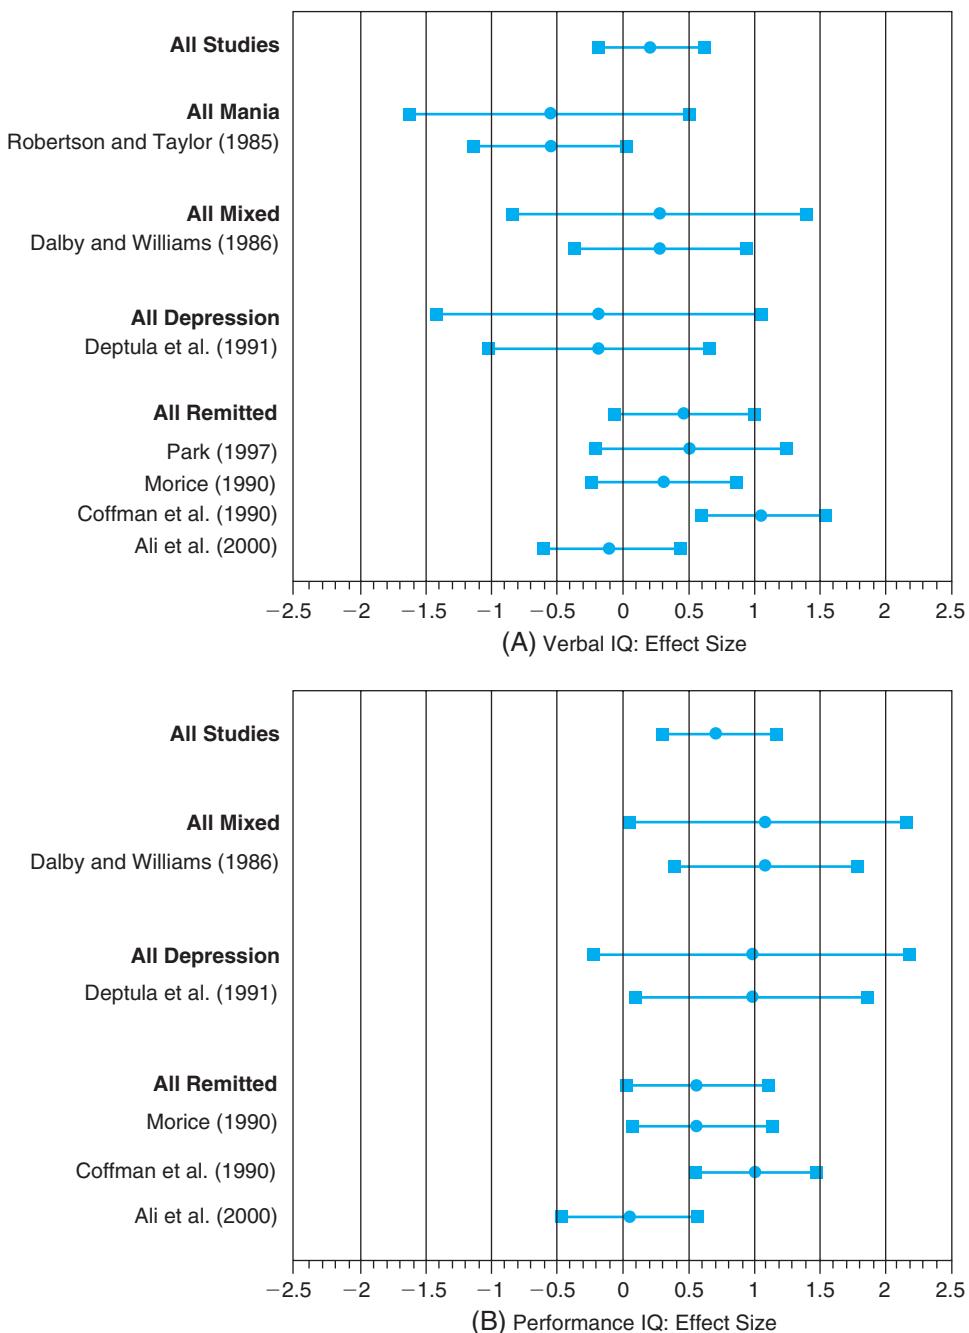

Figure 9-3. Meta-analysis of (a) verbal and (b) performance intelligence quotients (IQ). Effect sizes (Hedges' G) are presented for individual study comparisons of a bipolar sample with healthy controls, as well as for samples of bipolar patients in remission, depression, mixed state, or mania and across all studies. Squares=confidence interval; circles=mean.

frequency of marked discrepancies favoring VIQ in the bipolar group. However, the mean discrepancy in bipolar patients (14.52 ± 14.22) was not different from that in unipolar patients (12.04 ± 10.78).

Starting with Wechsler (1944), a common explanation for this discrepancy in mood disorder patients has concerned

the effects of psychomotor retardation on task performance. Four of the PIQ subtests (picture arrangement, picture completion, object assembly, and block design) are timed tests, while this is true of only one VIQ subtest (arithmetic). Therefore, slowed processing or motor execution could conceivably lead to diminished performance. This

issue was addressed in four ways. One approach involved testing the first 34 patients in the sample under conditions in which both timed and untimed performances were scored. In other words, the subtests were administered and scored in the usual manner, except that patients were allowed to complete each subtest after the standard time limit had expired. Scoring without time constraints had little impact on discrepancy scores, either before or after the course of ECT. The baseline discrepancy in the untimed condition averaged 11.35 ($SD=11.06$). Patients who met the RDC for retarded subtype ($n=46$) did not differ from the other patients ($n=54$) on this discrepancy score (retarded, 12.78 ± 12.03 ; nonretarded, 12.56 ± 11.54).

Another approach taken to this issue was to examine more broadly the relationships of symptom severity and other clinical features to the VIQ–PIQ discrepancy. A regression analysis was conducted on baseline discrepancy scores, with age, Hamilton Rating Scale for Depression (HAM-D) score (depression severity), duration of current depressive episode (chronicity), duration since onset of first affective episode, and number of previous affective episodes (recurrence) as predictors. Only baseline HAM-D scores showed a relationship. Greater symptom severity at baseline was associated with a smaller VIQ–PIQ discrepancy and lower VIQ scores. There were no other effects. Thus factors that varied with depression severity did

not appear to be responsible for the VIQ–PIQ difference, and marked severity tended to diminish the discrepancy. There was no evidence of an association with chronicity or frequency of recurrence.

Compatible with these findings were those of analyses conducted after readministration of the WAIS-R 1 and 8 weeks after completion of ECT. The 1-week group ($n = 26$) showed a slight decrease in the discrepancy at retesting, with average scores decreasing from 12.12 ± 11.16 to 9.64 ± 13.22 . Virtually no change was seen at the 8-week follow-up ($n=33$), with the average discrepancy decreasing from 13.48 ± 13.01 to 12.24 ± 12.86 . Restricting the follow-up sample to patients in remission had no impact.

These findings suggest that the VIQ–PIQ discrepancy was manifested independently of affective state and characterized patients in remission. Indeed, it is possible that the discrepancy is expressed before the first episode of mood disturbance. This possibility is supported by the results of studies of children of bipolar probands aged 7 to 14 (Decina et al., 1983; Sackeim and Decina, 1983). None of the children had yet expressed bipolar disorder, and relatively few had other diagnosable mood disorders, although behavioral disturbance was common. Nonetheless, a marked VIQ–PIQ discrepancy was observed on the Wechsler Intelligence Scale for Children-Revised (WISC-R) in the high-risk sample relative to healthy comparison volunteers. Similar

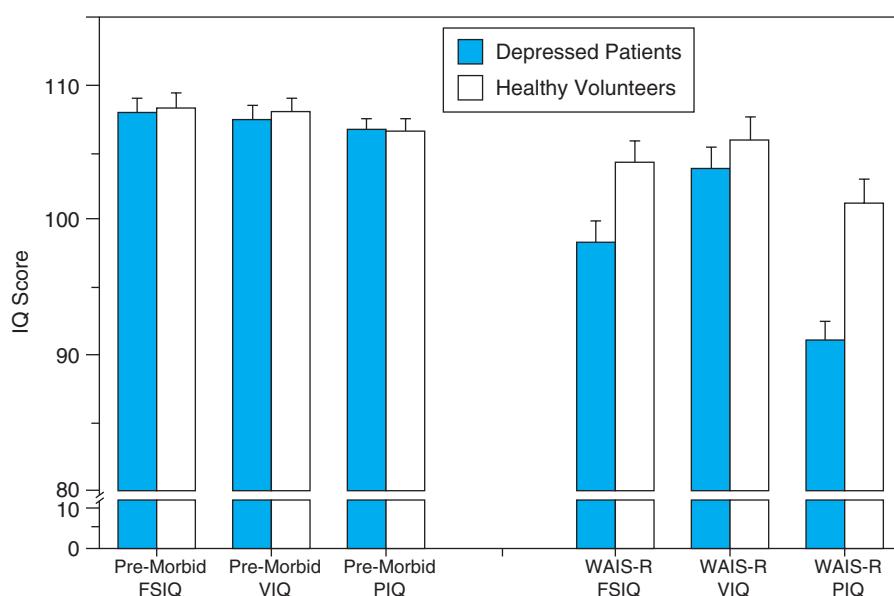

Figure 9-4. Premorbid intelligence quotient (IQ) estimates and IQ scores obtained with the Wechsler Adult Intelligence Scale-Revised (WAIS-R) in unmedicated patients with major depression and healthy controls. Premorbid estimates were identical in the patient ($n=100$) and control ($n=50$) groups. The patient group showed a marked discrepancy between verbal and performance IQ (VIQ > PIQ). FSIQ = full-scale IQ; PIQ = performance IQ; VIQ = verbal IQ.
(Source: Sackeim et al., 1992. Reproduced with permission of Psychology Press.)

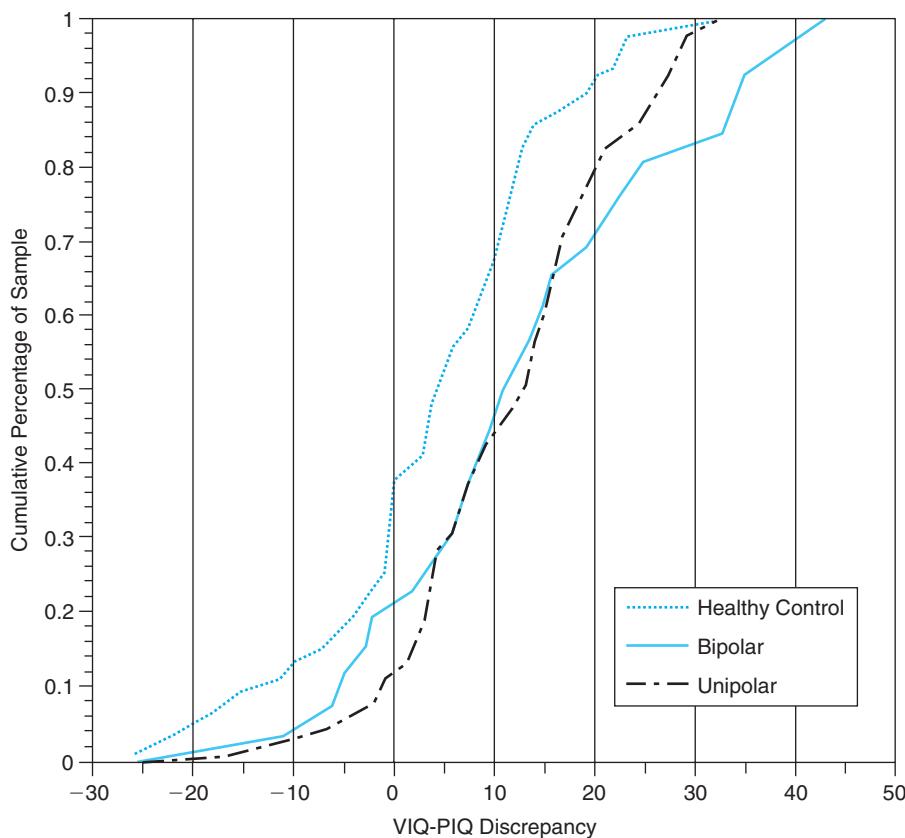

Figure 9-5. Cumulative distribution of verbal and performance IQ discrepancy scores for healthy controls and bipolar and unipolar depressed patients. Both patient groups are shifted to the right of healthy controls and have an average discrepancy favoring a verbal IQ approximately 10 points higher across the distribution in controls. (Source: Sackeim et al., 1992. Reproduced with permission of Psychology Press.)

results had been reported in an earlier, uncontrolled study of children at high risk (Kestenbaum, 1979).

Thus the notion that bipolar disorder is associated with a global intellectual impairment that is state independent should be revised. The reductions in full-scale IQ seen in mood disorders appear to be largely attributable to a decrement in PIQ, with preservation of VIQ. This differential deficit is relatively constant across states of euthymia, depression, and mania and may precede syndromal expression.

In interpreting this effect, it is important to consider whether the discrepancy arises from one or two subtests on the WAIS-R or WISC-R or reflects a more uniform difference in verbal and nonverbal task performance. In the study by Sackeim and colleagues (1992), a descriptive (canonical) discriminant analysis was conducted with diagnostic group (patient versus healthy volunteer) as the classification variable and scaled scores on the 11 subtests as the dependent measure. This analysis produced a single significant discriminant function, providing a description of the profile of subtests that distinguishes maximally

between the groups. Structure coefficients were determined for this linear function. These coefficients are more stable than the original weighting of subtests in the discriminant function (Huberty, 1984), and reflect the association between scores on a subtest and total scores on the composite discriminant function. The median structure coefficient for the five PIQ subtests was 0.53, with a range of 0.43 to 0.70. In contrast, the median structure coefficient for the six VIQ subtests was 0.13, with a range of 0.03 to 0.38. All five PIQ subtests made strong contributions to the differentiation between patients and controls. The comprehension (0.29) and digit span (0.38) VIQ subtests also contributed, but more weakly. Therefore, the results of this analysis suggest that the PIQ deficit in mood disorders is not specific to a particular PIQ subtest, but is expressed uniformly across all five PIQ subtests.

Thus the relative deficit in PIQ is uniform across the various subtests assessing this form of intelligence. The magnitude of this discrepancy appears to be independent of the phase of affective disorder, and may be a marker of a bipolar diathesis. Early work on children at risk indicated

that children with behavioral disturbances suggestive of early signs of bipolar disorder, such as grandiosity, conduct disorder, or separation anxiety, are especially likely to manifest the discrepancy (Decina et al., 1983; Sackeim et al., 1983a). While many researchers attributed this phenomenon to a differential impact of psychomotor slowing on PIQ, this hypothesis can now be rejected given the discrepancy's persistence in remission, manifestation in at-risk samples, and persistence even when performance is not constrained by timing.

In this light, two hypotheses have been advanced. One posits that the PIQ deficit reflects a fundamental disturbance in visuospatial processing and implies a differential right hemisphere deficit (Flor-Henry, 1979). The second hypothesis is that the discrepancy has little localizing value and reflects the greater sensitivity of PIQ and other forms of "fluid" intelligence to generalized impairment, in contrast to the "crystallized" intelligence reflected in VIQ subscales (Kluger and Goldberg, 1990; Bearden et al., 2001).

Were the discrepancy to reflect a fundamental deficit in visuospatial processing, it could be compatible with a right-hemisphere insult, especially in parietal cortex. This classic formulation is compatible with evidence that manifestation of mania without a history of major depression (i.e., unipolar mania) is seen principally in the context of brain insult and most commonly with right-hemisphere damage, generally involving parietal tissue. Thus, bipolar illness would be viewed as especially likely to manifest a form of right-hemisphere dysfunction. However, the evidence in mood disorders clearly reveals that the discrepancy is also manifested in unipolar depression, at least in samples with severe and/or recurrent disorder. Thus if this discrepancy indeed reflects a lateralized insult, it must be viewed as characteristic of recurrent mood disorders—that is, manic-depressive illness in Kraepelin's terminology.

The second hypothesis is that the discrepancy per se has limited lateralizing value. It is seen with both bilateral and right-hemisphere brain damage. The effect size seen in mood disorder samples is comparable to that seen in patients with bilateral brain damage, itself a notable fact, and below that seen in patients with right-hemisphere lesions (Kluger and Goldberg, 1990). There is no reason to suspect, for example, that the pathophysiological process resulting in right-hemisphere dysfunction in mood disorders would produce the same level of differential deficit as that seen in patients with gross brain lesions.

A broader perspective on the neuropsychological profiles of mood disorder patients may help resolve this issue. The laterality hypothesis would stipulate that mood disorder samples show especially marked deficits in tests that rely heavily on visuospatial processing. The view that the discrepancy arises from generalized brain impairment would

suggest that the deficit in PIQ is of the same magnitude as deficits across a host of cognitive functions, including attention and memory.

Indeed, our examination of the profile of cognitive deficits in bipolar disorder raises a third, novel hypothesis. There is indeed evidence of widespread and generally uniform cognitive deficit across the phases of bipolar disorder, with little indication that visuospatial abilities are especially impaired. Rather, verbal skills appear to be consistently preserved. The implication is that the cognitive systems subserving language are spared with respect to an otherwise generalized disease process, are constitutionally endowed at higher capacity, or are complemented by compensatory cognitive advantages of an as-yet undetermined nature.

Psychomotor Functioning

The domain of psychomotor functioning reflects the integrity of processes determining the speed of information processing and the speed and organization of motor behavior. Individuals may appear to be "slowed" because of dysfunction in motor output and/or in the speed of thought. Alternatively, individuals may appear to be "dull" or "slow" because of poverty of mental content, in essence a lack of thought. This domain pertains to functions as diverse as manual dexterity, reaction time, and levels of spontaneous activity. As reviewed by Sabin and Sackeim (1997), a variety of experimental techniques have been developed to assess the component processes that may underlie psychomotor disturbance in mood disorders.

Disturbances of motility and speed of processing have long been considered central to the phenomenology of mood disorders. Psychomotor disturbance has generally been regarded as a cardinal feature of endogenous or melancholic depression, and some have contended that careful assessment of psychomotor disturbances has predictive value with respect to treatment outcome. The racing thoughts of the manic state suggest dysregulation in speed of processing that is opposite to that often seen in the depressed state. Thus psychomotor function, like mood and sleep, may be one of the few domains to show opposite symptom manifestations depending on phase of illness.

Some theorists have taken this overlap between the mood and motor output systems to suggest that mood disorders are essentially disorders of motility (Flor-Henry, 1983). While this is clearly an overstatement, it is noteworthy that mood disturbance occurs at especially high rates in patients with movement disorder. This observation is especially well documented for Parkinson's and Huntington's diseases. As indicated earlier, Huntington's disease is of special note as perhaps the only neurological illness to produce both depression and mania at some frequency. In contrast, imaging research has yet to relate psychomotor disturbance in mood

disorders to basal ganglia dysfunction. Instead, the Hammersmith group found that psychomotor symptoms covary with the magnitude of regional cerebral blood flow deficits in prefrontal regions (Dolan et al., 1993). Indeed, they suggested that the prefrontal deficits commonly seen in both major depression and schizophrenia reflect a common psychomotor disturbance. Presumably, this disturbance pertains to executive functions that regulate the flow and speed of information processing.

Cognitive and Motor Speed

In a substantial literature over the last five decades, slowed reaction time has been documented in mood disorder patients during episodes of major depression relative to healthy participants (Marvel and Paradiso, 2004). The subgroups most likely to manifest this slowing were variously described in this work as manic-depressive, bipolar, psychotic, or presenting with endogenous depression compared with subgroups classified as neurotic, nonpsychotic, or reactive. Thus, there was a general impression that severity of illness was associated with psychomotor slowing. Frequently in this work, depressed samples had slower performance relative to healthy participants, nondepressed neurotic patients, and patients with acute schizophrenia. Nonetheless, the depressed samples were often less slowed than patients with chronic schizophrenia or brain damage. The investigators also found that clinical improvement was usually linked to improved speed of responding, suggesting that psychomotor slowing is largely a state-dependent phenomenon. In much of this work, time to complete tasks, such as the digit symbol subtest of the WAIS-R, was used to assess psychomotor slowing. Consequently, disturbances in cognitive processes and motor execution were confounded, and the source of the slowing was not identified.

While this issue is the subject of increasing attention (Sobin and Sackeim, 1997), it remains unresolved and may not have a simple answer. Cornell and colleagues (1984) varied cognitive load in a series of reaction-time measures when comparing patients who met diagnostic criteria for melancholia with nonmelancholic, nonendogenous depressed patients. They found that both groups manifested slow motor performance, and that this was a key abnormality independent of melancholia. In contrast, the melancholic subgroup was especially sensitive to the effects of cognitive load in further slowing motor response. This result was interpreted as reflecting an impairment in cognitive processing—a cognitive slowing—in melancholic patients.

Other dimensions to consider in studies of psychomotor speed concern the effects of distraction and the distinction between preferred rates of response and response speed when one is working at one's best. In a comprehensive study, Blackburn (1975) contrasted six groups of patients:

acutely symptomatic bipolar manic, bipolar depressed, and unipolar depressed and the same three groups at rest. Blackburn used separate tasks thought to measure principally mental and motor speed, although the motor task had more than nontrivial cognitive components. The mental task was administered with patients working both at their own speed (preferred speed) and as quickly as possible. The motor task was administered under conditions of no distraction, internal distraction (the patient counting), and external distraction (a news program played loudly during task performance). Acutely ill bipolar depressed patients were slower than all other groups on the motor task with no distraction. Surprisingly, both internal and external distraction resulted in improved performance among the bipolar depressed group but in deterioration among the unipolar patients, while results with the manic patients were equivocal. In contrast, on the mental speed test at the preferred rate of responding, the acutely ill manic patients were faster than the other two groups, but did not differ from the manic patients in remission. With instructions to respond as quickly as possible, the six groups had comparable scores.

The results of this study illustrate two points. First, most neuropsychological evaluations call for patients to perform at their best, which may obscure deficits in routine information processing. Second, this study provided evidence that bipolar depressed patients are especially likely to manifest marked psychomotor slowing. It has long been contended that psychomotor retardation is characteristic more of bipolar than of unipolar depression (Kotin and Goodwin, 1972; Dunner et al., 1976). We revisit this issue in reviewing the literature on spontaneous activity (see the later discussion).

Recent studies using reaction time measures have demonstrated that psychomotor disturbance is characteristic of elderly patients with bipolar disorder. Pier and colleagues (2004) manipulated task difficulty and contrasted speed of figure copying in 12 elderly depressed patients and matched healthy controls in an attempt to isolate cognitive from motor slowing. Pronounced psychomotor retardation was seen in the patient group, which reflected a cognitive and more pronounced motor slowing. However, patients were studied while medicated, and medication effects on psychomotor speed are commonly observed (Caliguri et al., 2003).

Surprisingly, three recent studies of psychomotor speed in bipolar adolescents failed to find differences from controls or other clinical groups (DelBello et al., 2004; Dickstein et al., 2004; McCarthy et al., 2004). Furthermore, there is only equivocal evidence for psychomotor disturbance in the first-degree relatives of bipolar probands. Zalla and colleagues (2004) compared euthymic bipolar patients, patients

with schizophrenia, the unaffected first-degree relatives of both patient groups, and healthy controls in performance on tests of verbal fluency—the Stroop Word Color Interference Test, the Wisconsin Card Sorting Test, and the Trail Making Test. Compared with healthy controls, patients with schizophrenia performed poorly on all measures. The only abnormality seen in the euthymic bipolar group and the two groups of unaffected relatives reflected increased slowness on the Stroop test. This deficit could have been attributable to an increased susceptibility to interference and/or psychomotor slowing in the context of increased cognitive demand. In contrast, Ferrier and colleagues (2004) found no evidence of psychomotor disturbance when contrasting the neuropsychological performance of 17 unaffected first-degree relatives of bipolar patients with that of matched controls. Instead, the relatives were significantly impaired in backward digit span, spatial span, and tasks of visuospatial declarative memory, while verbal declarative memory was intact.

It is premature to conclude that psychomotor disturbance is infrequent in children and adolescents manifesting bipolar disorder or in first-degree family members. These issues have been studied infrequently, and the extant research used relatively small samples, a key limitation in studies of familial transmission given heterogeneity in genetic diathesis. Furthermore, while there is substantial evidence that reaction time improves with clinical remission in mood disorders, as reviewed in the next section, there is also substantial evidence for persistent psychomotor disturbance in remitted bipolar patients on tasks that make significant motor demands in terms of both dexterity and speed (e.g., Purdue Pegboard). Little information exists on potential impairments in pediatric bipolar patients or first-degree relatives in the aspects of psychomotor dysfunction most persistent in adult patients with bipolar disorder.

There has been limited investigation of the neurobiological correlates of impairments in cognitive and motor speed in bipolar disorder. Caligiuri and colleagues (2003) conducted functional magnetic resonance imaging (fMRI) while patients in the manic or depressed phase of bipolar illness and healthy controls performed a manual reaction-time task. The study results implicated both basal ganglia disturbance and a dimension of laterality. Manic patients had higher blood oxygen level-dependent (BOLD) responses in the left globus pallidus and significantly lower activity in the right globus pallidus, while depressed patients showed the reverse pattern of asymmetry. Level of activity within the globus pallidus and caudate was associated with the severity of manic symptoms. Notably, patients not receiving antipsychotic or mood-stabilizing medications had higher BOLD responses throughout the motor

cortex, basal ganglia, and thalamus. These findings suggest that the depressed and manic states are related to excessive and lateralized activity within the basal ganglia, and that antipsychotics and mood stabilizers suppress cortical and subcortical hyperreactivity.

The results of subsequent research focused on the supplementary (SMA) and primary (M1) motor areas underscore the possibility of a disturbance in lateralized control over motor processes. Using fMRI and several reaction time tasks, Caligiuri and colleagues (2004) showed that healthy controls differentially activated the left and right SMA on right- and left-hand trials, respectively. In contrast, in the small samples of bipolar manic and depressed patients, the latter failed to suppress the ipsilateral right SMA in right-hand trials, while the former had bilateral SMA activation for both left- and right-hand trials. Both depressed and manic patients had greater activity in the left M1, and antipsychotic or mood-stabilizing medications were associated with increased reaction time, lower BOLD response in M1 and SMA, and a loss of normal hemispheric asymmetry. In addition to again raising the issue of a lateralized disturbance, the results of this work suggest that the psychomotor disturbance in bipolar disorder may be an outcome of excessive excitability in mediating brain regions. This formulation contrasts with the hypothesis, derived from resting positron emission tomography (PET) studies (Bench et al., 1992; Dolan et al., 1994), that psychomotor retardation reflects reduced activity in specific prefrontal cortical structures.

Recent work has also clarified the extent to which psychomotor disturbance in bipolar disorder reflects cognitive dysfunction that may interfere with the planning or initiation of movement and/or disturbance in the execution of movement. Caligiuri and Ellwanger (2000) administered a traditional psychomotor battery, as well as a measure of the integrity of motor programming, to 36 patients who met *Diagnostic and Statistical Manual (DSM)-IV* criteria for psychomotor retardation. The programming task assessed capacity to adjust velocity scaling of movement relative to movement distance. Compared with healthy controls, the patient group evidenced longer reaction time and impairment in velocity scaling. A significant subgroup had deficits that were akin to those observed with the bradykinesia associated with parkinsonian conditions. Thus the retardation was viewed as encompassing both the planning and the execution of movement. An earlier detailed review of this literature likewise suggested that psychomotor disturbance usually involves a mix of cognitive and motor deficits (Sobin and Sackeim, 1997).

Finally, limited attention has been given to the neurochemical imbalances that may result in disturbances in cognitive and motor speed. Swann and colleagues (1999)

compared unipolar and bipolar depressed patients and manic and mixed-state patients with healthy controls in tests of psychomotor speed and accuracy of tracking. The depressed groups were impaired on all behavioral measures, whereas the manic and mixed patients did not differ from the controls. Cerebral spinal fluid (CSF) and urinary measures of catecholamines and their metabolites were obtained. For virtually all behavioral measures, increased catecholamine function was associated with poorer performance in bipolar but not unipolar patients. Further, psychomotor function was related to depression severity in bipolar but not unipolar depression. The results of this preliminary study raise the possibility that psychomotor retardation in bipolar disorder is accompanied by, if not an outcome of, catecholamine overdrive. This view may be congruent with imaging findings that suggest excessive excitability or failure of inhibition in the motor control systems of bipolar patients. Indeed, at a speculative level, it has long been thought that catatonia, which may be viewed as an extreme form of psychomotor retardation, reflects an internal state of excessive arousal, rapidly reversed by interventions with sedative or barbiturate properties (amobarbital, lorazepam, ECT).

Motor Skills

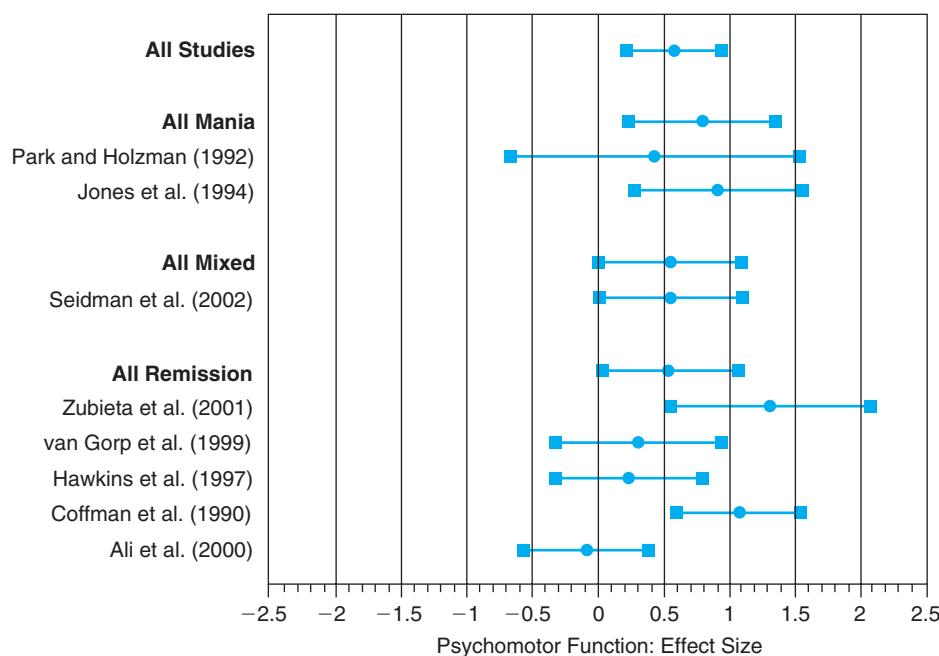

Traditional neuropsychological evaluations have placed little emphasis on assessment of reaction time per se. This

situation is changing rapidly with the increasing use of computerized neuropsychological batteries, which allow more readily for trial-by-trial computation of reaction time. Instead, psychomotor function has typically been assessed with a range of performance measures that are sensitive to the dexterity or accuracy of motor execution, as well as speed. In the studies contributing to our meta-analysis, the psychomotor tasks employed included the Purdue Pegboard, Pursuit Rotor, mirror writing, and motor sequencing tasks, among others. Given this diversity of tasks, a deficit in psychomotor function may reflect some fundamental or general impairment in motor execution or output.

Figure 9–6 presents the findings on psychomotor function from our meta-analysis. It is evident that despite the diversity of tasks, there was a consistent effect across all studies, with bipolar samples showing impaired performance relative to healthy participants (overall effect size = 0.55, SE = 0.18, $z = 3.12$, $p = .002$). This effect is significant when the analysis is restricted to studies of patients in remission; the magnitude of the deficit in psychomotor function is near that for PIQ.

The source of the motor abnormalities seen in mood disorders is still unknown. In fact, relatively little work has been done to better characterize the phenomenology of this motor disturbance. Exquisite methodologies have been

Figure 9–6. Meta-analysis of psychomotor measures. Effect sizes (Hedges' G) are presented for individual study comparisons of a bipolar sample with healthy controls, as well as for samples of bipolar patients in remission, depression, mixed state, or mania and across all studies. Squares = confidence interval; circles = mean.

developed to assay components of motor control, but they have rarely been applied to mood disorder samples.

There are suggestions of a lateralized component to the motor disturbances seen in mood disorders. Indeed, there have been isolated reports of individuals whose handedness covaried with the phase of bipolar illness (depression, euthymia, mania). However, the relationship between handedness and bipolar illness is far from clear. Various researchers have reported that the frequency of left-handedness in mood disorders is increased (Fleminger et al., 1977), decreased (Merrin, 1984; Yan et al., 1985), or unchanged (Merrin, 1984; Yan et al., 1985). Sackeim and Decina (1983) took a different approach to this issue. They examined the possibility that handedness moderates genetic factors in the transmission of bipolar disorder. They found that the handedness of bipolar patients was associated with family history of affective disorder and not with family history of sinistrality. Among the bipolar-I subgroup, for example, 49 percent of strongly right-handed patients had a positive family history of affective disorder, compared with 89 percent of weakly right-handed and left-handed patients.

The possibility of a lateralized dimension to the motor disturbance of bipolar disorder is supported by the results of studies examining grip strength. Flor-Henry and Yeudall (1979) found that patients in either the manic or depressive phase of mood disturbance showed greater right-hand than left-hand grip strength, implicating right hemisphere dysfunction. They also found that speed of finger tapping was reduced primarily in the left hand. Merrin (1984) obtained similar results with respect to grip strength, and the asymmetry distinguished mood disorder patients from both patients with schizophrenia and normal controls. Merrin observed that patients with bipolar disorder and psychotic features were most likely to show the asymmetry. More recently, it was found that instability in maintaining stable force with the index finger placed on a strain gauge was greater for the left than the right hand in patients with bipolar disorder, whereas the opposite was true in patients with schizophrenia (Lohr and Caligiuri, 1995, 1997). These scattered results, along with the imaging findings in bipolar patients showing lateralized disturbances in activation patterns during motor tasks (Caligiuri et al., 2003, 2004), point to the need for systematic study of motor asymmetry.

Spontaneous Activity

Routine clinical evaluations of psychomotor disturbance and those conducted using formal rating instruments typically address a different level of behavior from that assessed with neuropsychological or information processing measures. For example, the CORE is a well-studied instrument that quantifies the extent of psychomotor disturbance. Box 9-1 lists the 18 behavioral manifestations assessed by

BOX 9-1. Items in the CORE Measure of Psychomotor Disturbance

- Facial immobility (average across the interview)
- Postural slumping (average across the interview)
- Noninteractiveness (ability to respond to the social cues in the interview)
- Nonreactivity (rate any episode, not duration through the interview)
- Facial apprehension (rate any episode or fixed expression)
- Delay in responding verbally (average across the interview)
- Length of verbal responses
- Inattentiveness
- Facial agitation (movement; rate any episode—intensity rather than duration)
- Body immobility (amount, not speed; average across the interview)
- Motor agitation (rate any episode; intensity rather than persistence)
- Poverty of associations (ability to elaborate)
- Slowed movement (speed, not amount; average across the interview)
- Verbal stereotypy (rate any episode)
- Delay in motor activity (average across the interview)
- Impaired spontaneity of talk (ability to initiate conversation)
- Slowing of speech rate (average across the interview)
- Stereotyped movements (rate any episode)

the CORE. These aspects of psychomotor function are considerably more diverse than those assessed with the more atomistic approach of neuropsychological measurement. Further, these abnormalities are assessed in the normal course of interaction and not in relation to specific test demands. Of course, this sign- or symptom-based approach to assessment assumes a conceptualization of the boundaries and constituents of psychomotor disturbance. There would likely be strong consensus that some of the signs or symptoms in Box 9-1, such as facial immobility, delay in responding verbally, and slowed movement, reflect aspects of the construct. On the other hand, there could be considerable debate about the inclusion of other signs or symptoms, such as nonreactivity (lack of interest or pleasure), inattentiveness, and verbal stereotypy, in assessing the severity of psychomotor disturbance.

Parker and colleagues (1993, 1995a, 2000) contended that the assessment of signs and symptoms of psychomotor disturbance is of special importance in mood disorders. Specifically, they argued that such disturbance accounts for the lion's share of the variance in the diagnosis of melancholia. Melancholic and nonmelancholic depressed patients differ markedly in CORE scores, with the endogeneity of

symptoms accounting for a smaller portion of the variance.⁸ Parker and colleagues claimed that the fundamental symptomological characteristic of the melancholic patient is psychomotor disturbance. They also found that the severity of psychomotor disturbance has predictive value with regard to treatment outcome with ECT and medications (Hickie et al., 1990b, 1996; Parker and Hadzi-Pavlovic, 1993), and that the psychomotor disturbance in melancholic unipolar patients shares features with the bradykinesia of Parkinson's disease in demonstrating difficulties with the initiation of movement in the absence of external cues (Austin et al., 2000; Rogers et al., 2000). The theoretical importance of some of these findings is challenged by the notion that the broad definition of psychomotor disturbance incorporates assessment of cardinal features of melancholia (such as lack of mood reactivity) that may not reflect psychomotor abnormalities. Thus the associations between the CORE and melancholic diagnosis may be partly tautological, and the linkage to treatment outcome could conceivably be associated with items influenced by melancholic manifestations that do not reflect psychomotor disturbance (e.g., inattentiveness).

A recent study contrasted the CORE ratings of bipolar and unipolar depressed patients. Parker and colleagues (2000) compared 904 unipolar and 83 bipolar patients using three methods for subtyping melancholia (DSM, clinical classification, and CORE). With all three methods, bipolar patients were considerably more likely to be diagnosed with melancholia and psychotic depression. Prevalence of psychomotor disturbance and pathological guilt were the signs or symptoms that distinguished the groups.

While it can be argued that studies of reaction time and other aspects of information processing may provide too narrow a view of psychomotor disturbance, it is also true that the use of rating scales such as the CORE is limited in that ratings may be contaminated by patient behavior reflective of domains other than psychomotor disturbance. Patient reports of lack of interest, loss of pleasure, or marked psychic anxiety may affect ratings of psychomotor disturbance. An alternative approach is to examine objective measures that reflect broader aspects of psychomotor function. Two such measures examine spontaneous activity and speech rate.

Various devices are available for continuous recording of the amount of motor activity. For example, activity monitors, worn like a wrist watch, can provide 24-hour data on fluctuation in movements of the wrist or arm. The potential utility of this approach is illustrated by findings in movement disorders. Although Huntington's disease is characterized by chorea, patients with this disorder have shown less daytime spontaneous movement than healthy controls. Further, this hypokinesia correlates cross-sectionally with

impairment in voluntary movement, with disturbed posture and gait, and most robustly with reduced functional capacity (van Vugt et al., 2001). Over a 2-year follow-up period, van Vugt and colleagues (2001) also found that spontaneous activity remained unchanged in clinically stable patients, but worsened in those who deteriorated in functional capacity. Thus in this context, hypokinesia, as assessed by activity monitoring, showed a strong relationship with functional impairment.

A set of small-group comparisons reported by Kupfer and colleagues led to a number of explicit hypotheses about the patterns of gross motor activity in depression and mania.⁹ These investigators suggested that (1) manic patients have higher activity levels than severely agitated depressed patients; (2) unipolar depressed patients have higher activity levels than bipolar depressed patients; (3) clinical remission in depression is accompanied by an increase in activity levels; and (4) manic patients manifest their highest activity levels in the late evening and early nighttime, whereas hypomanic patients peak during the daytime (see Chapter 2 for a discussion of the overlap between agitated depressive and mixed hypomanic states). These observations were based on small subgroups; lacked comparison with a normal control group; and were derived from work on a specialized inpatient unit at the National Institutes of Health (NIH), where hospital routine and regimentation may have affected activity levels. While there has been surprisingly limited further research in this area since the mid-1970s, the additional studies that have been done have substantially clarified the nature of the deficit in spontaneous activity during episodes of major depression.

In a study by Wolff and colleagues (1985), a group of 18 normal controls was housed on the same ward and shared in the same activities as a group of 30 euthymic patients (25 bipolar, 5 unipolar). In addition, 27 patients were studied through at least two phases of illness (depression, euthymia, or mania); the depressed state was consistently associated with lower 24-hour levels of activity than euthymia. This difference was significant for the within-subject comparison during daytime but not nighttime periods. Mania was associated with higher activity levels than depression, with the difference seen mainly in the late evening and nighttime hours (7:00 PM to 4:00 AM). Although mania tended to be associated with higher levels than euthymia, none of these comparisons were significant; however, the sample size for comparisons with euthymia was substantially smaller for mania ($n=11$) than for depression ($n=23$). Of special note is that, in comparison with controls, euthymic patients still manifested lower 24-hour activity levels, attributable mainly to the daytime period (2:00 PM to 12:00 AM).

Royant-Parola and colleagues (1986) followed a group of 12 patients with major depression, monitoring their activity

throughout a hospital stay. In addition to the amount of activity, they assessed duration of immobility. Activity troughs and immobility peaks were bunched before noon and around 3:00 PM. With remission, activity levels increased, and immobility decreased. The authors suggested that immobility is a particularly sensitive measure, especially for patients with agitated depression, and that daytime manifestation may reflect release of an ultradian sleep–wake rhythm in major depression (see Chapter 16).

A reduction in daytime spontaneous activity does not appear to be an artifact of concomitant medications. Volkers and colleagues (2003) compared 67 unmedicated unipolar depressed patients with 64 matched healthy controls. Relative to the control sample, the patient group showed lower activity levels in daytime and higher activity levels and reduced immobility during sleep. It is not known whether this shift toward increased activity levels at night in depressed and manic samples contributes to or is an outcome of disrupted sleep, or both phenomena reflect the same underlying disturbance in rhythmicity.

As noted, these studies of spontaneous activity in mood disorders were conducted in inpatient samples, often with highly treatment-resistant patients. The generalizability of their findings to broader clinical populations was recently tested. Iverson (2004) conducted activity monitoring among 48 depressed patients being seen in primary care and 25 controls with general medical conditions. The depressed group was divided by a median split in scores on the Beck Depression Inventory (BDI) II (Beck et al., 1996). Patients with higher BDI scores had lower activity levels than the other depressed patients and the control group; this effect was most marked during 12:00 PM to 6:00 PM, in line with previous findings in the depressed state. However, the possibility of distinct subgroups was raised in a pilot study of geriatric patients with unipolar major depression. Teicher and colleagues (1988) compared eight geriatric depressed inpatients with eight elderly controls studied in similar settings and found that the depressed group had 29 percent higher mean total 24-hour activity levels, with no difference in circadian amplitude or frequency. Daily peak activity averaged slightly more than 2 hours later in the depressed sample, and the degree of this delay correlated with serum cortisol levels at 4:00 PM after earlier administration of dexamethasone. The heightened activity levels in this small geriatric sample contrast with the findings in unipolar and bipolar adult samples.

Overall, the findings in this area are consistent in indicating that episodes of major depression, whether bipolar or unipolar, are associated with reduced 24-hour activity, especially during daytime hours, and perhaps most markedly during the period 12:00 PM to 6:00 PM. There are suggestions in the study findings that bipolar depressed patients

manifest greater reductions in spontaneous activity than do unipolar patients, but work in this area with bipolar disorder has been limited in recent years. The evidence is robust and consistent that spontaneous activity levels improve with remission from the depressed state, although it is possible that this improvement fails to reach the levels of healthy controls. It is unknown whether the putative residual deficit is associated with the severity of residual depressive symptoms or is independent. The limited evidence indicates that mania is associated with increased activity levels relative to those of depressed patients, especially during the nighttime. However, it is not clear that the increase associated with mania exceeds the values obtained in healthy controls.

Clinical observation of psychomotor disturbance led to the original hypothesis that psychomotor retardation is more common and/or more severe in bipolar than unipolar patients (Kotin and Goodwin, 1972; Dunner et al., 1976). However, the need to ground such observations in objective measures is reflected in conflicting results obtained with the CORE. Mitchell and colleagues (1992) compared 27 age- and sex-matched pairs of unipolar and bipolar patients who met criteria for melancholia based on several diagnostic schemes. Bipolar patients were less likely to have slowed movement. In general, items reflecting psychomotor retardation were less common and agitation was more common in the bipolar cohort. In contrast, almost a decade later, Mitchell and colleagues (2001) compared the clinical features of 39 pairs of bipolar and unipolar patients using a similar methodology. The bipolar patients were more likely than the unipolar patients to manifest psychomotor-related melancholic features and symptoms of atypical depression. The authors suggested that psychomotor retardation, atypical features, and, less commonly, psychosis constitute the clinical signature of bipolar depression.

Speech Rate

Speech is a motor act. Clinically, it is common to observe severely depressed patients speaking in a halting, slow manner with frequent pauses, and often with a weak or raspy voice. It is also clear that manic patients often have racing speech along with racing ideas. Thus it is an empirical matter whether objective analysis of speech and voice characteristics will reveal abnormalities associated with mood disorders and/or provide information of prognostic significance.

The small literature in this area has presented consistent findings. The most common paradigm has been to examine automatic speech, as in counting from 1 to 10, where cognitive load is minimal,¹⁰ although there have also been studies that involved taking samples of natural speech, as might occur during a diagnostic interview (Bouhuys and Mulder-Hajonides van der Meulen, 1984; Alpert et al.,

2001; Cannizzaro et al., 2004). The most common dependent measure has been speech pause time (SPT), the duration of the silent interval between phonations. Szabadi and colleagues (1976) and later Greden and colleagues (Greden and Carroll, 1980; Greden et al., 1981; Greden, 1982) first claimed that SPT was elongated in major depression without a change in phonation time, and that SPT shortened with clinical remission. These claims have received substantial support and have been extended to bipolar depressed patients. SPT has shown significant associations with depression severity, the Widlocher scale (Widlocher, 1983) for assessing psychomotor retardation, and reaction time.¹¹ Other aspects of speech, including total speaking time, various quantitative features of fundamental frequency and pitch, and speed of voice change, have shown less consistent associations with mood disorders. There is surprisingly little information on the impact of manic states on these measures, and comparisons of unipolar and bipolar depressed patients have shown limited power.

Attention

Impaired attention and insufficient motivation are the two most common reasons given for the pattern of widespread neuropsychological deficit in mood disorders (Miller, 1975; Bearden et al., 2001). To the extent that motivational impairments resolve with remission of depression or mania, persistent neuropsychological impairments are unlikely to be due to motivational factors. Attentional processes are in many respects the gateway to learning, memory, and other higher cognitive processes. While some forms of learning (e.g., procedural learning) undoubtedly occur outside of awareness and do not depend on the integrity of attentional processes, such is not the case for much of our knowledge of ourselves and the world.

Attention is a complex concept that encompasses multiple distinct processes. The concept of working memory denotes the capacity to hold in awareness for a limited time a limited number of visual or auditory representations. This type of attentional process, as in “keeping in mind” a telephone number, can be assessed with various “span” tasks, in which patients recall or recognize a serial list of digits, letters, or shapes just presented. In contrast, the capacity to detect a rarely occurring target is the form of attention commonly referred to as vigilance. The classic example here is the air traffic controller who monitors a screen for representations of two aircraft on a collision course. Although this event is infrequent, detecting its occurrence is of obvious importance. In psychiatric research, vigilance is commonly assessed with the Continuous Performance Test (CPT), originally developed by Beck and colleagues (1956) to detect lapses in attention among epilepsy patients. Another form of attention concerns freedom from distraction

or interference. The capacity to carry out more than one task simultaneously requires that one split attention between tasks (e.g., speaking on the phone while driving) or rapidly shift attention from one task to another. One method of assessing distractibility involves using dichotic listening; individuals must monitor for the occurrence of a target embedded in information delivered to one ear (as in vigilance tasks) but with other, sometimes conflicting, information presented to the other ear. In this context, freedom from distractibility involves the capacity to disattend to irrelevant but competing information channels. A similar phenomenon is tapped by the Stroop test. In one condition of this test, individuals identify the color of nonmeaningful stimuli, such as a series of X's. In another condition, they report the color of visual stimuli that are color names. These names may be in conflict with the appearance of the stimuli. For example, the word “green” may be presented for a stimulus in the color blue. The interference produced by such color–color word conflict is assessed by comparing reaction time in this condition with that for simple color naming. Disattending to the meaning of the word and focusing only on the color would optimize performance on the Stroop test.

It has long been thought that attentional processes are impaired in episodes of major depression in a state-dependent fashion (Cronholm and Ottosson, 1961; Sternberg and Jarvik, 1976) and that attentional deficits limit the extent to which learning may occur. Meta-analyses have consistently shown that attention and learning are among the most markedly impaired functions in episodes of major depression (Zakzanis et al., 1998).

Figure 9–7 presents the results of our meta-analysis of attentional measures in studies of bipolar disorder. The effect size (Hedges' G^1) across all studies was 0.64 ($SE = 0.063$, $p < .001$) and was significant for studies of depression (effect size = 0.61 , $SE = 0.28$, $p < .03$), mania (effect size = 0.75 , $SE = 0.15$, $p < .001$), mixed states (effect size = 0.74 , $SE = 0.12$, $p < .001$), and remission (effect size = 0.54 , $SE = 0.10$, $p < .001$). While the effect size was smallest for studies of remitted patients and highest for studies of the manic state, formal testing failed to reveal a significant difference among the groups. Indeed, contrary to the notion that attentional disturbance is purely state dependent, deficits in this domain relative to healthy controls were seen in virtually all studies of patients in remission. This has been demonstrated in more recent studies of attentional deficits in euthymic patients as well.¹² A similar pattern of attentional deficits has been found in bipolar children and adolescents (see the review by Kyte et al., 2006; Kolur et al., 2006).

Our analysis of effects on attention involved 212 comparisons from 39 studies. Given that attentional processes are heterogeneous and are sampled by tasks differing radically

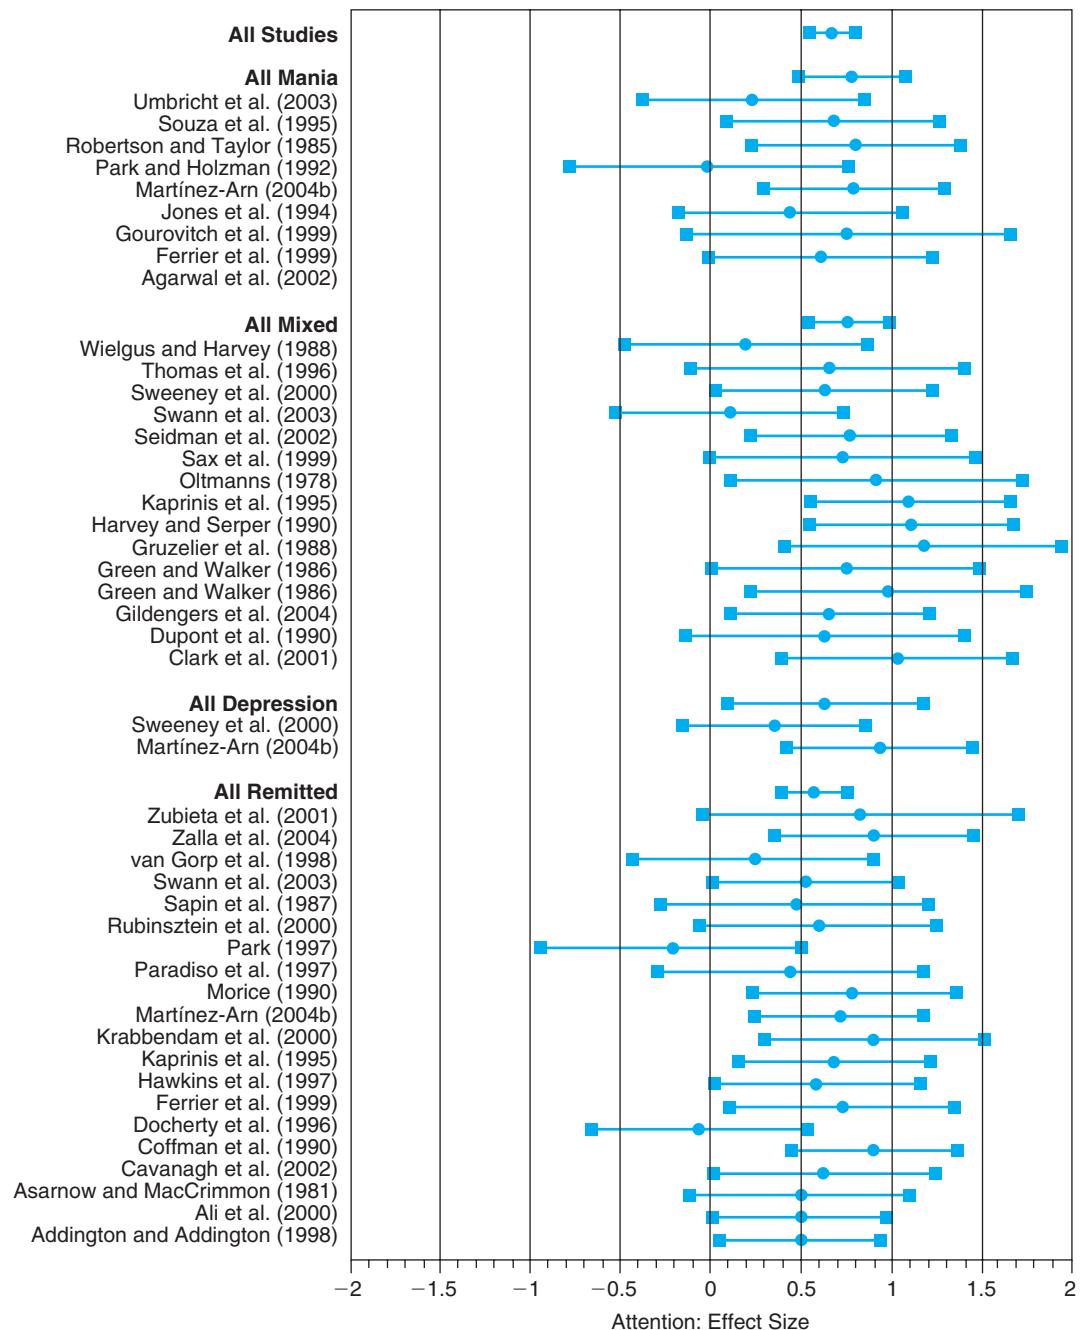

Figure 9-7. Meta-analysis of attention measures. Effect sizes (Hedges' G) are presented for individual study comparisons of a bipolar sample with healthy controls, as well as for samples of bipolar patients in remission, depression, mixed state, or mania and across all studies. Squares = confidence interval; circles = mean.

in their cognitive demands, averaging across distinct attentional measures could obscure more discrete patterns of deficit. Therefore, the analyses were predicated for studies of patients in remission and for all studies as a function of the specific neuropsychological procedure used to evaluate attention. As seen in Figure 9-8, although the number of studies contributing to results for individual tests is often small, a consistent pattern is evident. Except for working-memory

tasks, all other tests showed a consistent deficit in both the remitted state and across remission and the phases of bipolar illness. Indeed, except for cancellation tasks, the effect sizes are uniform for the remaining tasks and essentially equivalent both for studies restricted to remission and for all studies. The failure to find a deficit in working memory may be related to the small number of studies that addressed this area and to the use of simple tasks, such as

matching to sample (which may produce floor effects), to assess working memory. On the other hand, Harmer and colleagues (2002) noted that disturbance in sustained attention is a consistent finding in remitted bipolar patients, but that many vigilance tasks contain working components. By using tests of sustained attention that did and did not draw on working memory, they were able to demonstrate that the impairment in sustained attention did not derive from or depend on impairment in working memory.

Cancellation procedures require that targets embedded in an array of targets and foils be crossed out, with the rates of target identification (hits) relative to false identification (commission errors or false alarms) as the measure of performance accuracy. In brain-damaged individuals, right parietal injury is especially likely to disrupt cancellation performance, often producing a pattern of hemispatial neglect whereby failure to identify targets (false-negative errors) is overrepresented on the left side of arrays (Mesulam, 2000). While there was a robust effect size for deficits on cancellation tasks in patients in remission (effect size = 0.87, SE = 0.20, $p < .001$), the effect was even more robust when studies of patients in symptomatic

states were included (effect size = 0.134, SE = 0.37, $p < .001$). This difference is due to the three studies of mania, which produced an especially high effect size (1.96, SE = 0.84). Again, the small number of studies providing cancellation test data calls for caution in placing emphasis on this specification. Rather, the conclusion most justified from the findings summarized in Figures 9–7 and 9–8 is that attentional disturbance is broadly manifested in bipolar disorder across multiple instantiations of this cognitive domain. Not only is the magnitude of deficit relatively uniform across tasks, but it is surprisingly uniform across the phases of bipolar illness, including remission. Furthermore, given the centrality of attentional processes to the integrity of many higher-order cognitive processes, the findings of attentional deficits in remission imply that broad or diffuse cognitive impairment should characterize many individuals with bipolar disorder in remission.

Learning and Memory

Disturbances in learning and memory may be divided into at least six categories of disturbance, each with its own pathoanatomical correlates (Kopelman, 2002; Stern and

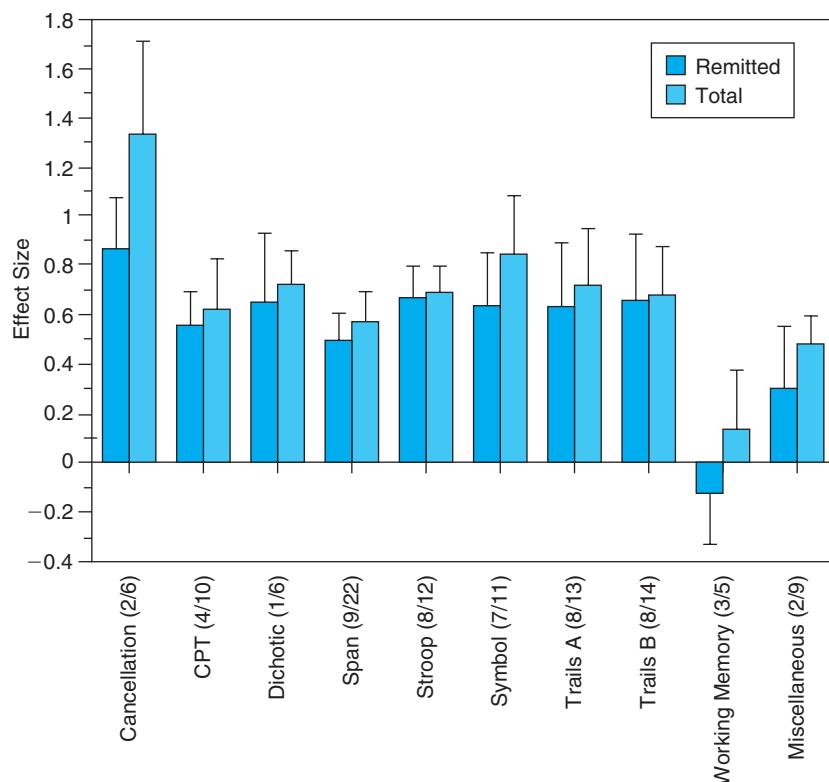

Figure 9–8. Effect sizes for various measures of attention. Effect sizes (Hedges' G) are shown for comparisons of bipolar patients in remission with healthy controls and for the total set of comparisons of bipolar patients across phases of illness with healthy controls. The numbers in parentheses indicate for each attentional measure the number of comparisons of remitted bipolar patients, followed by the total number of comparisons. CPT = Continuous Performance Test.

Sackeim, 2002; Squire et al., 2004): (1) Sensory memory deficits, involving modality-specific failures of preattentive information registration, at times associated with impairment of the reticular activating system or temporal or occipital neocortex; (2) Short-term or primary memory deficits, involving failures of acquisition and brief retention in a limited-capacity store, also associated with disturbance in prefrontal and temporal neocortex; (3) Abnormalities in acquisition and retention of long-term episodic memory, associated with prefrontal, medial temporal, and diencephalic impairment; (4) Disturbances of access to semantic memories, involving failures of storage or retrieval of language or knowledge that is not linked to temporal, sequential, or other contextual (episodic) information, and associated with disruption of posterior association cortex; (5) Deficits in the acquisition and retention of nondeclarative information, as reflected in procedural learning, priming, and classical conditioning (impairments in distinct neural systems are linked to the type of deficit, with striatal impairment tied to deficits in procedural learning and memory); and (6) Disturbances in the use of strategies mediating the acquisition and retention of information, with frontal cortex dysfunction linked to abnormalities in planning, encoding, and retrieval strategies.

When cast in this way, it is apparent that much of the landscape in learning and memory remains unexplored with respect to modulation by mood disorders. Although there has been some work suggesting subtle impairments of sensory and perceptual processes in major depression, including bipolar disorder, especially with respect to auditory processing (Yovell et al., 1995), investigation in this area has been extremely limited. The possibility of sensory memory deficits is largely untested, although not believed to be likely.

There is no evidence that mood disorder patients present with impairments of semantic memory, as tested, for example, by the information subtest of the WAIS-R. Memory for facts appears to be impervious to the effects of mood disorders.

In recent years, nondeclarative aspects of learning and memory, especially procedural learning, have been increasingly represented in neuropsychological batteries (Fig. 9–9). The preliminary evidence in bipolar disorder does not suggest impairment in procedural learning or memory, especially when remitted samples are examined (van Gorp et al., 1999; Altshuler et al., 2004). Preservation in this area may suggest that conscious awareness of mental contents is a property of the cognitive systems disrupted in mood disorders.

Of the six categories of memory disturbance, the focus of research in mood disorders has been on short-term memory, long-term episodic memory, and the strategies

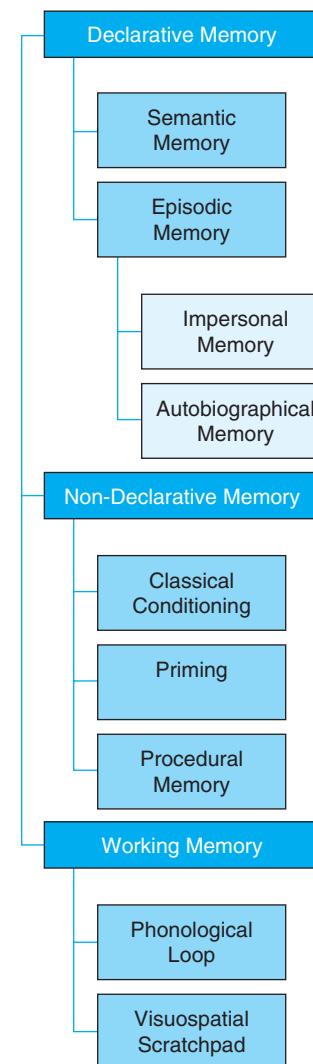

Figure 9–9. Schematic representation of the structure of memory. The main component systems are declarative, nondeclarative, and working memory. Each of these components comprises more elemental subcomponents. (Adapted from Stern and Sackeim, 2002).

used to acquire, retain, and recall declarative information. This focus has concerned almost exclusively the learning and retention of new information. Recall of information about the past, whether pertaining to autobiographical or public events, has rarely been assessed outside of studies of retrograde amnesia after brain insult. To establish a baseline for assessing the extent of amnesia following ECT, the Columbia University group compared unmedicated patients in episodes of major depression (bipolar and unipolar) with healthy controls on the “productivity” of memory for the past. Whether assessed in terms of autobiographical or public events and in terms of remembrance of the event itself versus details about the event, the depressed samples showed small but statistically significant deficits at baseline (McElhiney et al., 1995). The fact that these patients reported

slightly fewer memories about themselves or the world could reflect little more than an impairment of the acquisition of information during the affective episode, since what was not learned cannot be remembered. Alternatively, it is also true that what has not taken place cannot be remembered. Relative to the experience of healthy controls, reduced activities during episodes of illness may lead to a relative paucity of events about which to have recent memories. In any case, these data suggest that mood disorder patients are unlikely to have a fundamental or clinically significant deficit in the recall of past events or the details of past events. Furthermore, McElhiney and colleagues (1995) found no indication of a bias in depressed samples toward differential recall of negatively charged events.

Short-Term Memory

The distinction between short-term and long-term memory is arbitrary, and is usually taken as representing the methodological distinction between memory for new information tested after a very short delay (usually less than 10 seconds) and after longer delays (tens of seconds to years) (Wickelgren, 1973). This distinction is consequential because holding information in short-term memory is thought to be mediated by prefrontal working-memory processes, while the consolidation and retention of this information are determined by the integrity of the medial temporal lobe and other structures. The distinction is reflected in the common experience of not being able to reproduce a phone number when attention is directed away. In the absence of continual rehearsal, some information is lost, and in the case of bilateral hippocampal damage, retention of new declarative information may be limited to the period of rehearsal. Retention of new information over delays greater than tens of seconds depends on the integrity of consolidation and retrieval processes that are thought to involve initially the hippocampus and other structures.

By far the most common method for assessing short-term memory has involved forward and backward auditory digit span procedures, although word, letter, block, and shape span tasks are also available (Lezak, 1995; Spreen and Strauss, 1998). The early literature is not consistent in addressing the elemental question of whether auditory digit span performance is abnormal in mood disorders.¹³ However, as seen in Figure 9–8, more recent studies comparing patients with bipolar disorder and healthy controls have revealed a consistent deficit in the performance of span tasks, auditory or visual, and pertaining to digits, words, or shapes. Across 22 studies and all phases of bipolar disorder, the pooled effect size for this comparison was moderate: 0.58 ($SE=0.12, p<.001$). In the 9 studies contrasting patients in remission, the effect size was 0.50 ($SE=0.11, p<.001$).

It is conceivable that the impairment of span performance is specific to procedures not involving auditory presentation of digits. Baddeley (1986) proposed that the phonological loop challenged by digit span tasks is distinct from a visuospatial scratch pad, with both being key aspects of working or short-term memory (see Fig. 9–9). However, no differences are seen in a comparison of effect sizes in studies using digit span and those using other span procedures. Thus the conclusion is justified that bipolar patients, whether in remission or not, have a deficit in short-term memory, as reflected in span performance. This deficit is interpreted as reflecting impaired attention.

Verbal learning tasks present another context for assessing the integrity of short-term memory. However, recall or recognition after a single presentation of a list relies on both short- and long-term processes. This point is supported by the serial position effect, in which recall is best for the early (primacy effect) and late (recency effect) items in a list and poorest for the middle ones (Bayley et al., 2000). The recency effect reflects the integrity of short-term memory given the minimal interval between presentation of the last items on the list and recall. The primacy effect reflects the contribution of transfer to long-term memory and the consolidation process. Since many of the reports on learning in bipolar illness concern cumulative performance in recalling a list during repeated testing over several trials, such procedures, while involving minimal retention intervals since the last presentation of a list, nonetheless rely heavily on long-term memory.

Figure 9–10 illustrates the effect sizes obtained in comparisons of patients with bipolar disorder and healthy controls on learning tasks, both verbal and nonverbal. Across all studies, the effect size is 0.91 ($SE=0.11, p<.001$). In comparisons restricted to remitted patients, the effect size is 0.81 ($SE=0.15, p<.001$).

Without question, bipolar disorder is associated with a marked deficit in the acquisition of new information. This deficit is seen in all phases of the illness, and its magnitude does not appear to be lessened among patients in remission. However, cross-sectional comparison should be used only to establish the existence of deficits in specific phases of the disorder. Whether the deficits are truly comparable in mania, depression, or remission requires within-subject longitudinal investigation. For example, the reduced noise of measurement involved in neuropsychological assessment of remitted as opposed to acutely ill patients can inflate effect sizes indicating deficits in remission. Furthermore, it is common to evaluate clinical samples in a medication-free state when acutely ill at baseline, but to evaluate patients in remission who are medicated. Such a confound could also intensify the deficits observed in remitted patients.

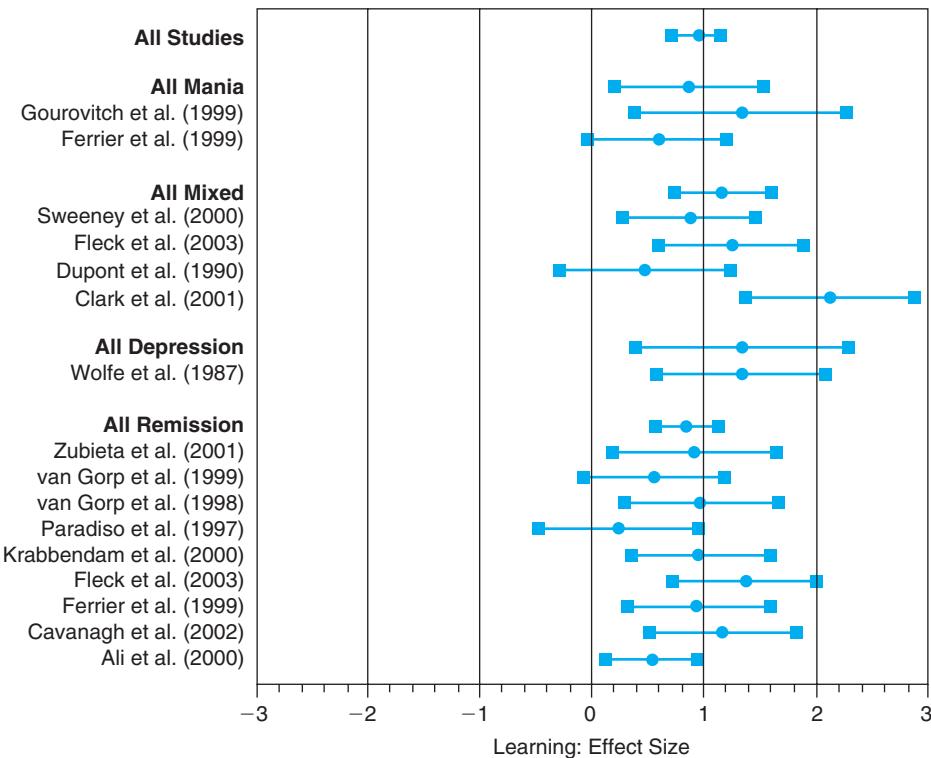

Figure 9-10. Meta-analysis of learning measures. Effect sizes (Hedges' G) are presented for individual study comparisons of a bipolar sample with healthy controls, as well as for samples of bipolar patients in remission, depression, mixed state, or mania and across all studies. Squares = confidence interval; circles = mean.

There has been very little investigation into bipolar-I vs. bipolar-II differences in attention, verbal learning and memory, and executive functioning. Recently, Torrent and colleagues (2006) compared 71 euthymic bipolar patients (38 bipolar-I, 33 bipolar-II) with 35 healthy controls on a battery of cognitive tasks. Both bipolar groups showed significant deficits in working memory, attention, and executive functions, with bipolar-II patients performing at a level between the bipolar-I patients and the healthy controls. Possibly confounding the results, bipolar-I patients were more likely to be taking lithium, carbamazepine, and/or antipsychotics; bipolar-II patients were more likely to be taking antidepressants. It is unclear which patients were taking more than one medication or what effects the medications may have had on performance.

Long-Term Memory

In recent years, it has been claimed that memory is the domain demonstrating the greatest impairment in mood disorders. Literature reviews and meta-analyses have indicated that relative to healthy controls, patients in an episode of major depression (bipolar or unipolar) manifest markedly inferior performance on tests involving the recall or recognition of information over a substantial delay or after

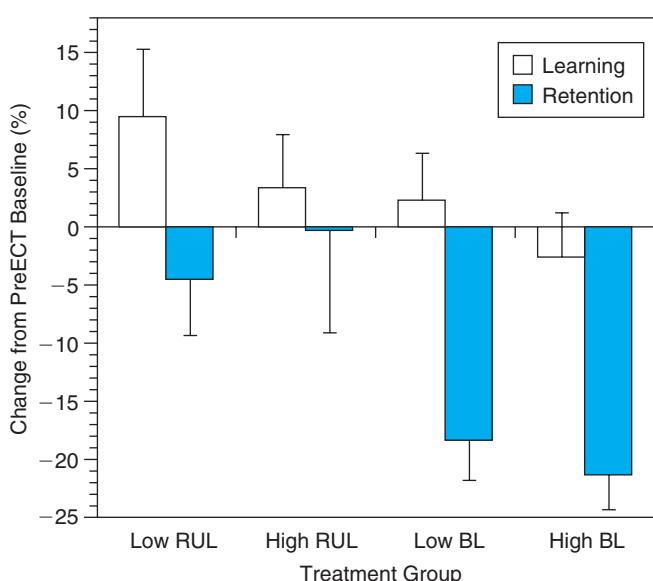

substantial training (Burt et al., 1995; Zakzanis et al., 1998). Further, it has been suggested that in recurrent unipolar disorder, lifetime duration of the depressive state is associated with both hippocampal atrophy and verbal memory deficits (Sheline et al., 1996, 1999). In line with this view, there is preliminary evidence that elderly bipolar patients show greater deterioration in memory processes than do elderly unipolar patients (Burt et al., 2000). Thus it would appear safe to conclude that long-term memory is especially impaired, that the impairment intensifies with disease progression, and that the impairment likely reflects dysfunction in medial temporal lobe structures.

The classic formulation of deficits in learning and memory in mood disorders presents a quite different view. Cronholm and Ottosson (1963) asserted that the depressed state is associated with a reduced capacity to acquire new information, but with no impact on the capacity to retain the information once it has been acquired. Thus in their work, patients were found to be notably deficient in learning verbal and nonverbal paired associates, but did not show proportionately greater loss of what was originally learned over a delay. In another influential study, Sternberg and Jarvik (1976) used similar tasks and also found that patients in an episode of major depression performed more poorly than

controls on learning but not on retention, as measured by a “forgetting score,” the mathematical difference in the number of items recalled before and after a delay. Following a pharmacological trial, the extent of clinical improvement covaried with improved learning (immediate memory).

One difficulty with this early work is that the integrity of long-term memory was assessed using a forgetting score that did not account for differences in the amount of material learned. Clearly the more one learns, the more material is available for forgetting. Steif and colleagues (1986a) raised conceptual and empirical issues in the assessment of these constructs. Despite more stringent controls, they also found that the primary deficit distinguishing unmedicated, depressed patients from controls was the learning or acquisition of new information, as opposed to the retention of what had been learned. Indeed, with retesting after a course of ECT, the authors were able to demonstrate a double dissociation. Whereas the state of depression involved impairment in learning and not retention, after ECT patients had a deficit in the retention of newly learned information, with no impact on learning. This type of effect is illustrated in Figure 9–11.

Figure 9–11. Dissociation in the effects of electroconvulsive therapy (ECT) on learning and retention of new information. Patients were randomly assigned to low- or high-dosage bilateral (BL) or right unilateral (RUL) ECT. Before and immediately after the course, they were administered a test of verbal list learning and retention using the selective reminding procedure (Buschke, 1973). Little change in immediate learning was seen when post-ECT values were compared with baseline values, with the exception of possible improvement in the low-dose RUL ECT group. In contrast, both low- and high-dose BL ECT resulted in clear-cut deficits in free recall of the list after a delay. The results illustrate the selective effect of ECT on the retention of newly learned information, which is thought to be due to a deficit in consolidation. (Source: Sackeim et al., 1993.)

Why, then, are there conflicting views, with some recent work emphasizing long-term memory as a source of impairment and earlier work emphasizing impaired learning? It is quite likely that this apparent conflict stems from the fact that attentional deficits compromise the intake of information and disrupt learning. In turn, if little is learned, little can be remembered. For the most part, the work on impaired memory in depression has not taken into account the earlier stages of processing and their contributions. Thus in a concrete sense, being able to report only 3 of 15 items on a list after a 2-hour delay could reflect anterograde amnesia if 12 items were recalled during learning. On the other hand, if only 4 or 5 items were learned, impaired acquisition of the information would be the central deficit.

Figure 9–12 presents the effect sizes for comparisons of bipolar patients with healthy controls on a variety of memory measures. While the effect sizes for the subgroups and across all studies are substantial, they are virtually identical to the values obtained when assessing learning only (see Fig. 9–9). Again, it is hazardous to draw conclusions about within-subject effects using cross-sectional data. Nonetheless, the most parsimonious account of this literature is that impaired attention, which persists in remitted patients, is the major factor determining the adequacy of learning and memory.

Mediational Processes

Many processes determine whether a particular memory will be retrieved. Some of these processes relate to the infrastructure of memory, so that there is a contrast, for example, between deficits in the storage of information as assessed by recognition tasks and in the active retrieval of information as assessed by recall performance. Other processes, such as the organization imposed on newly presented information and the resultant depth of encoding, may determine whether information is learned and/or stored. Still other factors affect not so much whether new information will be retained, but how the choice is made whether to recall events from the past. For example, the issue is hotly debated as to whether being in the depressed or manic state biases retrieval toward memories that share the same affective valence. This form of mood-congruence effect addresses the question of whether depressed patients have preferential access to or are biased to retrieve negatively evaluated information.

Storage Versus Retrieval. Assuming that information is acquired, failure to recall can be due to a breakdown either in consolidation or storage or in retrieval. Because recognition of information is far less demanding of retrieval processes but is dependent on the adequacy of storage, an

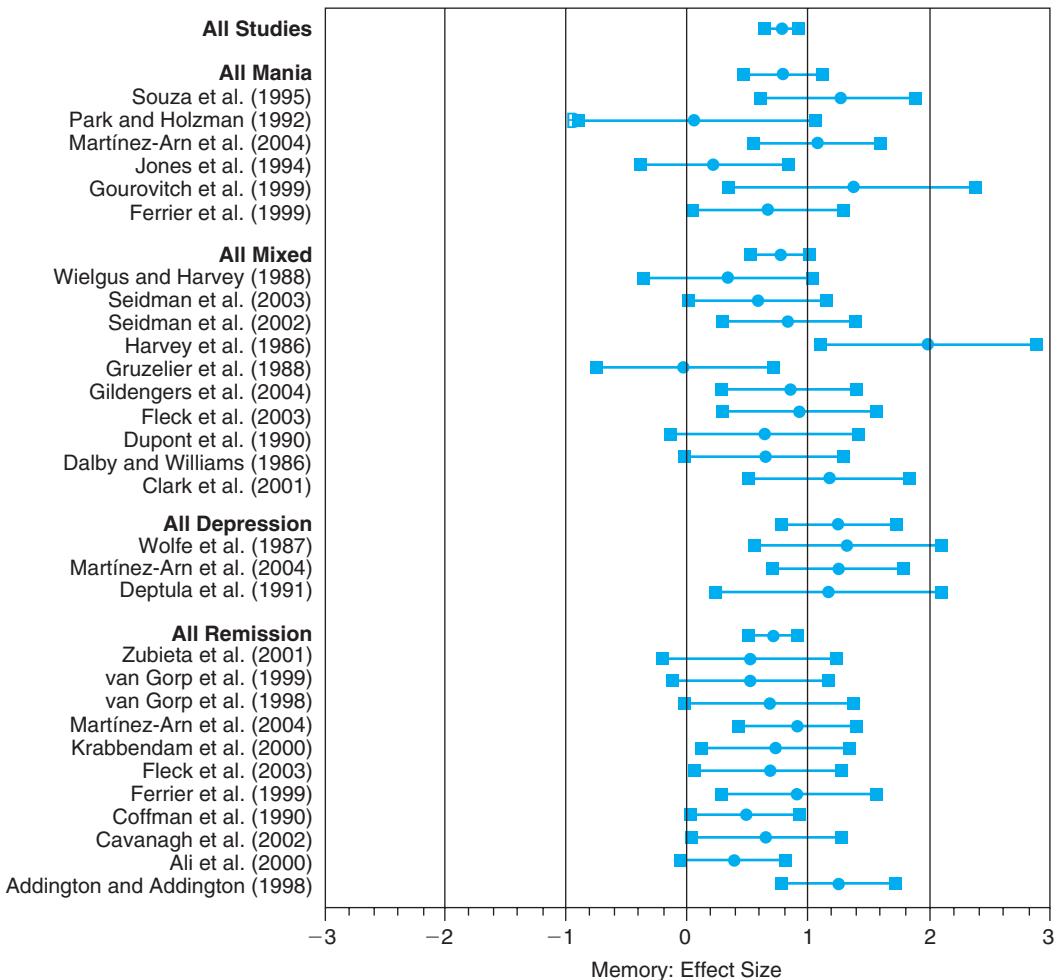

Figure 9-12. Meta-analysis of memory measures. Effect sizes (Hedges' G) are presented for individual study comparisons of a bipolar sample with healthy controls, as well as for samples of bipolar patients in remission, depression, mixed state, or mania and across all studies. Squares = confidence interval; circles = mean.

asymmetry whereby retrieval is impaired but recognition is intact could suggest a specific impairment in retrieval strategies—either the way information is organized for later retrieval or the way the search strategy is organized. However, recognition is intrinsically easier than retrieval, at least when the same information is tested, and claims of differential deficit are easily confounded with task differences in discriminating power and other psychometric properties.

A few authors have claimed that patients in an episode of major depression have a greater deficit in recall relative to recognition (Weingartner et al., 1977; Frith et al., 1983; Deptula et al., 1991). This work is problematic, however, because of the failure to compare recognition and recall paradigms directly or the lack of psychometric matching. These limitations were overcome by Calev and Erwin (1985), who used a matched-task paradigm. They found that depressed patients performed better on verbal recognition than on recall tasks, whereas healthy controls performed

similarly on both (demonstrating the adequacy of the matching). The recall disturbance was attributable to a reduced ability to organize the retrieval system. Thus, very limited data suggest the possibility of a particular deficit in retrieval processes in mood disorders. This deficit may be an example of a failure to engage in active, effortful processing.

Attention, Effort, and Levels of Processing. The deficits manifested by patients with mood disorders in tasks of learning and memory appear to be attributable largely to attentional dysfunction. Relevant here are well-established models from cognitive psychology that distinguish between automatic and effortful processing¹⁴ and models of depth or levels of processing.¹⁵ In the former models, attention is conceptualized as a limited-capacity resource. Automatic operations make minimal use of this resource and take place without intention or awareness. They do not interfere with

ongoing cognitive operations and do not benefit from rehearsal. For example, remembering where one put one's keys is typically an instance of automatic or incidental learning. Typically, one does not consciously attempt to remember this information, and one is usually unaware of learning it. Skill or procedural learning and other nondeclarative forms of memory do not involve explicit, consciously mediated cognitive rehearsal. In contrast, effortful processes require the use of limited attentional capacities and interfere with other cognitive activities. The cognitive operations are initiated voluntarily and benefit from practice.

Similarly, a levels-of-processing approach emphasizes that the amount of attentional capacity allocated to the initial steps of information processing (e.g., encoding) influences the later retrievability of the information. The deeper the level of processing, the greater is the attentional allocation and the better the retrieval. For example, if one's task in listening to a set of words is to determine which words rhyme with a target (acoustic or shallow processing), later memory of the list will be poorer than if the task is to determine whether each word has the same meaning as a target (semantic or deep processing). The two models are convergent in that engaging in greater depth of processing is often an effortful, attention-demanding process.

The notion that individuals in episodes of major depression have a deficit in engaging spontaneously in effortful or deeper levels of processing has received substantial, although not unequivocal (Christensen et al., 1997), support. In a now-classic study, Weingartner and colleagues (1981) found that depressed patients did not differ from healthy controls in recalling words that had been acoustically (shallowly) processed, but were inferior in remembering semantically (deeply) processed words. The control group showed the typical advantage of better recall of the deeply processed words. In contrast, the patient group had equivalent scores on the two tasks, suggesting that despite the difference in task requirements, the patients' encoding on both tasks was shallow.

A second study reported by Weingartner and colleagues (1981) demonstrated that when deep encoding was provided externally on a verbal memory task, depressed patients performed similarly to healthy controls. Essentially, when given a list of random words, a depressed sample was shown to have markedly impaired recall. When presented a word list drawn from discrete semantic categories in which the word order was clustered, however, patients were not distinguishable in recall from healthy controls. Both the extent of categorization of words and the overt clustering within categories determined the magnitude of the difference in recall between patients and controls.

The implication of this work is that depressed patients, when exposed to new material, are less likely than healthy

controls to apply preexisting knowledge and impose the organization that facilitates learning and memory. In this respect, the locus of abnormality is at the encoding stage and results in diminished learning. Fundamentally, the depth of encoding and the automatic versus effortful distinctions converge. Imposing organization is an effortful process, and in most circumstances, the automatic versus effortful distinction maps to shallow versus deep processing. This deficit pertains to the set of mediational processes termed by Moscovitch (1994) "working with memory." These processes involve the selection and execution of strategies used to enhance information processing and are thought to be heavily represented in prefrontal cortex. Further, effortful or deeper processing requires the allocation of attentional resources. Thus it is conceivable that the fundamental abnormality resides in an inflexibility or limited capacity of attentional mechanisms rather than difficulties with selecting or applying appropriate strategies for encoding or retrieval. Put another way, it would appear that the depressed state is characterized by a cognitive impairment likely to be most manifest on tasks that require complex processing, effortful processing, and/or independent structuring of information relative to preexisting knowledge.

This remains an active area of investigation, with repeated demonstrations that depressed patients are more likely than healthy controls to engage in shallow and/or noneffortful processing.¹⁶ However, almost all of this work has focused on demonstrating the phenomenon and establishing its boundaries. There is little clarity regarding the neurobiological basis of this abnormality or its implications for therapeutics. Roy-Byrne and colleagues (1986) suggested that the deficit in effortful processing is dopaminergically mediated, but this hypothesis has yet to receive substantial investigation.

One thread in this literature ties the lack of effortful processing to an entirely different domain of behavioral limitation. Cohen and colleagues (1982) found that severity of depressive symptomatology correlated negatively with grip strength, as assessed with a hand dynamometer. Both symptom scores and grip strength correlated with performance on a verbal memory test, with less effort on the motor task being associated with poorer memory scores. The results of this work suggest that in major depression, there is a parallel between the diminished effort in physical activity and the diminished mental effort that results in inattention and lack of structuring of incoming information. Certainly, it would be noteworthy were this the case. While the effort expended in voluntary activity has a voluntary quality, as in how strongly one grips a dynamometer, this is not the conception regarding the mental effort leading to more extensive encoding. The failure to impose organization and process at deeper levels should

be viewed as unconscious or automatic. Furthermore, the lack-of-effort analogy does not accord with what may be the most common reason for shallow processing in mood disorders. Under conditions of marked agitation or psychic pain, patients will often indicate that it is a struggle to get through the next 5 minutes, let alone attend to a task. With internal ruminations and marked distress, even reading a newspaper headline can be difficult. Thus it is probable that in some circumstances, the lack of effortful processing is due to the fact that the effort is being expended elsewhere.

It might be thought that this type of deficit in mediational processes should be fully state dependent. Otherwise, we would have to posit that patients with mood disorders engage in "shallow" processing even when in remission. Further, were this defect purely state dependent, it would have a rather limited role in accounting for the learning and memory deficits in patients with mood disorders. As described earlier, there is substantial evidence that attentional, learning, and memory deficits continue largely unabated during remission. Longitudinal investigation in this area has been limited, however. Hammar and colleagues (2003b) found that unipolar patients in a state of major depression were impaired in an effortful but not automatic visual search task. The deficit persisted for at least 6 months despite substantial clinical improvement. Further work of this type is needed.

Mood Congruence. *Mood congruence* refers to the notion that the efficiency of mnemonic processing is biased by the congruence between the current affective state and the affective tone of the material being remembered. In general, it is believed that dysphoric or negative life events are recalled more easily when individuals are in a depressed state than when they are in a euthymic or manic state (Blaney, 1986).

This phenomenon has been examined mainly in studies using laboratory manipulations, such as rigged experiences of success and failure in completing laboratory tasks. These studies have yielded some evidence that depressed patients can be biased in recalling negative events or can exercise a mnemonic selectivity that emphasizes neutrality over positivity.¹⁷ This type of mediational process, if of general consequence, would affect the content of remembrances, with the implication that this bias toward greater negativity in content may contribute to the monolithic experience of depression, and perhaps also to its maintenance. However, subtle demonstrations of bias in laboratory or real-world settings do not mean that this phenomenon is of general consequence. In intensive interviews regarding autobiographical events, severely depressed patients differ little from healthy controls in the richness of their reports of

positive or negative events in their recent and remote past (McElhiney et al., 1995).

Summary

Deficits in learning and memory characterize unipolar depression and bipolar disorder through all its phases. The effect sizes for these deficits are the largest among neuropsychological domains. While it has been common in recent years to assert that episodes of major depression are associated with a memory deficit, there is little evidence that the deficits seen in learning and/or memory processes extend beyond attentional disturbance. This attentional disturbance may be structural in the sense of dysfunction in a limited-capacity store, or perhaps more likely, a disturbance in the allocation of attentional resources. The substantial literature on bipolar patients in remission indicates that the deficits in learning and memory persist during euthymia. There are compelling findings that mood disorder patients in episodes of major depression are more likely to engage in shallow processing and to fail to impose the organization on incoming information that assists in acquisition and retention. This "cognitive laziness" results from a failure of executive function—in this case, the utilization of strategies that facilitate learning and memory. Thus it becomes especially germane to inquire whether there is a more general impairment of executive functions.

Executive Functions

The concept of executive functions became a driving force in much thought about the core deficits in psychopathology, especially schizophrenia and bipolar disorder, starting in the 1980s. Fundamentally, disruption of these functions is deemed responsible for the lack of self-regulation on a variety of dimensions in patients with these disorders. Executive functions perform the brain's housekeeping, strategizing, and oversight roles, and come closest in principle to the neuropsychological concept of a neural homunculus in charge of neural resource allocation and other administrative functions or, perhaps, the concept of will.

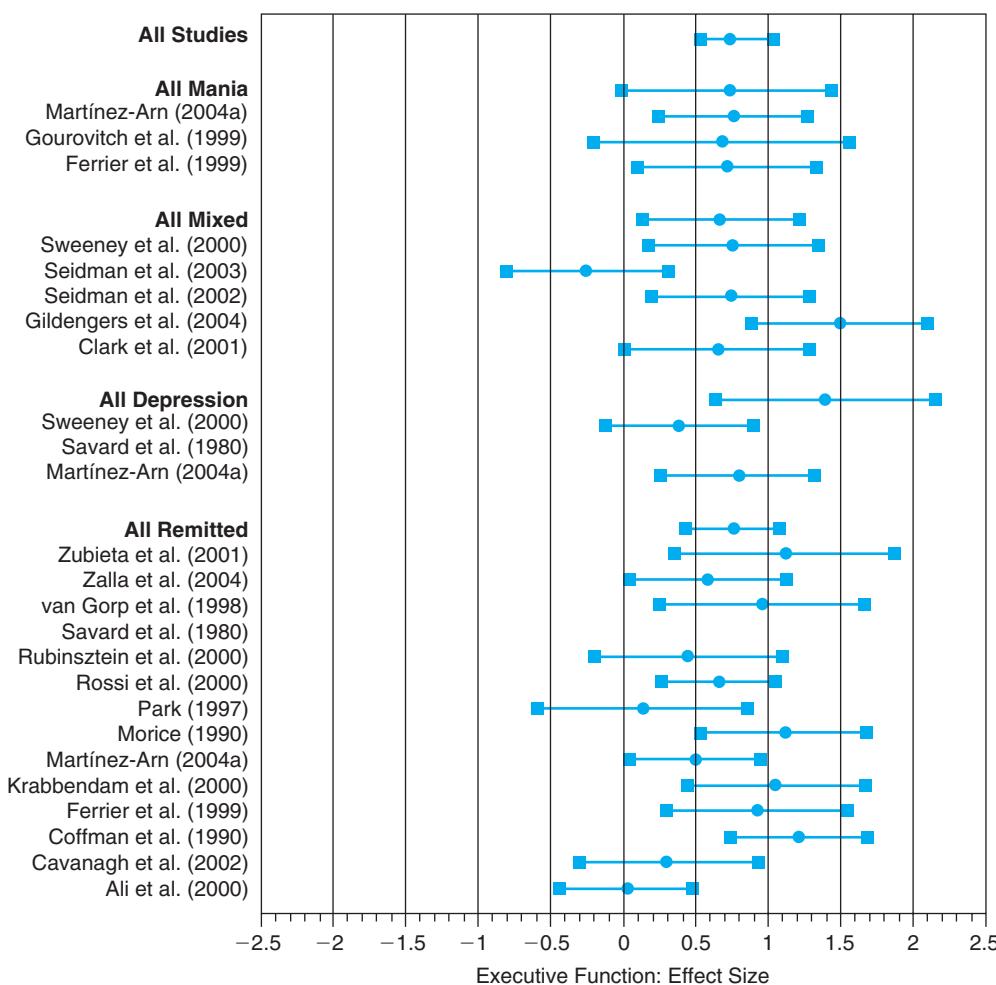

The vagueness of definitions and descriptions of executive functions is to be expected given the vast and complex aspects of psychic functioning likely devoted to strategic, integrative, planning, inductive, and deductive activities. Indeed, at one level the type of executive functions involved in optimizing learning strategies by imposing conceptual organization (chunking) on incoming information automatically and without awareness must be quite distinct from the processes involved in making career choices, anticipating danger while driving, or inhibiting a prepotent response. Thus executive functions address our capacity to reason, to anticipate, to shift conceptual or perceptual sets, to solve problems, and so on.

Despite this richness of possibilities, a very limited range of executive functions has been studied in bipolar disorder. Figure 9–13 presents the results of our meta-analysis of comparisons involving executive functions other than reasoning. Tests of reasoning or concept formation were examined separately, partly because they are so strongly dependent on language and verbal abilities; these findings are presented in Figure 9–14. The instruments used most commonly to test the integrity of executive functions are the Wisconsin Card Sort Test (WCST) and the Category Test of the Halstead-Reitan battery. Both involve complex procedures in which individuals derive rules or abstractions from experience. The WCST also assesses the capacity to shift sets upon recognizing that the rules have changed. It is considered a test of executive functions in part because it requires strategic planning,

organized searching, use of feedback to shift conceptual set, goal-oriented behavior, and the capacity to inhibit impulsive responding (Spreen and Strauss, 1998). Other instruments used to test executive functions include the Tower of London, which places heavy emphasis on planning (Shallice, 1982) and involves the rearrangement of balls in a vertical column to match a prespecified order using a minimum of moves, attentional set-shifting tasks, and decision-making tasks.

As seen in Figure 9–13, substantial deficits in executive functions were observed in all phases of bipolar disorder. Across the 25 studies contributing data, the overall effect size was 0.79 ($SE = 0.13, p < .001$). In the 14 studies that examined remitted bipolar patients, the effect size was 0.75 ($SE = 0.18, p < .001$), hardly suggestive of a state-dependent effect. Two recent studies also have found pervasive deficits in executive

Figure 9–13. Meta-analysis of executive function measures. Squares = confidence interval; circles = mean.

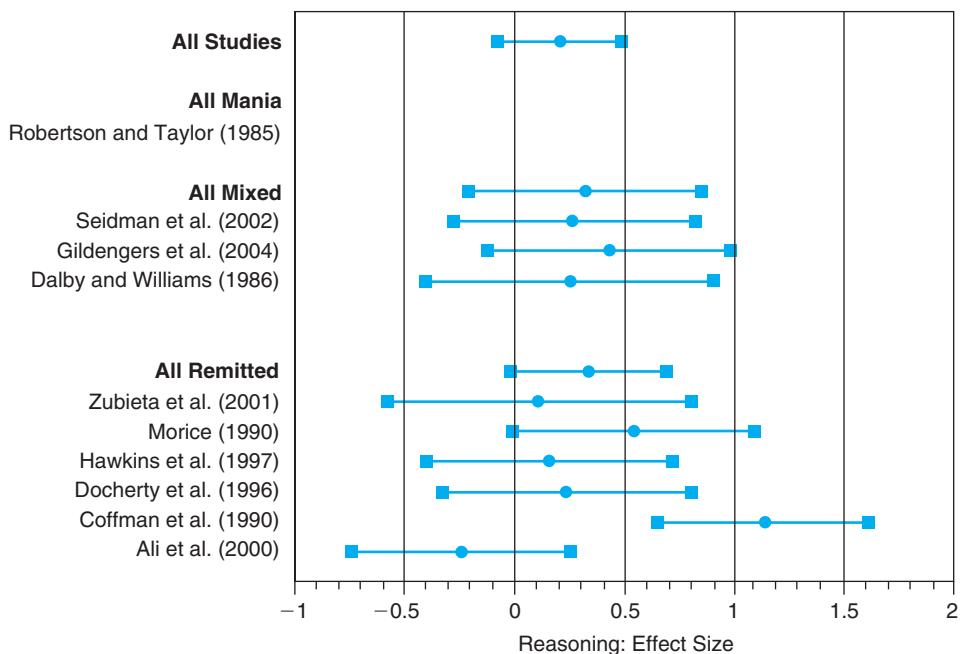

Figure 9–14. Meta-analysis of reasoning measures. Effect sizes (Hedges' G) are presented for individual study comparisons of a bipolar sample with healthy controls, as well as for samples of bipolar patients in remission, depression, mixed state, or mania and across all studies. Squares = confidence interval; circles = mean.

functioning in bipolar patients (Nehra et al., 2006; Robinson et al., 2006).

As in unipolar disorder, then, there is substantial evidence that periods of acute illness in bipolar disorder are associated with diminished executive functions, especially with respect to concept formation and set shifting. Recent studies have demonstrated this as well (Frangore et al., 2005; Goswami et al., 2006), including one that looked at executive functioning in patients with pediatric bipolar disorder (Pavuluri et al., 2006). Imaging studies have shown that, in healthy samples, the procedures examined in this domain result in activation of the dorsolateral prefrontal cortex (DLPFC). Abnormalities in DLPFC function in mood disorders have been reported from the earliest brain imaging studies of cerebral blood flow (CBF) or cerebral metabolic rate (CMR_{glu}), and more than 20 imaging studies have reported inverse relationships between depression severity and DLPFC, CBF, or CMR_{glu} .¹⁸ It is noteworthy that these studies did not include significant sampling of ventral or orbital prefrontal cortex functions, notably inhibition of prepotent responses, as in “go–no go” tasks. In terms of what was studied, there is strong evidence for persistent impairment of executive functions despite remission. Indeed, it is noteworthy that the effect size for remitted patients is equivalent to that for patients in acute affective episodes.

However, inspection of Figure 9–14 suggests that the deficit in executive functions may not be uniform across various component processes. Values for one study (Robertson and Taylor, 1985) were omitted from the figure because they reflected an extreme outlier, in this case manic patients having clearly superior performance on a reasoning task compared with healthy participants. Inclusion of these values would further reduce the evidence for a deficit in reasoning. As it stands, the overall effect size is small, 0.21 ($\text{SE} = 0.14, p = .15$), and for studies of remitted patients is 0.33 ($\text{SE} = 0.18, p = .07$). A deficit in reasoning relative to controls was not significant within any of the four subgroups.

The tests that contributed to our meta-analysis on reasoning included the similarities and arithmetic subtests of the WAIS-R and tests of abstraction and concept attainment. Commonly, results of tests of reasoning correlate substantially with verbal abilities. The relative preservation of reasoning skills against a backdrop of marked deficits in other executive functions may reflect a pattern in which cognitive operations that are heavily dependent on language are among the least affected of the higher cognitive functions.

Verbal and Visuospatial Skills

The final cognitive domains subjected to this meta-analysis were verbal and visuospatial skills. Work in the verbal domain has been dominated by tasks assessing controlled

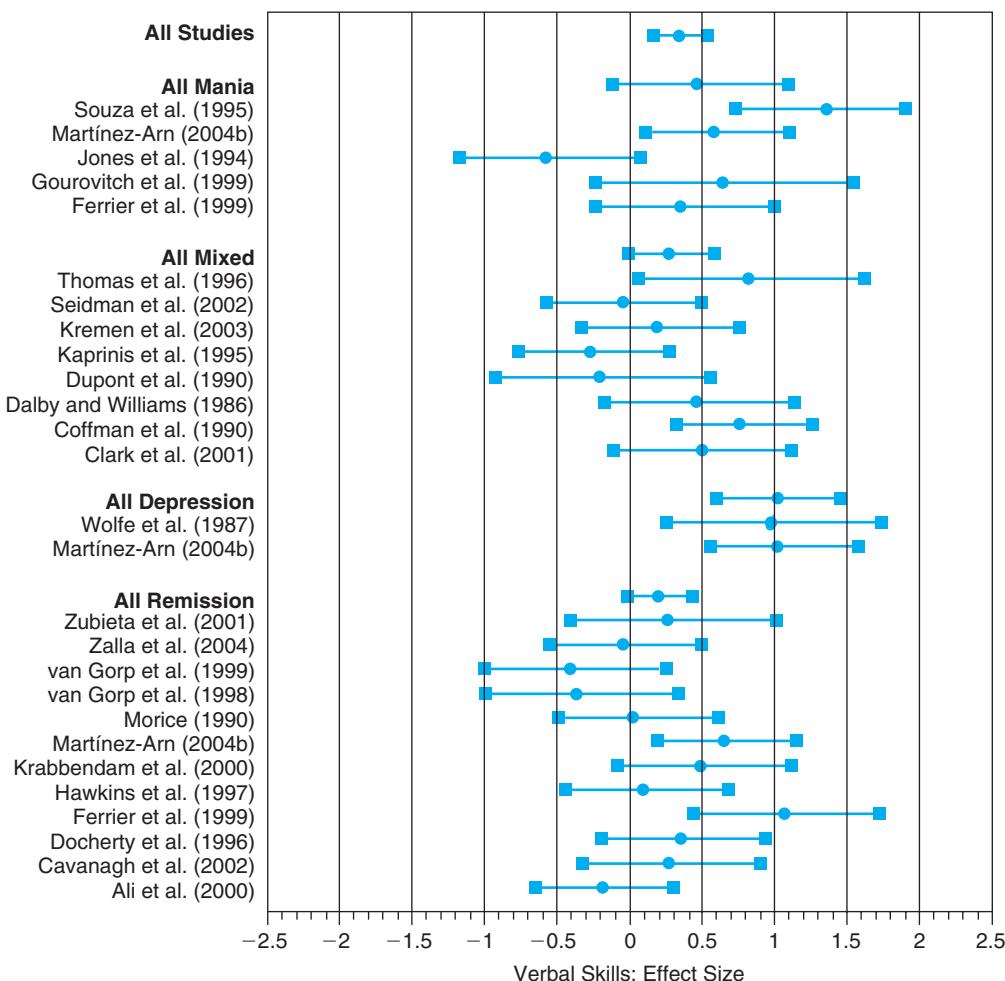

oral word association (COWA). Such tests assess the spontaneous production of words beginning with a given letter, usually F, A, or S (FAS test), within a stipulated period of time. Alternatively, the tests may assess production of words as instances of a concept, such as animal naming. Verbal fluency, especially letter fluency, has often been taken as another type of executive function. Indeed, there is evidence that COWA is one of the last measures of prefrontal function to mature, with developmental improvement extending beyond age 12, whereas adult levels are achieved considerably earlier for many other measures (Lewis, 1983). There is some evidence from both imaging and lesion studies that temporal lobe regions may make more of a contribution to category than to letter fluency. However, this distinction and the stronger claim that letter fluency is subserved largely by prefrontal regions are supported only partially by lesion analysis and imaging

activation effects, with exceptional findings suggesting more widely distributed representations.¹⁹

The copy portion of the Complex Figure Test (Rey, 1941) is the task used most commonly to represent visuospatial functions. This task involves copying a detailed and complex figure, with accuracy of reproduction being scored for 18 portions of the figure. The copying portion of the procedure is followed by delayed reproduction purely from memory. To focus on visuospatial constructional ability, as opposed to visual memory, we included only copy procedures in this domain. Other tests commonly used to sample visuospatial functions are the WAIS-R block design subtest and tests of perceptual organization, such as line orientation, gestalt completion, and embedded figures.

Figures 9–15 and 9–16 present results of our meta-analysis for the verbal and visuospatial domains, respectively. The deficits seen in verbal skills are moderate at best

Figure 9–15. Meta-analysis of verbal skill measures. Effect sizes (Hedges' G) are presented for individual study comparisons of a bipolar sample with healthy controls, as well as for samples of bipolar patients in remission, depression, mixed state, or mania and across all studies. Squares = confidence interval; circles = mean.

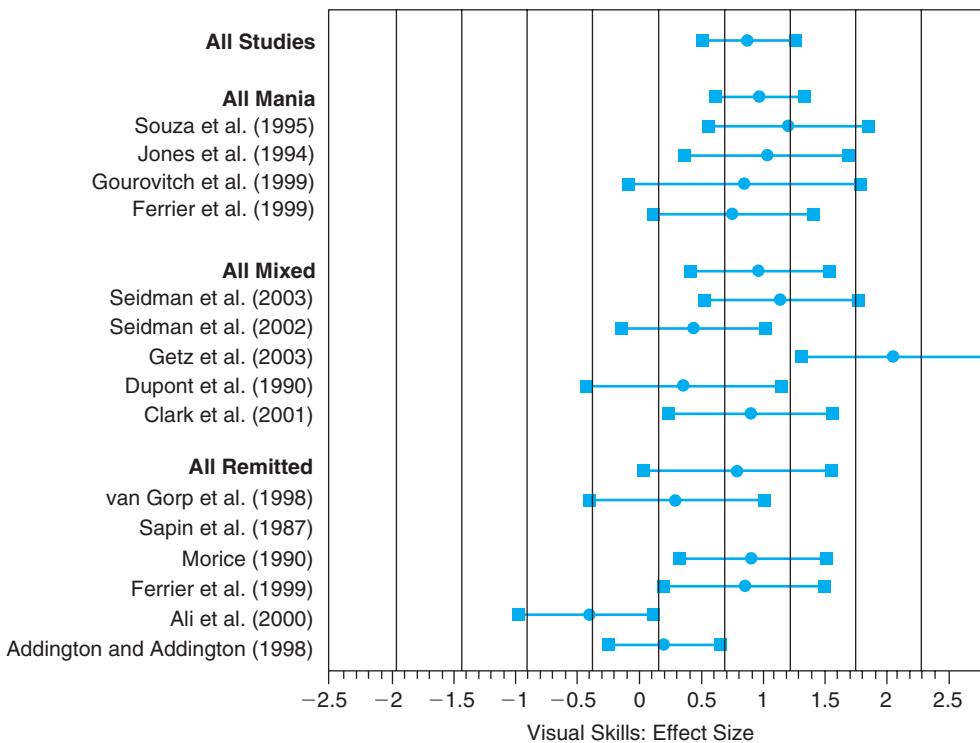

Figure 9-16. Meta-analysis of visual skill measures. Squares = confidence interval; circles = mean.

(see Fig. 9-15). The effect size (Hedges' G) for the comparison of bipolar and healthy control groups across all studies ($n=26$) is 0.35 ($SE=0.09, p<.001$). However, the effect is not significant across 12 studies of remitted bipolar samples (effect size=0.22, $SE=0.12, p=.064$) or 5 studies in mania (effect size=0.495, $SE=0.31, p=.11$). Relative to the pattern of widespread impairment across symptomatic and remitted states, verbal skills appear to have been preserved. In the few cases in which bipolar samples had inferior verbal fluency performance relative to healthy controls, the patient groups tended to make more incorrect responses (e.g., repeating the same word) and did not differ in number of responses (Wolfe et al., 1987; Coffman et al., 1990).

A different level of deficit is manifest in Figure 9-16, which summarizes our meta-analysis of visuospatial performance measures. One study (Sapin et al., 1987) was excluded because of an outlying value that only accentuated the deficit in remitted patients. Across all studies, the effect size is 0.65 ($SE=0.18, p<.001$), and in remitted bipolar patients it is 0.57 ($0.28, p<.01$).

Comparisons across Domains: The Topography of Cognitive Deficit in Bipolar Disorder

Figure 9-17 combines the values on effect size reported for the various cognitive domains and presents the cognitive

deficit profiles for the comparisons of depressed, mixed-state manic, and remitted samples with healthy controls, as well as the comparisons across all phases of illness. The profile is relatively invariant across the phases of illness. Three central points can be made.

First, the same pattern of strengths and weaknesses is seen in remission and during episodes of affective disturbance. This invariance suggests that the core disturbance is state independent. Second, it is often claimed that the magnitude of deficit is generally greatest during mania, still marked during major depression, and least evident in remission. The deficit noted by investigators as residual during remission varied considerably among the studies included in our meta-analysis. Indeed, limited power, differences in the reliability of measurement, and other factors make it likely that different tasks would achieve statistical significance in separating remitted patients from controls. By combining these findings in a meta-analysis, it became evident that the remitted samples generally had the same level of deficit as the acutely ill groups in the areas most disturbed, and perhaps somewhat less marked deficits in the areas most disturbed in the acutely ill groups (e.g., learning and memory). The larger point is that the cognitive deficits observed in remitted patients were not a pale shadow of the deficits seen during affective disturbance,

but were substantial, reliable, and of the same distribution as those seen during acutely ill states.

The third point is that against a background of generalized deficit, verbal processes as reflected in VIQ, verbal skills (i.e., verbal fluency), and reasoning are relatively preserved. This novel observation recasts the initial question about the meaning of the VIQ–PIQ discrepancy in bipolar disorder. The deficit in PIQ may not be of special note, and it may not signal, *per se*, a right-hemisphere abnormality. Rather, the effect sizes for PIQ and visuospatial skills are in the range of those for motor disturbance, attentional deficits, and other domains. What may be consequential is that verbal processes are preserved and, across the phases of illness, show less deterioration than virtually all other higher cognitive processes.

Why might this be, or better yet, what can this tell us about the neurobiology of bipolar illness? First, the fact that deficits in attention and concentration are reliably observed across the phases of bipolar illness means that cognitive impairment must be generalized. This point is underscored by the findings suggesting consistent impairment of

executive functions. Attention and concentration may be seen as the fuel of higher cognitive processes, determining the capacity and efficiency limitations on processing. Executive functions determine resource allocation and thus also broadly shape the integrity of cognitive processing. Indeed, with respect to learning, memory, and visuospatial skills, there is little evidence that deficits reflect more than an attentional disturbance. Therefore, rather than positing multiple specific deficits in bipolar disorder, one could hypothesize that a persistent noradrenergic or dopaminergic disturbance gives rise to attentional impairment that in turn produces the widespread, more generalized pattern (Swanson et al., 1998; Cools and Robbins, 2004).

But why do we see the preservation of verbal processes? Surely attentional mechanisms also drive performance in this area. There are several possibilities. First, some of the areas of preservation concern aspects of cognition that are relatively protected against the effects of brain injury. The WAIS-R vocabulary and information subtests are often considered “hold” scores, indices more likely to reflect premorbid abilities than are tests more sensitive to the effects

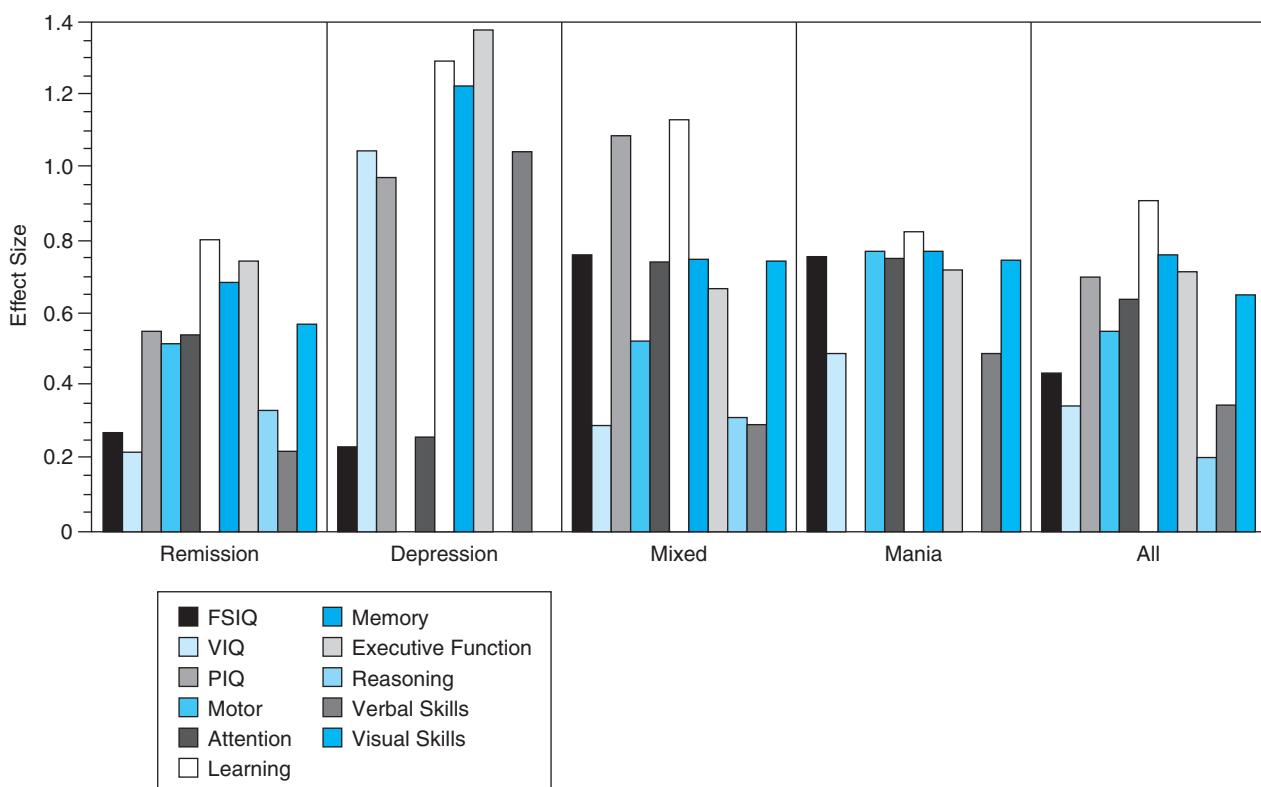

Figure 9-17. Profile of neuropsychological impairment in bipolar disorder. Effect sizes are shown for comparisons of a bipolar group (in remission or in a phase of depression, mixed state, or mania) with healthy controls for 11 cognitive domains. All bipolar subgroups, including remission, show deficits relative to controls. These impairments are most accentuated for the learning, memory, and executive function domains and are pronounced for all domains except those heavily involving verbal skills (verbal IQ, reasoning, and verbal skills). The preservation of verbal skills against a background of generalized impairment may be the salient dissociation. FSIQ = full-scale IQ; PIQ = performance IQ; VIQ = verbal IQ.

of brain damage (Lezak, 1995). These subtests assess semantic memory, or knowledge of facts, which has not been found to be impaired in bipolar disorder. Specifically, these subtests, by posing specific questions, may place few demands on attention or any form of new learning. This view posits, therefore, that the relative preservation of verbal skills is due to their escaping the deleterious and otherwise generalized impact of the core cognitive disturbance, presumably in the area of attention. However, the findings regarding verbal fluency and reasoning may belie this view since it is difficult to argue that attentional processes do not contribute to their performance.

A second alternative is to view this preservation of verbal processes as indicating a disassociation in the cognitive neural systems dysregulated in bipolar disorder. At the grossest level, this view would suggest preservation of left-hemisphere subsystems involved in verbal processing. How this could come about and the neurochemical and/or neurodevelopmental processes responsible for such a dissociation are a matter of speculation.

Finally, this asymmetry may be an endophenotype of bipolar disorder. We should not assume that the topography of cognitive function is a flat playing field in this patient population. As discussed at the outset, there is good reason to suspect that intellectual endowment is distributed differently in the families of bipolar probands than in the general population. Indeed, one of the earliest studies of children at risk found that the VIQ–PIQ discrepancy was robust before the onset of the first affective episode and was most common in children with prodromal symptoms (Decina et al., 1983; Sackeim and Decina, 1983). Thus the genetic transmission of bipolar disorder may confer a relative advantage for verbal processes. The insult that results in manifestation of the disorder may have a rather generalized effect, leading to impairments in multiple domains. This decrease in function is shared relatively equally, and verbal functions appear to be preserved only because their baseline was elevated. Research on the neuropsychological profiles of first-degree relatives of bipolar probands (Keri et al., 2001a) and of monozygotic twins discordant for bipolar disorder (Gurovitch et al., 1999) is in its infancy, but has indicated that impairments are evident in tests of learning and memory but not in verbal skills.

Other Neuropsychological Domains

A number of other cognitive functions have been studied in bipolar disorder, but with insufficient frequency to be included in our meta-analysis. These functions include auditory perception, somatosensory function, pain perception, impulsivity, processing of facial affective displays, and the extent of thought disorder. The paucity of research in these domains indicates a parochialism in the mapping of cognitive

functions in this disorder, with a strong focus on measures of attention, executive functions, and learning and memory. For example, rates of suicide are elevated in bipolar disorder, and diathesis–stress models of suicide often assume that a predisposition for impulsive behavior provides the “diathesis” and acute depressive or manic symptoms the “stress” that results in the act²⁰ (see Chapter 8). However, there are virtually no longitudinal data on measures of impulsivity or aggression in bipolar disorder, and at the clinical level, impulsivity would not be expected to be invariant, but to be accentuated during manic or mixed states. Further, characterization of the essential deficit as being in the domain of impulsivity or aggressivity may be too narrow.

An especially comprehensive neuropsychological study recently compared the profiles of medication-free depressed patients with a history of a high-lethality suicide attempt, a low-lethality suicide attempt, and no history of suicide attempt, and healthy controls. The cognitive domains sampled included general intellectual functioning, motor functioning, attention, memory, and executive functioning. A discriminant analysis indicated that different dimensions distinguished the total depressed sample from the healthy controls and distinguished the high-lethality attempters from the other patient groups. Impairment in attention and memory distinguished the patients from the controls, again highlighting that a basic attentional disturbance may be a key factor in determining the cognitive sequelae of mood disorders, both unipolar and bipolar. Impaired executive function distinguished high-lethality attempters, with the executive function measures not being restricted to indices of impulsivity. The results of this work raise the possibility that a more broad-based deficit in executive function, perhaps related to self-monitoring functions, is disturbed in individuals with a history of high-lethality suicide attempts.

Recent years have seen a movement away from the study of “cold” cognition to the study of “hot” cognition in bipolar disorder.²¹ This distinction is thought to make neuropsychological investigation more ecologically valid and more likely to address core deficits in bipolar disorder. The movement to assess hot cognition is instantiated in studies in which the information being processed, such as facial emotional expression or the meaning of affectively laden words, has affective significance. Thus in both bipolar disorder and schizophrenia, there has been a significant increase in reports on facial emotion discrimination and other aspects of the processing of emotionally laden information. A particular emphasis in this work has been the extent to which such processing is biased by the affective state of patients (depressed versus manic) (Murphy et al., 1999).

Work in this area is insufficiently developed to yield conclusions. A cautionary note is in order, however, especially in light of the enthusiastic recommendations being made to incorporate affective processing tasks in studies of mood disorders. The processes involved in the regulation of mood appear to be wholly independent of the processes that subserve the “reception” of emotion (i.e., the processing of emotionally laden information). As noted earlier, brain injury can result in highly specific deficits in aspects of emotional processing and have no impact on the regulation of mood or emotional expression. Alternatively, there can be marked disturbance in mood without apparent impact on emotional processing. It is unclear to what extent determining that the intonation of a voice is sad differs fundamentally from determining that the speaker is male, that the voice is raspy, and so on. It is clear that the presentation of such stimuli rarely has an impact on affective state. Determining that a voice is sad does not require that one feel sad, and thus these procedures cannot be said to be indirect mood manipulations.

Often the outcome of such investigation is an indication of biased processing on the part of patient subgroups. Using an affective go–no go task, Murphy and colleagues (1999) alternated happy and sad words in blocks as either targets requiring response or distractors requiring inhibition of response. Compared with healthy controls, manic patients were slower to respond to sad but not to happy targets, whereas depressed patients were slower when responding to happy but not to sad targets. Manic patients also had an excess of response inhibition errors (responding to a distracter). Thus, the results of this study suggest a difference between depressed and manic patients in attentional bias as a function of affective valence. This effect was not seen in remitted patients in a subsequent study (Rubinsztein et al., 2000). Note that this effect can be distinguished from mood congruence effects. In the study by Murphy and colleagues (1999), patients were impeded in processing targets that did not correspond to their affective state. Mood congruence phenomena reflect privileged access to evaluations, memories, and so on that are congruent in emotional content with the current mood state.

Nonetheless, there is evidence that current affective state impacts the processing of ongoing affectively charged information. More broadly, mood congruence effects also pertain to the differential retrieval of memories, the attributions made for ongoing positive and negative events, and other aspects of complex cognitive function. For example, the depressed state is frequently characterized by a marked cognitive bias, referred to as depressive realism. When healthy controls, or for that matter patients with schizophrenia, are confronted with success, the tendency is to assume that they caused this outcome, they should be

praised, and the outcome was very good. In contrast, when confronted with failure, healthy controls will often state that the outcome was uncontrollable, they should not be blamed, and it was not so bad anyway. While patients with major depression might be expected to show a reverse bias, to overaccentuate the negative, their attributions tend to be much more even-handed than those of controls, and thus by most accounts, more realistic (Sackeim and Wegner, 1986). Therefore, it is fair to say that the states of depression and euphoria are characterized by a gross alteration in cognitive schema, reflecting diminished or absent self-serving biases in the depressed state (Taylor and Brown, 1988, 1994; Colvin and Block, 1994). If the objective of recent work on hot cognition in mood disorders is to address state-related biases in information processing, it is far from clear that studies of facial emotional identification provide the optimal models.

FACTORS AFFECTING COGNITIVE FUNCTION

Treatment

In many of the studies included in our meta-analysis, bipolar patients were tested in an unmedicated state when depressed or manic, but were medicated when studied in the remitted state. This convention arises from the fact that a period of medication withdrawal in acutely ill patients is considered acceptable before starting a new treatment. Indeed, in some cases such withdrawal is of clinical value. On the other hand, the risks of relapse are so high that withdrawal of treatment in recently remitted patients is unacceptable. Consequently, this pattern introduces a potentially serious confound in much of the neuropsychological and neurobiological investigation of state-independent phenomena in bipolar disorder. Specifically, could the widespread neuropsychological impairment seen in remitted patients be a result of an adverse and generalized cognitive effect of continuation and maintenance treatment? Could lithium, the anticonvulsant medications, or the antidepressants be responsible for this cognitive profile? To the extent that patients in some studies are abruptly withdrawn from psychotropics, what impact does drug withdrawal have on cognitive function?

For example, Martinez-Aráñ and colleagues (2004a) conducted a comprehensive study of cognitive impairment in euthymic bipolar patients, contrasting 40 such patients with 30 healthy controls and accounting for the effects of subsyndromal symptomatology. After controlling for age, premorbid IQ, and subsyndromal symptomatology, the patient sample still manifested deficits on several measures of memory and executive functions. The extent of verbal memory impairment was related to a longer duration of illness,

a higher number of manic episodes, and prior psychotic symptoms. However, 38 of the 40 patients were receiving psychotropic medications at the time of testing: 33 of the 40 were being treated with lithium carbonate, 12 with carbamazepine, and 7 with valproate; 11 patients were receiving more than one mood stabilizer; 23 were also being treated with antipsychotic medications (15 of which were on atypical antipsychotics), 17 were being given benzodiazepines, and 8 were receiving antidepressants. The complexity of these medication regimens is characteristic of the long-term treatment of bipolar disorder and illustrates the difficulty of ruling out adverse medication effects or interactions in naturalistic studies.

The most rigorous way of addressing this question is to conduct a randomized, placebo-controlled trial. Given the possibilities of state-related changes in cognition, fluctuating clinical symptomatology, effects of ancillary medications (e.g., benzodiazepines), practice and order effects, and other factors, adverse cognitive effects of primary mood-stabilizing or adjunctive sedative medications could easily be falsely accentuated or underestimated. Especially in clinical populations, however, the feasibility and ethics of such a study are questionable.

The best alternative in such a circumstance is longitudinal investigation using an ABA design, with patients being tested while on (A) and off (B) medication. Perhaps the most critical study in this area used such a design. Shaw and colleagues (1987) studied 28 outpatients with mood disorders maintained on lithium prophylaxis. Of these 28, 22 completed the protocol, 6 being dropped because of clinical deterioration; a criterion for participation was maintaining euthymia throughout. On average, patients had been maintained on lithium for 9.4 years ($SD=5.8$ years), with an average level of 0.80 mEq/L ($SD=0.23$ MEq/L). Patients were tested at the same time each week at each of five weekly sessions. The first session took place while patients continued to receive lithium, the second and third while they received substituted placebo, and the fourth and fifth after they had returned to lithium. Motor speed was assessed using the finger-tapping procedure, and the Buschke Selective Reminding Test was used to evaluate effects on learning and memory.

Over the 5 weeks of this study, depression and mania symptom scores were flat and in the euthymic range. Lithium levels went from a mean of 0.83 mEq/L at the first session to 0.05, 0.04, 0.71, and 0.74 at sessions 2 through 5, respectively. Figure 9-18 presents the results for the finger-tapping task and Figure 9-19 those for the memory test. Motor speed was quantified as the mean number of taps per five 10 s trials with both the dominant and nondominant hand. There was a significant difference in tapping performance across the 5 weeks, with motor speed improving after

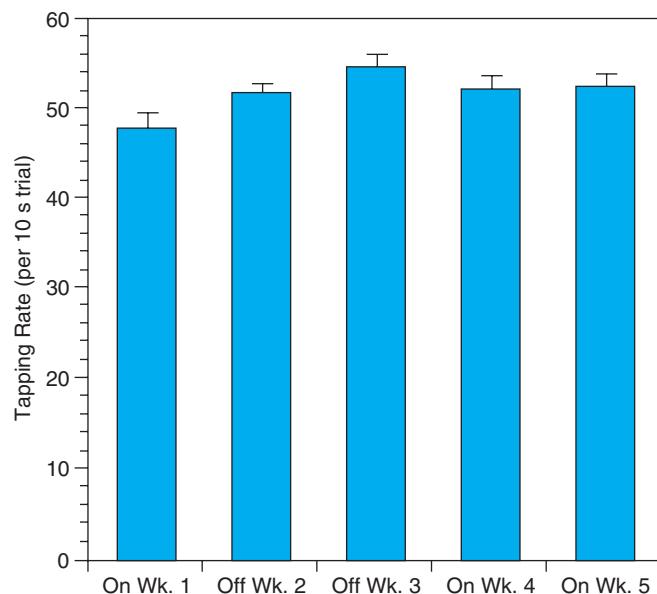

Figure 9-18. Tapping rate with lithium discontinuation and reinstatement. Twenty-two patients were retested for tapping speed weekly for 5 weeks. Lithium was discontinued after the first week and reinstated by the fourth week. Tapping speed improved in weeks 2 and 3 off lithium and slowed with lithium reinstatement. (Source: Shaw et al., 1987.)

discontinuation of lithium and deteriorating with its reintroduction. The magnitude of this effect, while consistent, was small. For example, the deterioration between weeks 3 and 5 ($p < .02$) averaged a 4.2 percent reduction in tapping rate.

The study by Shaw and colleagues (1987) constituted the first report of reversible lithium-induced motor speed impairment. Several previous studies of patients and healthy participants had suggested that lithium had a negative effect on performance of the WAIS-R digit symbol test and possibly on perceptual-motor tasks (Demers and Heninger, 1971; Judd, 1979; Squire et al., 1980). The digit symbol subtest is usually regarded as an attentional measure. Given its timed nature, however, motor slowing would have a negative impact. Thus the findings of the Shaw et al. (1987) study raise the possibility that lithium resulted in a subtle slowing of basic motor movement, which could affect any timed procedure.

The findings obtained with the Buschke Selective Reminding Test are illustrated in Figure 9-19. This test produces a variety of indices of the adequacy of short- and long-term memory, and a representative index of each is plotted in the figure. Short-term recall is heavily influenced by attention and reflects the recall of items just recently presented, as in the reminding procedure. Long-term recall concerns the number of words recalled at some interval since original presentation or reminding. No impact of

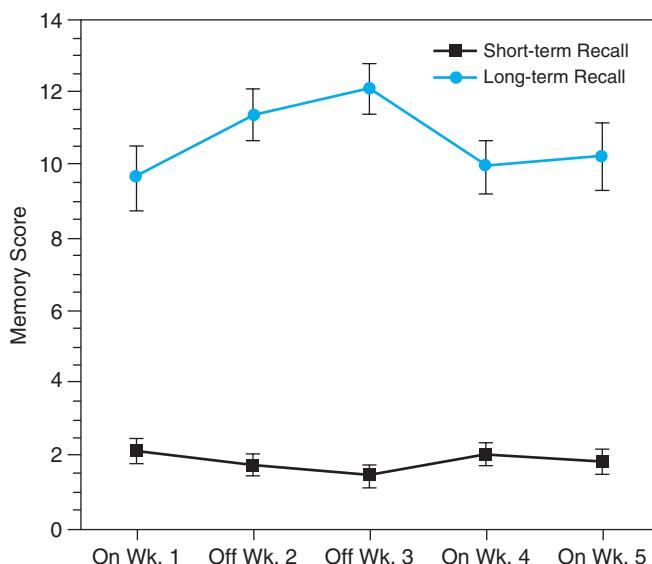

Figure 9-19. Short- and long-term recall on a verbal learning and memory test with lithium discontinuation and reinstatement. Lithium was discontinued after the first week and reinstated by the fourth week. Short-term or immediate memory was unaffected by lithium status. Long-term recall was reduced when patients were given lithium. (Source: Shaw et al., 1987. Reprinted with permission.)

lithium withdrawal or reintroduction on the short-term memory measures was observed. Instead, substantial improvement in long-term memory measures occurred when lithium was removed, and deterioration when it was reintroduced. At face value, these data suggest that lithium had little impact on the attentive processes involved in the immediate recall of new information, but produced a significant compromise (about 20 percent) in the amount of information that could be recalled with a delay since presentation. In other words, these data suggest that lithium produced a mild anterograde amnesia.

In fact, although negative findings have been reported regarding lithium's effects on memory (Squire et al., 1980), a substantial literature is consistent with these effects. Reus and colleagues (1979) compared 17 bipolar manic patients receiving lithium with 7 other patients who had discontinued lithium for at least 3 weeks (5 because of pregnancy). Using procedures similar to those of Shaw and colleagues (1987), they found that the lithium group had a deficit in long-term recall. Specifically, this deficit pertained to the capacity to recall consistently material for which earlier learning had been established. This finding supports the possibility that lithium has negligible effects on attention and the intake or encoding of new information, but interferes with the retrieval of what has been learned. Were this the case, it would represent a neurocognitive profile distinct from that which appears to characterize bipolar patients in

remission, in whom learning and memory appear to be equally disrupted (see Fig. 9-17). Other research has yielded findings that support this framework. Two studies of healthy participants found that retrieval of information after a long delay (7 to 14 days) was impaired by lithium (Karniol et al., 1978; Kropf and Muller-Oerlinghausen, 1979). And in a study of 18 bipolar patients, Christodoulou and colleagues (1981) found no effect of a 16-day placebo period on short-term memory measures.

In this light, the findings of naturalistic studies of cognitive impairment in bipolar disorder may take on different meaning. Lund and colleagues (1982) found that chronic bipolar patients stabilized on lithium performed in the low-average range on tests of attention and memory, below expectations given their educational achievement. This pattern in remitted patients could reflect both a trait-level deficit in attentional and executive functions and a specific deleterious effect of lithium on long-term retrieval. Kessing (1998) found that both the number of affective episodes and treatment with lithium were associated with inferior performance on two of five tests of diffuse cognitive function. In this case, exposure to lithium and the effects of chronicity could not be separated. Finally, Engelmann and colleagues (1988) conducted a longitudinal cognitive investigation of bipolar patients treated with lithium. They found little evidence of a cumulative deleterious effect, as there was significant decline over a 6-year follow-up period in only 1 of 10 memory subtests. However, evidence from discontinuation and reinstatement studies indicates that adverse effects of lithium on cognition are expressed immediately, and reverse at least partially with discontinuation. The findings of Engelmann and colleagues (1988) are critical in suggesting that any short-term negative impact is not cumulative.²²

Cognitive impairment is a common complaint of patients treated for bipolar disorder, and undoubtedly contributes considerably to nonadherence to treatment regimens (see Chapter 21). It has been common for clinicians to dismiss such complaints of clouded thinking, slowed processing, or memory impairment as reflecting the ravages of the illness, somatization and negativism on the part of the patient, and the like. Teasing out which if any cognitive effects reflect disease processes and which indicate adverse pharmacological effects is next to impossible for any individual patient. Given the neurotoxicity of lithium at high doses, it should not be unexpected if some individuals show cognitive sensitivity and experience a range of cognitive impairments while receiving the drug. In some cases, these effects can be addressed through dosage reduction. However, especially for patients in whom lithium is clearly more effective than alternative maintenance agents, there may be no choice but to accept these side effects as part of the price of maintaining

remission. In this respect, the absence of evidence that lithium per se has a cumulative deleterious influence and the clear evidence of reversal of deficits once the drug is discontinued should be reassuring. So, too, should the accumulating body of evidence indicating that lithium exerts a neuroprotective effect (see Chapter 14).

As noted earlier, an especially common complaint of patients receiving long-term treatment with lithium is blunting of creativity. Similar to the notion that lithium can blunt the peaks of extreme dysphoric and euphoric states, some patients report that lithium interferes with the highest levels of creativity. Given the apparent overrepresentation of bipolar illness among individuals in the creative arts, the frequency of this complaint is not surprising (see Chapter 12).

Evaluating the validity of this claim is difficult, however. Enhanced creativity is frequently reported in hypomanic states, with a concomitant increase in productivity. Rather than a reduction in creativity being attributable to lithium, effective treatment of bipolar disorder and the maintenance of sustained remission may have this untoward consequence. Were this the case, however, complaints about reduced creative abilities should be reported for any agents that produce or sustain remission. Yet experience indicates that such complaints are especially common among those being treated with lithium as opposed to other mood stabilizers. Indeed, a preliminary and, as far as we know, as yet unreplicated case study, has been reported in which complaints of diminished creativity were reduced by switching from lithium to sodium divalproex (Stoll et al., 1996).

The obvious difficulty here involves operationalizing the construct of creativity. No single neuropsychological test fully captures this construct. Shaw and colleagues (1986) conducted a critical study in this area, which is one of the only controlled studies to date of lithium's effects on the creative process. When given a word association task, such as providing associations for the word "camera," individuals will differ in the number and in the novelty or idiosyncrasy of the associations they report. Norms in fact exist for the frequency of particular associations. "Photograph" would be a highly common association for the stimulus "camera," whereas "chamber," "private," "stealth," or "sub rosa" would be understandable but idiosyncratic responses. Using the same methodology over a 5-week testing period involving discontinuation and reinstatement of lithium, Shaw and colleagues (1986) found that upon discontinuation, remitted patients were more generative and also showed an increase in idiosyncrasy of association. Both effects reversed when lithium was reinstituted (see Chapter 12 for further discussion of this and related studies). In a subsequent study, this effect of discontinuation was reaffirmed (Kocsis et al., 1993). Therefore, the extremely limited data available suggest that lithium may result in a

diminution of unusual associations, making the case for an impact on creativity more plausible. The effect may be complicated in those patients in whom discontinuation of lithium precipitates a rapid relapse to hypomania and thus an increase in associational fluency secondary to mood state.

This focus on the cognitive sequelae of lithium should not be taken as implying that the major alternatives to lithium, anticonvulsant mood stabilizers, do not present similar issues. Rather, it is only in the case of lithium that there is a substantial empirical literature on potential adverse cognitive effects. Indeed, examination of the neuropsychological effects of the anticonvulsants is standard in evaluating their use in seizure disorders.

Clinical Features

A good deal of medical research involves searching for clinical-pathological correlations in an effort to identify individuals at heightened risk or to further our understanding of disease processes. Once it has been accepted that manic-depressive illness, especially its bipolar form, is associated with a profile of cognitive deficits, a host of questions arise regarding the factors that influence the expression of such neuropsychological disturbances. For example, do all individuals manifest the cognitive deficits characteristic of bipolar illness, or do subgroups manifest these effects more intensely? Alternatively, does the manifestation of cognitive deficits change with development? In particular, does chronicity of illness affect the expression of such deficits? Is the adult pattern of cognitive deficit seen in pediatric bipolar disorder or in children at risk for the disorder? If so, does this obviate the potential confound of medication effects? And to what extent does the severity of cognitive deficits covary with structural abnormalities of the brain, especially the burden of hyperintensities as revealed by fMRI?

Psychotic Features

A number of studies have found a link between the presence of psychotic features and a more chronic and severe course of bipolar illness with respect to both symptomatic and functional outcomes.²³ Especially since cognitive impairment is linked to poorer functional outcomes in bipolar disorder (Zarate et al., 2000), one might surmise that psychotic features are predictive of poorer neuropsychological outcome. This conjecture has received some empirical support. Albus and colleagues (1996) failed to find differences in cognitive performance between first-episode nonpsychotic patients with mood disorders and healthy controls. In contrast, mood disorder patients with psychotic features performed as poorly as patients with first-episode schizophrenia. Thus in this study, the presence of psychosis

was found to be a greater determinant of neuropsychological profile than the diagnosis of mood disorder or schizophrenia. In light of the neuropsychological deterioration often seen early after the onset of psychosis in first-episode schizophrenia and the hypothesis that psychotic states are intrinsically toxic (Wyatt, 1991, 1995), it is especially important to examine the validity of this association and to determine whether early intervention can improve cognitive and other long-term outcomes in patients with bipolar disorder with psychotic features. The duration of untreated psychosis in patients with first-episode schizophrenia is associated with both the quality of symptomatic outcomes and the extent of cognitive deterioration (Norman and Malla, 2001; Amminger et al., 2002).

Chronicity and Other Developmental Effects

An active effect of psychiatric illness on brain structure and function need not be restricted to psychotic subtypes. Altshuler (1993) and others have contended that episodes of depression and mania may have similar consequences. Indeed, a particularly popular view is that the release of excessive glucocorticoids during such episodes leads to hippocampal atrophy and consequent disruption of declarative memory processes (Brown et al., 1999) (see Chapter 15). This possibility accords with data indicating that the lifetime duration of depression is associated with hippocampal volume and verbal memory performance in euthymic women with recurrent major depression (Sheline et al., 1996, 1999). A role for interventions is supported by recent evidence that the linkage between lifetime duration of days depressed and structural and functional outcomes holds only for periods without active antidepressant treatment (Sheline, E., personal communication, May 2004).

Bipolar patients can vary in the chronicity of their disorder, differing in the number of episodes, type of episodes, number of hospitalizations, duration of episodes, and severity of symptoms. The directions of these effects are not necessarily uniform. An unremitting, continuous episode of illness may indicate greater chronicity than a history of recurrent but responsive episodes. Adequate metrics by which to evaluate the course of bipolar illness are unavailable. Nonetheless, patients with more severe symptomatic presentations and with courses of illness lacking long periods of remission (e.g., chronic and/or recurrent) tend to have poorer neuropsychological outcomes.²⁴ Cognitive outcomes in bipolar patients have been linked to a rapid-cycling course (McKay et al., 1995), number of prior hospitalizations (Tham et al., 1997), and lifetime duration in episodes of mania or depression (van Gorp et al., 1998). Denicoff and colleagues (1999) found that number of episodes, longer duration of illness, and more frequent hospitalizations were each associated with performance on tests of

attention, abstraction, and memory. Kessing (1998), using regression techniques, found a linkage to cognitive dysfunction for number of episodes and not for duration of illness (see Chapter 4).

While the consensus on this issue is impressive, each of the supportive studies used a cross-sectional design. Two observations illustrate the problem: (1) a more virulent course is associated with neuropsychological deterioration, and (2) patients in remission manifest a profile of cognitive dysfunction, noteworthy mainly for the relative sparing of verbal functions, but otherwise widespread. It is conceivable that the abnormalities seen in remitted patients reflect the deterioration associated with chronicity and are not present from the onset of illness. If so, longitudinal evaluation should detect this change over time. Unfortunately, longitudinal investigation of cognitive function in bipolar disorder has rarely been conducted. An exception in this regard is a study conducted by Dhingra and Rabins (1991). They followed for 5 to 7 years 25 bipolar patients who initially presented in a manic state with no signs of cognitive impairment. At long-term follow-up, approximately one third of the sample had clinically significant cognitive impairment.

Another approach can be taken to determine whether the cognitive deficits seen in euthymia precede the classic expression of illness, accompany the onset of the first affective episode, or are a result of the expression of the disorder. Evaluating family members of bipolar probands, children at risk for bipolar disorder, or pediatric manifestations of bipolar disorder can provide clues to the unfolding of cognitive deficits in this illness. For example, Dickstein and colleagues (2004) compared 21 bipolar children with 21 age- and gender-matched controls on the Cambridge Neuropsychological Test Automated Battery. The bipolar children had a profile of deficits similar to that seen in adults, with deficits in attention, set shifting, and visuospatial memory. Post hoc analyses indicated that these deficits could not be attributed to manic symptoms or the presence of attention-deficit disorder. The average age of the bipolar sample was 12.7 years (range 6 to 17 years), and it is conceivable that the medications used to treat the condition or other ancillary factors distorted cognitive performance. Clarification of the neuropsychological profiles of children at risk (as well as family members) could help clarify these issues while minimizing the confounding effects of illness expression and treatment.

Results of a study by Burt and colleagues (2000) suggest that neuropsychological course may be quite different in bipolar and unipolar patients. The authors compared young and elderly unipolar and bipolar patients in an episode of major depression on the performance of a variety of memory measures. No differences in performance were found

between the young bipolar and unipolar groups, while the elderly bipolar patients had markedly inferior performance compared with all other groups. The authors speculated that the history of more frequent affective episodes and the earlier age at onset in the bipolar group resulted in a more pronounced deteriorative process.

The evidence, reviewed earlier, that lithium has negative but quickly reversible cognitive effects does not contradict the possibility that the drug also exerts neuroprotective effects (Manji et al., 2000a,b) (see Chapter 14). To date, there is no evidence that long-term exposure to lithium, as opposed to any other agent, has a specific or general impact on the cognitive deficits characteristic of bipolar disorder. Research to address these issues is essential.

Structural Brain Abnormalities

The fact that some neurocognitive effects reverse with the discontinuation or reinitiation of lithium demonstrates a causal pathway. However, medication effects are unlikely to account for the bulk of the deficits seen during symptomatic or remitted states. There appears to be a core pattern of cognitive deficit that is manifested across the phases of illness. Some evidence indicates that duration of lifetime exposure to major depression covaries with hippocampal volume and a measure of verbal memory. More generally, the evidence for persistent cognitive deficit raises the issue of neuroanatomical correlates (see Chapter 15). There are particular reasons for investigating the relations of MRI hyperintensities (HI) to cognitive manifestations in bipolar disorder.

In comparison with healthy controls and other neuropsychiatric groups, elderly patients with major depressive disorder have consistently shown high rates of abnormality in MRI evaluations. These abnormalities appear as areas of increased signal intensity in both balanced, T_2 -weighted and fluid-attenuated inversion recovery (FLAIR) images. T_1 -weighted sequences maximize the contrast between gray and white matter and provide fine anatomic detail. In contrast, T_2 -weighted and FLAIR sequences are particularly sensitive in identifying fluid-filled areas, which appear as areas of high signal intensity.

The abnormalities can be classified into three types. Periventricular hyperintensities (PVH) are a halo or rim adjacent to ventricles that in severe forms invades surrounding deep white matter. Alternatively, single, patchy, or confluent foci may be observed in deep white matter hyperintensities (DWMH), with or without PVH. HI may also be found in deep gray structures, particularly the basal ganglia, thalamus, and pons. These abnormalities have been referred to as leukoencephalopathy, leukoarosis, subcortical arteriosclerotic encephalopathy, encephalomalacia, and unidentified bright objects (UBOs). Because the HI in major depression

are not restricted to white matter and their etiology has not been established, we use the term encephalomalacia.

Figure 9–20 illustrates a moderate-to-severe case of encephalomalacia. FLAIR images are presented for a patient with late-onset, first-episode major depression. The image on the left illustrates PVH, with thick bands of high signal intensity (white) adjacent to the lateral ventricles. Note that on the left side of this image, the HI are extending into the deep white matter. The image on the right is of a higher MRI slice from the same patient and shows multiple confluent HI through the DWMH. In patients presenting with these MRI findings, clinicians typically receive radiological reports that emphasize ischemic small-vessel disease.

In one of the largest prospective MRI series in major depression, all 51 elderly patients (aged >60) referred for ECT presented with HI, more than half rated moderate to severe, and 51 percent had lesions of subcortical gray nuclei (Coffey et al., 1990). These rates of abnormality greatly exceeded those found in a healthy control sample, with basal ganglia abnormalities being most discriminative (Fig. 9–21). The depressed samples studied to date have often included patients with comorbid medical illnesses, without adequate controls for risk factors for cerebrovascular disease (CVD), medications being taken, or drug abuse. Nonetheless, in the work of Coffey and colleagues (1990), when depressed patients with preexisting neurological conditions were excluded, the rate of encephalomalacia greatly exceeded that found in normal controls. In a replication study, patients with major depression showed marked increases in the frequency of PVH, DWMH, and basal ganglia and thalamic HI relative to controls matched for CVD risk factors (Coffey et al., 1993). The age-adjusted odds ratio for PVH was 5.32. In other, often large population studies of elderly healthy controls, when the halos or caps commonly seen at the top and bottom of the lateral ventricles were excluded, approximately 10 to 30 percent presented with MRI white matter abnormalities, with typically mild severity and low rates of subcortical gray matter abnormalities (Breteler et al., 1994).

The rate or severity of encephalomalacia in geriatric depression may equal or exceed that in Alzheimer's disease (Erkinjuntti et al., 1994) and may be comparable to that in multi-infarct dementia (Zubenko et al., 1990; see Sackeim et al., 2000a, for a review). Meta-analyses have supported the excess of HI in geriatric unipolar depression (Videbech, 1997). These abnormalities tend to be overrepresented in frontal lobe white matter and in the basal ganglia, perhaps with a left-sided predominance (Greenwald et al., 1998). For instance, Greenwald and colleagues (1998) found that left frontal DWI and left putamen HI discriminated between an elderly unipolar sample and a matched healthy comparison group.

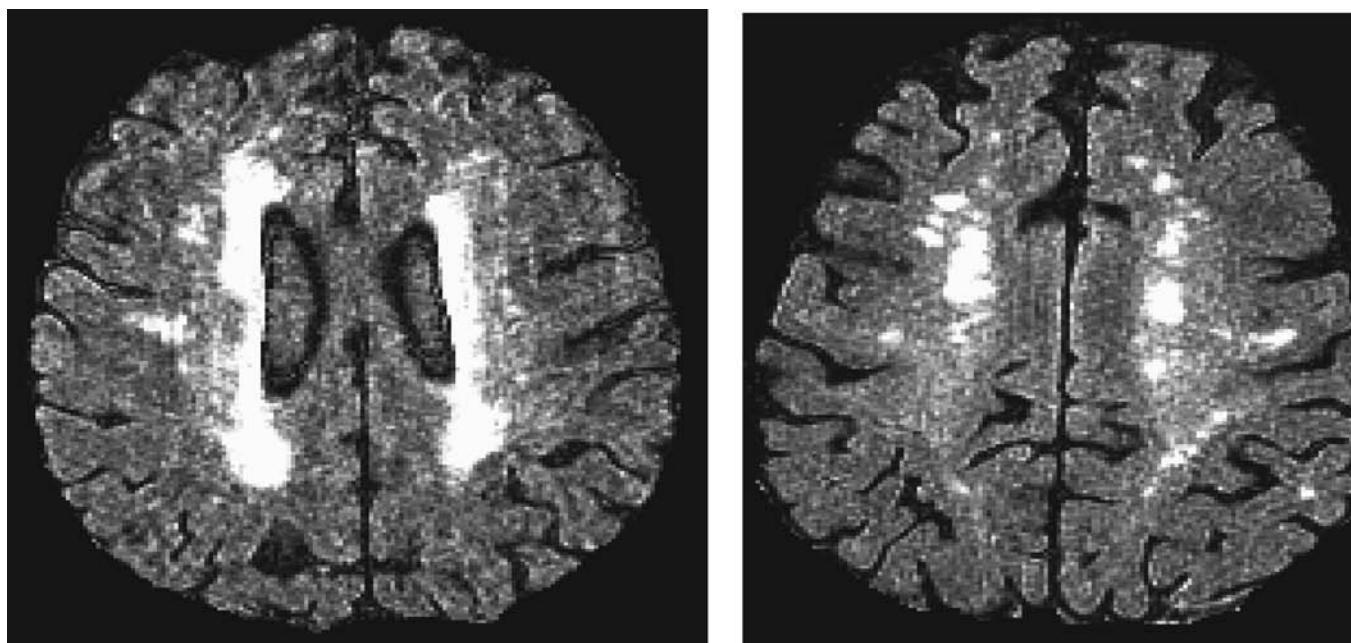

Figure 9–20. Fluid-attenuated inversion recovery (FLAIR) images of a patient with late-onset major depression. White or bright areas show magnetic resonance imaging (MRI) hyperintensities. The image on the left demonstrates periventricular hyperintensities, with a broad band of increased signal adjacent to the lateral ventricles and invading the deep white matter. The image on the right, from the same patient at a higher level, shows multiple, confluent foci of hyperintensities in the deep white matter (centrum semiovale).

Several correlates of HI burden have been suggested in studies of elderly unipolar patients. The excess of HI appears to be most marked in patients with late- as opposed to early-onset mood disorder.²⁵ In turn, this association may be due to a greater rate of cerebrovascular risk factors in the late-onset population. Indeed, as in normal and neurological samples, the strongest predictors of encephalomalacia in unipolar depression are age and cerebrovascular risk factors. There are also suggestions that, in addition to late onset, absence of a family history of mood disorder is predictive of HI burden (Krishnan et al., 2004). This finding regarding transmission of mood disorder would suggest determination of whether family history of CVD is overrepresented in unipolar or bipolar patients with significant encephalomalacia, an issue yet to be resolved.

In unipolar patients, the presence of encephalomalacia has predictive power with respect to treatment outcome and subsequent course. In naturalistic studies, greater HI burden has been associated with poorer acute response to antidepressant medications and ECT.²⁶ The limited information on longitudinal follow-up suggests that encephalomalacia in unipolar disorder may be a marker for cognitive decline and the development of dementia (Hickie et al., 1997; Baldwin et al., 2000).

In normal, nonsymptomatic subjects, some degree of encephalomalacia may be observed, and its prevalence and

extent are linked to aging. It is unclear whether the limited encephalomalacia in normal samples is associated with cognitive impairment, and there may be threshold effects for HI volume (Boone et al., 1992). Nonetheless, in normal and neurological samples, there is a body of replicated findings associating encephalomalacia specifically with deficits in attention, motor speed, and executive function (e.g., Breteler et al., 1994; see Sackeim et al., 2000a, for a review). As noted earlier, these are hallmark deficits in unipolar and bipolar depression. In nonpsychiatric patient samples, the most common neurological abnormalities associated with encephalomalacia are gait disturbances, tendency to fall, extensor plantar reflex, and primitive reflexes.²⁷

There has been limited investigation of the neuropsychological correlates of encephalomalacia in unipolar major depression. Ebmeier and colleagues (1997) found that the severity of DWMH was inversely related to global cognitive function (Mini-Mental State scores) in elderly depressed patients. In an especially comprehensive study, Lesser and colleagues (1996) compared 60 late-onset (>50 years of age) unipolar depressed patients, 35 early-onset (<35 years of age) depressed patients, and 165 normal controls. All subjects were at least 50 years of age. The late-onset group had greater DWMH than either of the other groups. Cognitive deficits were most marked in the late-onset group and pertained to nonverbal intelligence, nonverbal memory, constructional ability, executive function,

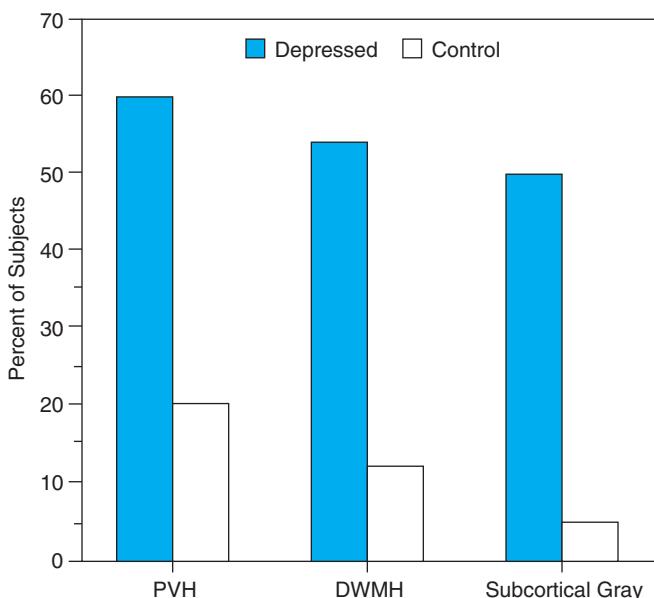

Figure 9–21. Representation of the findings of Coffey and colleagues (1990). The percentages of patients with major depression and control subjects are contrasted in rates of periventricular hyperintensities (PVH), deep white matter hyperintensities (DWMH), and hyperintensities in subcortical gray matter structures.

and speed of processing. Patients with greater severity of DWMH had significantly poorer executive function.

Jenkins and colleagues (1998) found that elderly depressed patients with HI showed poorer performance on a number of learning and memory indices, with the pattern of deficits resembling that observed in subcortical degenerative disorders (i.e., Huntington's and Parkinson's diseases). Simpson and colleagues (1997b) conducted neuropsychological assessment after treatment of an elderly unipolar depressed sample. Signal abnormalities in the pons were associated with reduced psychomotor speed, basal ganglia HI were linked to impaired category productivity (executive function), and PVH were associated with recall deficits. It should be noted that since the severity of encephalomalacia in this study was also associated with clinical outcome, the findings regarding neuropsychological correlates may have been confounded with clinical state. Yet the findings of these and other studies indicate that in general, encephalomalacia in elderly unipolar patients is associated with impairments of psychomotor function, attention, executive function, and learning and memory. There is also evidence that specific cognitive domains may be affected by the anatomic location of HI (deep white matter, periventricular, or subcortical gray matter structures).

The characterization of encephalomalacia in bipolar disorder is less certain, in part because it has received less research attention. Nonetheless, encephalomalacia clearly has different meanings in bipolar and unipolar disorder.

In considerably younger samples than those studied in unipolar disorder, several groups have reported that MRI HI are more common among young bipolar patients than controls.²⁸ Aylward and colleagues (1994) found that older (>age 38) and not younger bipolar patients had an excess of HI. Brown and colleagues (1992) failed to detect an excess in young bipolar patients, although they did observe that severe HI were overrepresented in elderly patients with major depression. In a sample of 600 psychiatric patients who underwent MRI, Breeze and colleagues (2003) failed to observe a difference in rates of DWMH in bipolar patients compared with other psychiatric groups. However, in the same sample, this group reported that bipolar patients had a clear excess of *severe* DWMH compared with other groups (Lyoo et al., 2002). In relatively small samples, Silverstone and colleagues (2003) compared bipolar depressed, unipolar depressed, and healthy participants and found that the bipolar patients had twice the rate of severe DWMH relative to unipolar patients or healthy controls. Ahn and colleagues (2004) recently confirmed an excess of DWMH in bipolar adults relative to healthy controls, with the discrimination being strongest for more severe structural abnormality.

The findings of two recent studies are particularly revealing. Pillai and colleagues (2002) compared rates of white matter HI in adolescents with bipolar disorder and schizophrenia and matched healthy controls. These HI were more common in the bipolar group (67 percent) relative to the schizophrenic (37 percent) and comparison (32 percent) groups. HI occur in individuals with early-onset bipolar disorder and have been reported at first psychiatric contact. Ahearn and colleagues (1998) conducted MRI examinations of the affected and unaffected first-degree relatives of bipolar probands. Of the 21 family members examined, 15 had HI, including 6 of 10 family members with no history of mood disorder and all of those with bipolar disorder. Lesions of both white matter and subcortical gray nuclei were seen. The authors raised the possibility that these HI serve as a biomarker of bipolar disorder.

The literature on encephalomalacia in bipolar disorder is somewhat less consistent than that in unipolar disorder in demonstrating this structural abnormality. On the other hand, some authors claim that encephalomalacia is especially marked in bipolar disorder. The reasons for this discrepancy are not well understood. Nonetheless, reports demonstrating differences from healthy participants and other psychiatric groups are sufficient for us to conclude that bipolar disorder is characterized by an excess of these structural abnormalities. In their meta-analysis, Bearden and colleagues (2001) found a pooled odds ratio of 7.2 for the likelihood of HI in bipolar patients relative to healthy participants.

The striking thing is that the correlates of these abnormalities appear to differ in bipolar and unipolar disorder. There is a dramatic difference in age at manifestation. In all populations studied to date, HI burden increases with advancing age. This may also be true in bipolar disorder. What is exceptional, however, is that adolescents with bipolar disorder show the abnormality (Botteron et al., 1995; Lyoo et al., 2002; Pillai et al., 2002). In unipolar patients and neurological samples, the presence and severity of HI are linked to CVD. Indeed, the predominant view is that encephalomalacia is an outcome of ischemic changes in white matter watershed areas that are fed by tiny arterioles and have limited collateral vascular supply. Rigidification of these small vessels or blockage through arteriosclerosis will result in ischemic damage. Not surprisingly, then, age and cerebrovascular risk factors would be key determinants. Further, given this hypothesized vascular etiology, it is not surprising that encephalomalacia is especially prevalent in late-onset depression in patients without a family history of mood disorder. It is CVD that is the primary agent, and not a genetic liability to depression. Indeed, the invasion of fibers in the white matter by HI must be a random process. If the right fibers are damaged, major depression may result as disconnection syndrome (Geschwind, 1965). Further, it makes sense that encephalomalacia, by reflecting ischemic brain changes, is associated with specific forms of cognitive impairment and predicts future course.

The young age at which many bipolar patients show this abnormality makes it unlikely that these HI are the outcome of an ischemic disease process. Indeed, the notion that the severity of the MRI abnormalities covaries with cerebrovascular risk factors has not been established in bipolar samples. Excluding patients or controlling for CVD risk factors still results in an excess of HI in bipolar samples relative to controls (Altshuler et al., 1995; Hickie et al., 1995). Thus while a vascular, age-related etiology for encephalomalacia is most likely in unipolar disorder, a different etiology may be at play in bipolar disorder. In turn, it cannot be assumed that HI burden is associated with neuropsychological impairment in bipolar disorder.

Limited investigation has been done in this area. In a small sample, Dupont and colleagues (1990) found that bipolar patients with HI were more impaired than bipolar patients without HI or healthy controls on tests of attention, letter fluency, visuospatial skills, and memory. In contrast, Krabbendam and colleagues (2000) compared matched groups of remitted patients with bipolar disorder, patients with schizophrenia, and healthy controls. The groups did not differ in the presence or severity of HI. More surprisingly, no differences in cognitive performance were found between patients with and without white matter lesions. Clearly, this

area needs further attention, and the pathoetiology of encephalomalacia in bipolar disorder remains a mystery.

NEUROPSYCHOLOGY AND THE CONCEPTUALIZATION OF MOOD DISORDERS

However revealing about the disorder, a detailing of the areas of cognitive strength and weakness in manic-depressive illness is a highly incomplete account of the neuropsychological contribution to theories of the nature of the illness. The application of psychometrics to affective processes lags considerably behind advances in cognitive assessment. However, the study of brain-behavior relationships with respect to the regulation of emotion draws on a vast clinical and experimental literature involving psychiatric, neurological, and healthy samples to derive conclusions about how emotional states are represented in the brain and what may go wrong such that some individuals are subject to recurrent bouts of depression or mania. The remainder of this chapter is devoted to a brief review of some of the key questions addressed in this literature.

Are Mood Disorders Deficit States or Release Phenomena?

Theorists such as Donald Klein have viewed major depression as a deficit state, the affective equivalent of an aphasia (Klein et al., 1980). The depressed patient is characterized by an inability to feel pleasure, lack of interest, sleep and appetite disturbance, lack of energy, immobility, and so on. By this view, then, basic appetitive, motoric, and hedonic functions are disturbed, much as sensation, movement, or speech is lost in neurological disorders resulting from destructive brain lesions.

An alternative view is that these affective states are manifested as highly integrated behaviors with mood, motor, cognitive, and conative components. Normal states of sadness and euphoria or, by extension, depression and mania are “positive symptoms” in the sense of Hughlings Jackson (1985), reflecting “hyperfunction” more than “hypofunction,” and are expressed through excitatory or disinhibitory mechanisms (Head, 1921). By this view, depression and mania are more akin to automatic speech than to speech arrest (Sackeim, 1986).

What type of evidence might support such a view? First, complex affective states can reliably be provoked by stimulating specific regions of the brain. Indeed, they can be turned on and off by changing the electrical stimulation. During the course of deep-brain stimulation for movement disorders, it has become clear that stimulation at a particular contact on an electrode in the subthalamic nucleus (or elsewhere) can provoke an overwhelming feeling

of depression, accompanied by crying, beliefs of worthlessness or hopelessness, and other classic phenomena associated with the depressed state.²⁹ Turning the stimulation off turns off the emotional display. The importance of such demonstrations lies not so much in the hints about localization, but more in the fact that the immediacy of the depressive mood and of the changes in emotional expression and worldview indicate the triggering of an integrated “depressive system” that alters the content of both mood and thought. Thus the brain, at least in this context, behaves in a way envisaged neither by James (1890) nor by Schachter (Schachter and Singer, 1962). We do not come to have a feeling because we are expressing the emotion (e.g., we know we are afraid because we are running), as suggested by James. Nor do we come to have a feeling because of an appraisal we have made about our surroundings that explains why we are aroused, as suggested by Schachter. In the case of deep-brain stimulation, mood, expression, and thought present simultaneously as integrated psychic phenomena triggered by a manipulation of brain tissue. None has primacy, as would be demanded by these earlier theories.

Depressive-catastrophic reactions during the Wada procedure are another example of provoked and transient mood disorder. This procedure involves injecting a barbiturate into the internal carotid artery to temporarily “barbiturate” the ipsilateral hemisphere (Snyder and Harris, 1997; Wada, 1997). Contralateral flaccid hemiplegia or hemiparesis and homonymous hemianopsia soon result. The procedure is used to establish laterality of language and verbal memory in individuals scheduled for neurosurgery (Branch et al., 1964; Cohen-Gadol et al., 2004; Takayama et al., 2004). At a point when sensorimotor function and cognition return toward baseline, some patients report depressed mood and catastrophic beliefs (e.g., their lives are ruined, the world is coming to an end). Since the 1950s, some investigators have claimed that left-side injections are more likely to produce this outcome, whereas right-side injections are more likely to result in a euphoric reaction.³⁰ While this idea is subject to controversy (Kolb and Milner, 1981; Kurthen et al., 1991), results of a recent study using masked ratings of facial expression during the Wada procedure support the notion that depressive reactions are more common with left-side injection.

Normal functioning is characterized by its own mood swings. Profound sadness, as during mourning or other losses, is a normal variant and shares virtually all the symptoms of the clinical disorder. What distinguishes major depressive episodes from the normal experience of intense dysphoric states is not so much the phenomenology of these presentations as the fact that major depression does not resolve as quickly. Viewing these phenomena in normal individuals as a deficit state strains credibility. Furthermore,

states of euphoria and mania also involve integrated manifestations in mood, motor function, cognition, and conation, with many of these functions appearing to be in overdrive.

Another argument regarding the status of depression and mania as release phenomena concerns the fact that the disorders most clearly reflecting deficits in emotional processes are distinct from depression and mania. Individuals may have agnosias for emotional communications. In other words, they may be incapable of identifying affective intonation or emotional facial expressions. For example, prosopoaffective agnosia refers to the inability to discern facial emotional expression without an accompanying deficit in processing of facial identity (Vuilleumier et al., 1998). Other neurological disorders can result in an incapacity to display emotions, either voluntarily or spontaneously (Borod et al., 1988; Ghacibeh and Heilman, 2003). And alexithymia is a disorder involving the capacity to feel or process affectively laden information (Becerra et al., 2002; Kano et al., 2003; Larsen et al., 2003); some refer to this condition as emotional blunting or emotion blindness. If affective disorders have a form of negative symptoms reflecting a fundamental defect or incapacity, these conditions would be exemplars.

Are We Wired to Be Depressed, and What Are the Therapeutic Implications?

The difference in conceptualization discussed above is not academic. The release model essentially claims that we are wired to be depressed and euphoric. Depressive or manic states do not arise because of a disruption of various discrete functions, such as sleep and appetite, but represent the expression of excitatory or disinhibitory release of distributed networks that subserve the integrated features of mood disorder (Tanaka and Sumitsuji, 1991). Concretely, this conception posits that there are depression and euphoria circuits in the brain, just as there are circuits for fear.

By positing that excessive excitation or disinhibition leads to release of the affective states, this perspective also has implications for our understanding of therapeutics. ECT is the most effective short-term treatment for both the depressed and manic phases of bipolar disorder. As reviewed in Chapter 19, bipolar depressed patients remit at the same rate as unipolar patients but require fewer treatments (Daly et al., 2001). Regardless of the form of ECT that was used in a series of randomized, controlled trials at Columbia University, bipolar patients on average required about 1.5 fewer treatments than unipolar depressed patients, with optimal forms of ECT resulting in immediate remission rates of 60 to 80 percent (Fig. 9-22). The immediate remission rate in mania is also on the order of 80 percent, and improvement is often

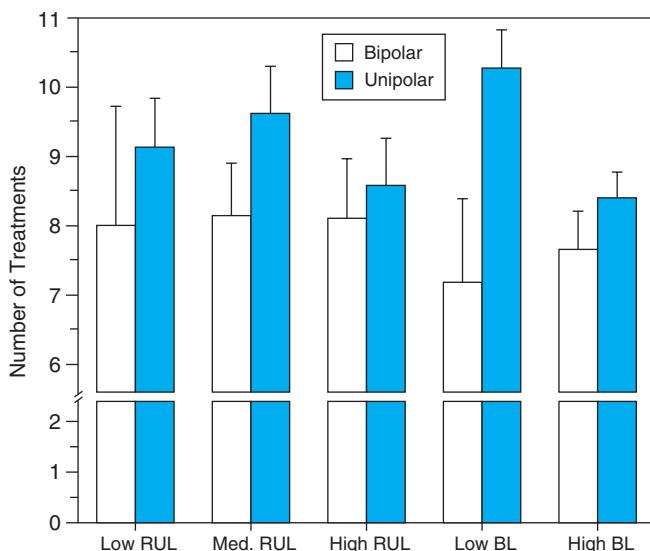

Figure 9–22. Number of electroconvulsive therapy (ECT) treatments for bipolar and unipolar depressed patients. Based on data pooled across four studies at the New York State Psychiatric Institute/Columbia University, 78 bipolar patients required on average about 1.5 fewer treatments than 185 unipolar depressed patients. Patients were randomly assigned to forms of ECT that differed in electrical dosage (low, medium, and high) and electrode placement (right unilateral [RUL] versus bilateral [BL]). An analysis of variation (ANOVA) was conducted on the number of treatments administered, with diagnosis (bipolar versus unipolar), treatment condition (five levels), and the interaction of those two factors as between-subject terms, and age and pre-ECT Hamilton Rating Scale for Depression (HAM-D) score as covariates. The main effects of diagnosis ($p=.0008$) and pre-ECT HAM-D score ($p=.0002$) were significant. (Source: Adapted from Sackeim et al., 1987, 1993, 2000b, and Sackeim, 2004.)

brisker than in major depression (Mukherjee et al., 1994). Why is ECT unique among therapeutics in both the breadth of its therapeutic action and its success rate? Why is a treatment that results in a hyperexcited state of the brain effective in treatment conditions that we posit reflect the release of function?

ECT is a profound anticonvulsant.³¹ The induction of the seizure initiates a set of endogenous inhibitory processes that terminate the seizure (Madsen et al., 2000); the leading theories on what mediates this anticonvulsant effect involve increased transmission of gamma-aminobutyric acid (GABA), endogenous opioids (Sanacora et al., 2003), or other peptides (Tortella and Long, 1985). ECT raises the seizure threshold for itself and all agents that trigger seizures through GABAergic antagonism (Green et al., 1982). It also results in progressive shortening of seizure duration and weakening of seizure expression (Sackeim, 1999). Increasing the threshold for seizures and blocking or weakening seizure expression are the two conditions to be satisfied in determining whether a drug has anticonvulsant

properties. In a variety of animal models, including kindling, electroconvulsive shock (ECS) exerts more powerful anticonvulsant properties than drugs such as carbamazepine or valproate. In this light, it is not surprising that ECT has been of value in the treatment of resistant seizure disorders, including status epilepticus (Sackeim et al., 1983b; Lisanby et al., 2001).

The therapeutic properties of ECT have been linked to its anticonvulsant effects. Forms of ECT that result in the most marked increases in seizure threshold tend to be the most effective (Sackeim, 1999). The strength of the inhibitory process immediately after the seizure can be indexed by the presence or absence of postictal suppression of the electroencephalogram (EEG). Postictal suppression (bioelectric silence) is predictive of a favorable outcome (Nobler et al., 1993; Suppes et al., 1996; Perera et al., 2004). Most critically, since Kety's work initiated the field of brain imaging (Kety et al., 1948), it has been clear that ECT results in marked reductions in CBF (and CMR_{glu}).³² Recent work has revealed powerful relationships between the extent of this suppression in prefrontal regions and clinical outcome in both major depression and mania (Nobler et al., 1994, 2000b, 2001). Consonant with this perspective, ECT results in a marked increase in slow-wave (delta) activity. The efficacy of the procedure has been linked to a topography dominated by increased slow-wave activity in prefrontal regions (Sackeim et al., 1996a). Thus depressed and manic patients may have “bad brakes,” resulting in a failure to diminish activation in the released mood circuitry. ECT, at least temporarily, enhances inhibitory tone, reducing expression of the released mood circuitry.

The large imaging literature on antidepressant effects is mainly in keeping with this view (Mayberg et al., 1999; Drevets et al., 2002; Seminowicz et al., 2004). Although there are disagreements about the sites of inhibition that are most critical, the antidepressant effects of ECT, sleep deprivation, and antidepressant medications have commonly been tied to reductions of regional cerebral blood flow (rCBF) or CMR_{glu} in specific brain regions. Frontal pole, medial orbital prefrontal cortex, anterior cingulate, and amygdala have been identified as primary in reflecting the covariation between reduced CBF or CMR_{glu} and clinical outcome.³³

Of course, this view readily accommodates the fact that several anticonvulsant agents have mood-stabilizing properties. Thus to the extent that depressed or manic patients can be said to have “bad brakes,” treatments with prophylactic properties may exert tonic inhibition.

Does the Brain Regulate Depression and Mania Differently?

Bipolar disorder is one of the few illnesses in which polar-opposite symptoms (euphoria and depression) are

experienced as part of the same illness. It is tempting to view these abnormal states as the ends of a seesaw, such that when one side is up, the other is down. This analogy presumes that some force is tilting a balance toward or away from depression or mania, thus regulating both. However, the nature of regulatory control probably differs for euphoric and dysphoric states. Take the example of uncontrollable laughing and crying. In the context of destructive, silent (nonepileptic) lesions, pathological crying is more frequent than pathological laughing (Mills, 1912; Davison and Kelman, 1939; Tateno et al., 2004). Uncontrollable outbursts of laughter as a prodrome or during seizures are referred to as gelastic epilepsy (Daly and Mulder, 1957; Gascon and Lombroso, 1971). As peri-ictal manifestations, these highly organized behavioral displays occur in the context of excessive cerebral excitability, during states of hypersynchronous neuronal firing (Arroyo et al., 1993). Dacrystic epilepsy refers to the occurrence of crying as a prodromal or ictal event. When we collected the world literature on gelastic and dacrystic epilepsy, we found a pattern with pathological laughing and crying: there were 91 cases of laughing as a peri-ictal event, but only 6 cases of crying outbursts and 6 cases that presented laughing and crying outbursts to an equal extent (Sackeim et al., 1982b).

It is unlikely that the paucity of dacrystic epilepsy and excess of gelastic epilepsy case studies reflects only a reporting bias. As noted, in the context of silent, nonirritative lesions, reports of pathological crying are common. Taken at face value, this difference in rates of occurrence suggests that uncontrollable crying is released more readily through disinhibitory mechanisms as opposed to an excitatory process, while laughter is readily released through “irritative” or excitatory as well as disinhibitory mechanisms.

Even granting such a possibility, it is not evident that the pattern of neural control over these emotional displays is of consequence for the regulation of mood. At issue is whether these examples of dysregulation of spontaneous emotional expression should serve as a model for the pathophysiology of abnormal mood states. Three key arguments support the validity of this model.

First, as noted earlier, in a substantial minority of patients with pathological laughing and/or crying, mood is altered during the outbursts in a manner that is consonant with the expressive outburst. Thus these individuals report marked sadness during pathological crying and euphoria during pathological laughter. This same pattern holds for gelastic and dacrystic epilepsy. This would suggest that in some cases, the physiological state that results in release of the expressive outbursts also releases these organized mood states (Black, 1982). Precise data are lacking on the prevalence of mood alterations during ictal events. It is noteworthy that fear and euphoria are commonly reported.

For example, Dostoyevsky stated that he would give up 10 years of his life for the brief period of ecstasy he experienced as a peri-ictal event.

Second, the therapeutics of pathological laughing and crying supports the concept that mood and emotional expression are part of an integrated emotion circuit. In controlled trials, antidepressant medications, including tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRIs), have been found to be effective.³⁴

Third, the lateralization of brain damage (or seizure foci) in these cases of uncontrollable emotional display matches that seen for depressive and euphoric mood changes that occur after destructive, silent lesions. As with the Wada procedure, and also not without controversy, a significant body of research has linked acute depressive reactions following brain insult to damage in left-sided regions, especially in frontal cortex, and euphoric mood changes to right-sided damage.³⁵ Figure 9–23 presents ratings of the predominant side of lesion in cases of pathological laughing and crying; the raters were blinded to the nature of the affective display (Sackeim et al., 1982a). As in the literature on mood change, crying outbursts are associated with an excess of left-sided lesions, and laughing outbursts with an excess of right-sided lesions.

Sackeim and colleagues (1982b) hypothesized that the opposite pattern would obtain when these outbursts occurred in the context of epilepsy as prodromal or ictal events. Focal seizure activity has unique localizing value. For example, lateralized somatosensory alterations have 100 percent correspondence to contralateral seizure activity in somatosensory cortex. Hughlings Jackson (1985) described the “homunculus,” the ordered representation of the body in motor and somatosensory cortex based on the march of motor symptoms during Jacksonian seizures, a description later validated by Penfield with direct electrical stimulation of motor cortex (Penfield and Jasper, 1954). Sackeim and colleagues had further hypothesized that depressive and euphoric mood states following lateralized silent (nonepileptic) lesions reflect disinhibition in contralateral brain regions that subserve depressed or euphoric states—that is, breaking a brake over contralateral regions. Thus, for example, they posited that euphoria results from right-sided brain damage due to release of the left-sided regions that subserve this affective state. This hypothesis derived partly from data indicating that right hemispherectomy (removal of the anterior two thirds of the cerebral hemisphere) often results in a syndrome of increased jocularity, poor judgment, lack of responsibility, and so on (Sackeim et al., 1982b). These affective changes cannot be mediated by the broad expanse of cortex that has been removed, but only by remaining subcortical regions in the ipsilateral hemisphere or by release of the

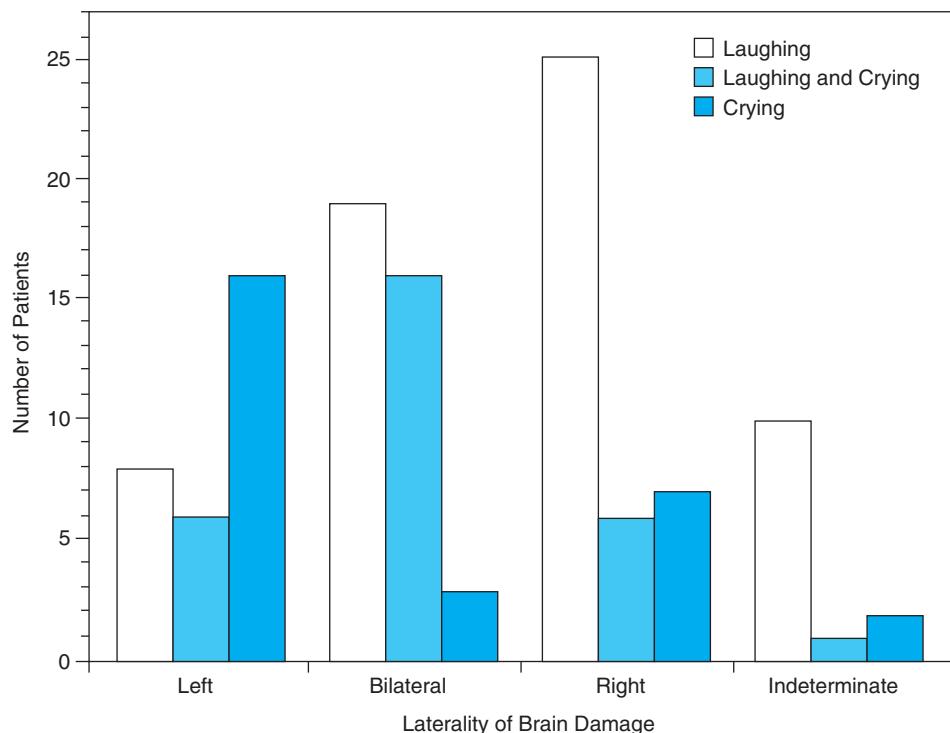

Figure 9–23. Distribution of primarily left-sided, right-sided, bilateral, and indeterminate nonirritative lesions in patients with pathological laughing only, laughing and crying, and crying only. Left-sided and right-sided lesions are associated with pathological crying and laughing, respectively, whereas bilateral lesions are associated with presentation of both uncontrollable laughing and crying. (Source: Sackeim et al., 1982b.)

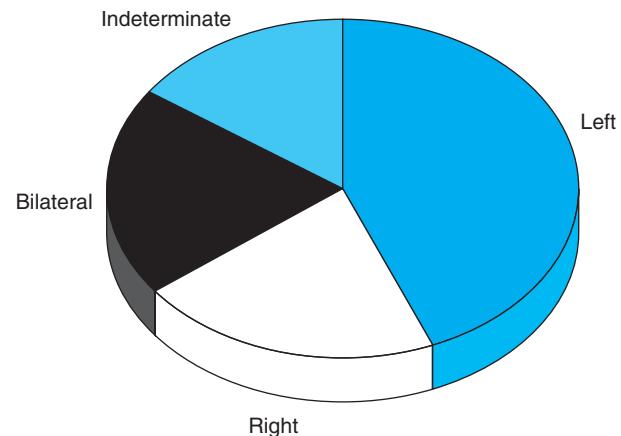

regions in the contralateral hemisphere. Likewise, the affective changes seen after barbituration of the left or right hemisphere suggest that contralateral disinhibition may be at play.

Figure 9–24 presents findings regarding the lateralization of epileptic foci in cases of gelastic epilepsy. There was an overwhelming excess of left-sided foci, as predicted—the opposite of what was seen with pathological laughing in the context of silent lesions. Thus, the model offered by Sackeim and colleagues (1982b) stipulated that depressed and euphoric states are under reciprocal inhibitory control. Depressive phenomena are released mainly by disinhibitory mechanisms, while euphoric mood changes and laughter are released by disinhibition or direct excitation. The model did not require that the inhibitory control mechanisms be reciprocal. Including this element implied a partial seesaw effect. Reciprocal regulation would mean that depression and euphoria cannot be experienced simultaneously, an issue that is key to the conceptualization of mixed states.

Our conceptions of how emotional processes are represented in the brain are rudimentary. Undoubtedly the model of Sackeim and colleagues is overly broad and, at best, an echo of the true state of affairs. Nonetheless, the

evidence that led to this model was consistent and illustrated the power of using experimental invasive techniques (e.g., deep brain stimulation, Wada test, hemispherectomy), along with experiments in nature (lateralization of epileptic foci and silent lesions), to constrain theorizing

Figure 9–24. Distribution of left-sided, right-sided, and indeterminate epileptic foci in patients with gelastic (laughing) epilepsy. Foci were more than twice as likely to be left-sided than right-sided. (Source: Sackeim et al., 1982b.)

about fundamental mechanisms in the regulation of emotion.

There are other speculative grounds for postulating a fundamental difference in the neural control of euphoric and dysphoric states or, as some have suggested, emotional states involved in approach or avoidance (Davidson, 1995). A long list of pharmacological agents, including laughing gas, stimulants, opioids, cocaine, and others, can reliably induce euphoric mood in the majority of people. Many of these effects are immediate, occurring within seconds or minutes after exposure. In contrast, despite intensive research efforts and standard surveillance techniques during drug screening, not a single pharmacological agent has been identified that can reliably induce depression in the majority of naïve individuals. In only a minority of individuals with a family history of mood disorder, reserpine will elicit a depressive reaction (Kraemer and McKinney, 1979). Similarly, tryptophan depletion has no impact on mood in healthy individuals, except for a small change in a minority of individuals with a positive family history (Ellenbogen et al., 1996; Shansis et al., 2000). This discrepancy in the likelihood that pharmaceutical agents can provoke depression or mania is curious, and its significance is reinforced by the psychometrics of psychological mood manipulation.

Symbolic representations can drive mood change. Being told that one is deficient, unloved, corrupt, or ineffective affects mood. Clearly, we are built such that our ideas about the world and ourselves can alter our mood. Indeed, a small industry has developed that uses psychological manipulations to produce mood changes in specific directions (e.g., from sadness to euphoria) (Velten, 1968; Bouhuys et al., 1995; Richell and Anderson, 2004). This literature suggests that the range or intensity of affect produced by psychological manipulations is often greater for inductions of sadness than those of happiness. In other words, it appears to be much easier to induce clear-cut sadness as opposed to euphoria through words or music (symbolic representations).

If these observations are valid—and much work needs to be done on the psychometrics of mood change—they may advance our understanding of how pharmacological agents and psychological manipulations constitute intrinsically different types of triggers or pathways for mood alteration, perhaps because of intrinsic differences in modulating disinhibitory versus excitatory processes.

Functional Brain Asymmetry and the Localization of Mood Systems

In the first edition of this text, laterality and kindling were identified as key concepts in theories about the neural origins of manic-depressive illness. At the time, it was common to hypothesize that schizophrenia was an outcome of

left-hemisphere dysfunction, while manic-depressive illness derived from right-hemisphere deficits (Flor-Henry, 1976). Another view was that a cumulative history of stress, affective episodes themselves, and biological predisposition fueled a kindling process that resulted in manifestation of mood disturbance and progressively more frequent and intense episodes of illness (Post, 1990, 2002).

Neither hypothesis has remained the focus of mainstream research. In both cases, this shift in attention reflects in part advances in basic neuroscience that have produced research tools and concepts with the potential to provide great explanatory power with respect to fundamental abnormalities in clinical populations, as well as opportunities for designing new interventions. Understanding of intracellular cascades and the factors that promote cellular resilience or the expression of neurogenesis has led to new conceptualizations of pathoetiology and potential avenues for treatment (see Chapter 14).

In a number of respects, the lateralization view was a dead end. On the one hand, linking disorders to dysfunction at the level of a hemisphere, even if true, was hardly precise in terms of localization. The total right hemisphere could not be abnormal in mood disorders. Furthermore, this hypothesis was imprecise as to whether this right-hemisphere dysfunction is the core problem resulting in periodic manifestations of depression and mania or in an expression of these affective states.

Perhaps the greatest limitation of the laterality hypothesis was its lack of practical application for diagnosis or treatment or for the development of a direct method for testing validity. Until recently, psychiatry had no means other than ECT of targeting biological treatment to specific brain areas. Systemic administration of medications allows no control over the neural systems being modulated. In contrast, left and right unilateral ECT produce profound asymmetries in the physiology and function of the brain. Unilateral ECT produces marked decreases in CBF and CMR_{glu} and marked increases in EEG slow-wave activity in the hemisphere ipsilateral to the side of stimulation (Kriss et al., 1978; Nobler et al., 1994; Sackeim et al., 1996b). It also produces marked disjunctions in neuropsychological measures. For example, assessment of orientation and language functions in the postictal period immediately following left and right unilateral ECT is as reliable as the Wada test in identifying laterality of language (Pratt et al., 1971; Pratt and Warrington, 1972). Thus the view that euphoric and depressed states reflect release of function in the left and right hemispheres, respectively, would imply that left unilateral ECT is more effective than right unilateral ECT in the treatment of mania, with the reverse holding true for depression. Although some findings in the ECT literature support both predictions (Small et al.,

1993), the larger point is that left and right unilateral ECT both show considerable efficacy in the treatment of mania and depression, and that any difference in therapeutic effects is relatively minor compared with the shared variance. Given the asymmetrical physiological and cognitive effects of unilateral ECT, the efficacy data largely contradict a prominent role for functional brain asymmetry in treatment mechanisms and, by extension, in the pathophysiology of depression and mania.

A key observation that promoted interest in lateralization effects was the association between localization of stroke and other forms of brain damage and manifestation of mood disturbance. Clinically, as mentioned earlier, it has long been noted that “unipolar mania” (i.e., manifestation of mania without prior or subsequent episodes of major depression) occurs almost exclusively in the context of coarse brain injury (Jorge et al., 1993; Fujikawa et al., 1995; Robinson, 1997). Further, it is generally agreed that such lesions are predominantly right-sided (Cummings and Mendez, 1984; Starkstein et al., 1988a).

In contrast, the relationships between location of brain lesion and manifestation of depression have become less certain with additional research. Interest in the laterality of emotion was sparked by findings relating side of brain injury to affective state (Gainotti, 1972) and to uncontrollable emotional expressions (Sackeim et al., 1982a), by the demonstration of asymmetry in the emotional expressions of the human face (Sackeim et al., 1978), and by the linkage of disturbances in the processing of affectively laden information to right-sided brain damage (Heilman et al., 1975). However, the relevance of a laterality dimension to mood disorders was contingent on reliable associations between side of brain damage and manifestations of mood disturbance.

Gainotti (1969, 1972) was the first to examine systematically the distinct differences in emotional reactions of patients with left- and right-hemisphere stroke. Right-sided damage was associated with anosognosia (denial of illness) or anosdisaphorie (lack of concern about illness, i.e., a carefree attitude) and a “euphoric-indifference reaction.” Robinson’s research, however, catalyzed interest in this area. In a seminal paper, Robinson and colleagues (1984) linked the severity of depressive symptoms shortly after stroke to damage to left-sided prefrontal regions. The closer the lesions were to the left frontal pole, the more severe was the depressive syndrome. Right parietal lesions were also linked to depression, but at lower incidence and with lesser intensity of depressive manifestations. This work had important methodological limitations, such as the exclusion of patients with significant aphasia, which possibly distorted the sample of patients with left-sided injury, and problems in the blinding of assessment given the motor,

sensory, and cognitive deficits that reveal the side of lateralized brain damage. Most of the subsequent studies failed to replicate Robinson’s core findings, and some meta-analyses of this literature contested the existence of an association between lesion location and depressive manifestations (Carson et al., 2000; Narushima et al., 2003; Yu et al., 2004).

Missing from this perspective were the results of long-term follow-up of individuals with penetrating head wounds after World War II. Mood disturbance was common in such patients. In particularly careful work, Lishman (1968) noted that right posterior head wounds were far more likely to be associated with depressive and manic manifestations than were injuries to any of the remaining three quadrants. It hardly appeared likely that different forms of nonirritative brain insult—stroke versus head wound—could fundamentally alter the linkage between side of brain insult and depressive symptoms.

One possibility accounting for the discrepancies in this literature concerns the issue of time since stroke. Robinson’s early work involved patients who were examined very soon after stroke, recruited at emergency room presentation. Later studies often examined patients months to years after their cerebrovascular accident. There has been little longitudinal work addressing whether localization of damage is related to the persistence (chronicity) and/or late emergence of depressive symptoms. Nelson and colleagues (1994) evaluated affective symptoms in patients with lateralized stroke at 2-week, 2-month, and 6-month time points. Initially, the group with left-hemisphere stroke experienced a slower rate of recovery from depressive symptoms. At the 6-month time point, however, the emotional functioning of the right-hemisphere group worsened. The evidence regarding temporal interval as a moderator of the relationship between lesion location and affective disturbance is not consistent, and considerably more work is necessary (Carson et al., 2000). Nonetheless, the positive findings in this area introduce a dynamic element to the relationships between brain injury and altered affective states.

One interpretation of this literature would be to argue that in the acute poststroke period, depressive symptoms are most severe when the lesion is closest to the left frontal pole. The most recent meta-analysis (Narushima et al., 2003) supports this association. However, manifestation of this syndrome is time-limited, and depressive symptoms spontaneously remit within a few months. In contrast, right parietal lesions result in milder depressive symptoms in the acute period. Yet this disturbance is more likely to be chronic, and these lesions may also result in late-emerging affective disturbance. Following the disinhibition model for nonirritative lesions, both left anterior and right posterior stroke may disinhibit right prefrontal areas critical to

the manifestation of depressed mood. Prefrontal-parietal connectivity is well established, and reciprocal inhibitory pathways have been demonstrated (Goldman-Rakic, 1987; Woods et al., 1993). Thus this view, albeit post hoc in accounting for discrepancies, leads to the assertion that the functional consequences of brain lesions are time dependent, and this temporal effect may differ based on laterality. That such temporal effects can occur is amply demonstrated in the neurosurgical literature on the treatment of highly resistant mood disorders. Therapeutic benefit from psychosurgery usually is manifest only months after the intervention.

Dissociating Therapeutics and Pathophysiology

Although the linkage of right-sided damage to mania remains uncontested, there is uncertainty about the role of lateralized brain damage in the manifestation of depressed states. Indeed, one possibility yet to be raised is that the strength of association for lateralized effects is stronger for euphoric or manic than for dysphoric or depressed states. As seen in Figure 9–22, the association between pathological laughing and right-sided silent lesions is stronger than that between pathological crying and left-sided lesions. As seen in Figure 9–24, there is also a robust association between laterality of epileptic focus and uncontrollable laughter as a peri-ictal phenomenon.

Until recently, data-driven formulations of this type had little possibility of being tested experimentally. The common denominator in this sort of theorizing is that disinhibition of right prefrontal structures is the common final pathway for depressive manifestation. If that were the case, selective suppression of such activity would be expected to have antidepressant properties, and left prefrontal suppression to have antimanic effects.

The development of noninvasive methods for focal neuromodulation resulted in new life for this area of research. For example, repetitive transcranial magnetic stimulation (rTMS) offers a means of suppressing or enhancing activity in regions under the coil or at a distance through patterns of connectivity. Because the scalp and skull are transparent to the magnetic field, it is possible through use of appropriate coil geometry to restrict stimulation to target brain areas. There is considerable evidence that slow-frequency rTMS (one or fewer pulses per second) produces an inhibitory effect, whereas fast-frequency rTMS (five or more pulses per second) has a poststimulation excitatory effect (Wassermann et al., 1993; Terao and Ugawa, 2002; Wu et al., 2002).

There is now a substantial literature on sham-controlled studies testing the efficacy of rTMS in major depression, and the meta-analyses of this literature have all reached the same conclusions (Holtzheimer et al., 2001; McNamara et al.,

2001; Burt et al., 2002). The active rTMS conditions compared with sham have been fast-frequency left DLPFC stimulation and slow-frequency right DLPFC stimulation. Both interventions yield moderate to large effect sizes for antidepressant properties; in other words, both are consistently superior to sham. However, these findings are of greater theoretical than practical importance. In absolute magnitude, the therapeutic effects in the active conditions, although superior to those in sham, have commonly been modest, and the durability of the benefit derived has rarely been tested. For rTMS to have a role in routine practice, these issues must be addressed (Sackeim, 2000b).

From a theoretical perspective, however, it is extraordinary that a highly lateralized intervention can display these antidepressant properties, and moreover, that antidepressant effects can be achieved with opposite physiological alterations (inhibition versus excitation) that are dependent on the laterality of the brain region stimulated. Taken at face value, for example, these effects could indicate that the key to exerting antidepressant properties is the state of the “seesaw”: any intervention that tips the seesaw toward greater left prefrontal or reduced right prefrontal expression in the DLPFC will have antidepressant properties. This formulation could mean that mood states are not attributable to the physiological status of a specific brain region, but are an emergent property reflecting the balance of activity among regions in a distributed network. Another possibility is that different individuals benefit from slow right or fast left rTMS, and that left-sided hypofunction and right-sided hyperfunction are alternative routes to major depression (Kimbrell et al., 1999; Speer et al., 2000).

Focal brain stimulation offers an experimental means of testing key concepts about the neuroanatomy and neurophysiology of mood disorders and their treatment. Two caveats are in order about the state of knowledge in this area. First, while it is established that slow right and fast left rTMS have antidepressant properties, however modest, it is assumed that fast right and slow left rTMS are ineffective, something that has never been adequately tested. For example, were slow left DLPFC to exert equal antidepressant properties, a fundamental role for laterality in generating therapeutic effects would be seriously questioned. The key experiment, in which depressed patients are randomly assigned in a 2×2 design to slow- or fast-frequency stimulation and left or right DLPFC, has not been conducted, and is essential to further understanding of the effects of this intervention on mood.

The second caveat is more general. It is often assumed that knowledge of the mode of action of a therapeutic agent (e.g., serotonin reuptake blockade) dictates conceptualization about the underlying pathophysiology (or vice versa). However, there are many examples in medicine in

which the optimal treatment for a condition acts through a mechanism distinct from the pathoetiology of the illness. It is doubtful that anyone ever became depressed because of lack of a seizure, and yet ECT is the most effective antidepressant. Put more forcefully, many of our pharmacological interventions produce chronic alterations in brain neurochemistry and other aspects of physiology that are simply not seen otherwise in nature and do not restore the brain to a normative state. Thus the circuitry involved in achieving an antidepressant effect may be distinct from that responsible for manifestation of the mood disorder. The therapeutic properties of interventions such as rTMS may reveal a great deal about the pathways that modulate or ameliorate the experience of major depression. However, these pathways may be distinct from those that generate the abnormal mood state.

Ultimately, progress in genetics and molecular biology is likely to produce breakthroughs in our understanding of the pathoetiology of bipolar disorder and recurrent unipolar depression and in our ability to provide more effective therapeutic interventions. Nonetheless, these disorders need to be understood at a system level. Discrete aspects of emotional life have neural representation. System theories draw on evidence from neurological, psychiatric, and normal populations to constrain hypotheses about the neuroanatomy and physiology that subserve abnormal mood states and that mediate therapeutic outcomes. We are just entering an era in which these hypotheses can be tested through the controlled use of anatomically targeted alterations of physiology and neurochemistry. It can be anticipated that the formulations presented here will be refined or undone, and that the next edition of this text will offer superior descriptions of the neural networks dysregulated in manic-depressive illness.

CONCLUSIONS

Normal Findings in Bipolar Patients

Bipolar patients have normal VIQ, a finding that challenges the idea that bipolar disorder is associated with pervasive intellectual impairment. One possible explanation is that the cognitive systems underlying language are spared from the otherwise generalized bipolar disease process; or they may be constitutionally endowed at higher capacity. Likewise, preliminary evidence indicates that procedural learning and memory are not significantly affected by bipolar illness, while limited data suggest that the ability to recall past events, or details of past events, is not significantly impaired in bipolar patients.

Alone among the executive functions, reasoning remains relatively preserved in bipolar illness. Because the results of tests of reasoning correlate substantially with the

results of tests of verbal ability, this finding may reflect a pattern in which cognitive operations heavily dependent on language are among the higher cognitive functions least affected by bipolar disorder.

Neuropsychological Deficits in Bipolar Patients

Intelligence is somewhat reduced in bipolar illness in both the remitted and manic states as reflected in diminished IQ scores. Reasoning remains intact. The marked deficit in PIQ among bipolar patients is commonly ascribed to the effects of mood-dependent psychomotor retardation on task performance, but the presence of the deficit during remission and in individuals at risk for bipolar disorder, as well as its persistence when performance is untimed, argues otherwise. It now appears that the discrepancy is independent of the affective state and may even be present before the first episode of mood disturbance. The above proposed explanation for normal VIQ scores in bipolar patients can also help account for the deficit in PIQ: although the cognitive systems underlying language are spared by the disease or are constitutionally endowed at higher capacity, those underlying other components of intelligence, including performance, are not.

Attention comprises several distinct processes, and its overall integrity is central to the normal functioning of higher cognitive processes such as learning and memory. Disturbances of attention ("impaired concentration") are typical of bipolar disorder, and attention is among the most dramatically impaired functions in patients during episodes of major depression, and indeed across all phases of the illness, including remission. With respect to learning, memory, and visuospatial skills, there is little evidence that deficits reflect more than an attentional disturbance. Short-term memory deficits are typical of bipolar patients, even in remission. It is possible that these deficits result from impaired attention. Bipolar patients also have decided and uniform difficulty in acquiring new information during all phases of the illness, including remission.

Executive functions come closest to the idea of a neural homunculus in charge of administering neural resources. Only a very limited range of executive functions in bipolar disorder has been studied, however. The studies that have been conducted have found substantial deficits in all phases of bipolar disorder. Severe illness has been associated in particular with difficulty in concept formation and set shifting.

Those only, who lived for some time with [Lord Byron], could believe that a man's temper, Proteus like, was capable of assuming so many shapes. It may literally be said, that at different hours of the day he metamorphosed himself into four or more individuals, each possessed of the most opposite qualities; for, in every change, his natural impetuosity made him fly into the furthermost extremes. In the course of the day he might become the most morose, and the most gay; the most melancholy, and the most frolicsome . . . the most gentle being in existence, and the most irascible.

—Julius Millingen (*Byron's physician*), 1831

The intense emotions and troubling thoughts and behaviors of manic and depressive states often confound the person who has bipolar disorder and family members alike: What is due to the illness? What is due to personality? Where does one end and the other begin? Will treatment alter not only the disorder, but also personality? Do pathological mood states reflect the real self, or is there a coherent self despite the mood swings that characterize the disorder? Scientists and clinicians ask related questions: Are there unique and characteristic personality styles associated with bipolar disorder, and are they present when the person is not affectively ill? Are there predisposing or precursor “traits”? Do personality characteristics affect the course of the disorder? (Related questions concerning the mild forms of bipolar disorder that may be continuous with personality patterns are discussed separately in Chapter 2.)

Questions about “personality” are both personally meaningful and clinically and theoretically important because they may help shed light on the enormous variability among individuals with bipolar disorder and aid in achieving a fuller understanding of the disorder’s development. Issues of personality have been addressed in various ways by psychologists and psychiatrists, and in the first section of this chapter we review both the complexities of the questions examined and the research results.

We next address the issue of personality disorders, the enduring and dysfunctional patterns of behaviors and traits defined by Axis II of the *Diagnostic and Statistical Manual* (DSM), that may accompany Axis I diagnoses of any kind. Personality disorders may profoundly color the experience of the coexisting psychological disorder, as well as affect both the clinical and social adjustment of the individual and the success of treatment. They have been the focus of many recent studies in the field of bipolar research, and the

results of these studies may help inform patients and clinicians about how individuals with a diagnosis of bipolar illness can be so different from one another in presentation and prognosis.

Finally, we discuss the interpersonal functioning of individuals with bipolar disorder in major role areas, such as intimate relationships, social behavior, and family relations. There is increasing interest not only in the clinical manifestations of bipolar disorder, but also in the ways in which individuals with the disorder live their lives and cope with their condition. What are the unique interpersonal patterns and challenges for the bipolar patient, and what does the social milieu itself contribute to the understanding of the course of the disorder? Of particular importance is growing awareness of the discrepancies that sometimes exist between social functioning and clinical status.

Prior to DSM-III the term “manic-depressive illness” could either mean what we now call bipolar disorder or include all recurrent affective disorders. When the context of the older literature makes clear that it is referring to bipolar disorder, we use that term. Because the literature relevant to this chapter rarely distinguishes recurrent from nonrecurrent forms of unipolar depression, we focus on the bipolar subgroup of manic-depressive illness.

PERSONALITY AND BIPOLAR DISORDER

In this section, we begin by reviewing a number of conceptual and methodological issues associated with studies of the relationship between personality and bipolar disorder. We then examine, in turn, the findings of studies addressing personality during mania and depression, comparisons of two major dimensions of personality—neuroticism

and extraversion–introversion—among remitted bipolar patients and normal groups, comparisons of the personality traits of bipolar and unipolar patients, effects of medication on personality, and predictive associations between personality characteristics and the development and outcome of bipolar disorder.

Conceptual Issues and Key Definitions

The terms *personality*, *character*, and *temperament* are sometimes used interchangeably. They differ in important ways, however.

Personality generally refers to the unique aspects of an individual, especially those most distinctive or likely to be noticed by others in social interactions. Personality theorist Gordon Allport (1961, p. 35) suggested that personality is simply “what a person ‘really is’”—his or her most typical and deeply characteristic features. Yet there are as many psychological definitions of personality as theorists writing about the subject. Two prominent theorists summarized these many definitions succinctly as focusing on one or more of the following facets: “the individual’s social stimulus value; the integrative or organizational function of personality; an individual’s general adjustment; the unique or individual aspects of behavior; and the essence of man” (Hall and Lindzey, 1970, p. 8). In the absence of any universally accepted definition, most personality theorists define the construct by the assessment instruments they use to measure it. Clearly, some theories of personality lend themselves more readily to empirical research than others.¹

Personality has traditionally been viewed as having several qualities: it is stable across time and situations; it encompasses an organized set of traits forming a coherent personality style; and it is the underlying psychological “cause” of a person’s specific behaviors and beliefs. These assumptions have been challenged because we have learned that behaviors and beliefs are overtly and subtly determined by experiences, by current environmental demands, by cognitive capacities and styles, by genetic and constitutional factors, and certainly by affect and emotion. Nevertheless, researchers are increasingly attempting to account for the complexities involved by defining a few traits that can be used to describe most people and by taking into account the biological, temperamental features of personality and the environmental determinants that greatly shape its expression.

Character has been defined as “personality evaluated”—that aspect of an individual which bears a moral stamp and reflects the person’s integrative and organizing functions. The concept of character is employed less frequently in the United States than in Europe, although it is often used interchangeably with that of personality. In part, the

concept of personality disorder addresses the issue of a person’s character traits.

Temperament has always been viewed as having a more constitutional, genetic, and biological basis than either personality or character. Hippocrates and Galen, for example, based their theories of temperament on the four humors of the body. According to Allport (1961, pp. 33–34), “Temperament refers to the characteristic phenomena of an individual’s emotional nature, including his susceptibility to emotional stimulation, his customary strength and speed of response, the quality of his prevailing mood, and all peculiarities of fluctuation and intensity in mood, these phenomena being regarded as dependent upon constitutional make-up, and therefore largely hereditary in nature.”

The affective temperaments that reflect the milder manifestations of the bipolar spectrum are discussed extensively in Chapter 2. Although there is overlap between the topics of personality and the bipolar spectrum, we attempt in this chapter to limit the discussion to several specific issues detailed in the following sections.

Relationship of Personality to Affective Disorders

Several researchers (Akiskal et al., 1983; Clark et al., 1994) have noted the complex relationship and interactions between personality and affective illness, especially depression. From their work and that of many others, four major models have been formulated:

- Personality is a *predisposition* to affective illness. This model assumes that personality patterns precede and therefore predispose an individual to develop affective illness. This view, fundamental to psychoanalytical thought and writing, also is reflected to varying degrees in the writings of cognitive and behavioral psychologists who have formulated various theories about predisposing characteristics for depression, such as negative views of the self and depressive attributional style. There is a relatively small literature on personality antecedents of bipolar disorder.
- Personality is an *expression* of affective illness. Personality patterns are viewed as manifestations of mild to moderate forms of the underlying affective illness. The individual’s temperament is assumed to be intricately bound up with the genetic predisposition to mania and depression. This view, integral to the work of Kraepelin and Kretschmer, is shared in part by most of the modern researchers who posit a continuum of affective states (see Chapters 1 and 2).
- Personality is a *modifier* of affective illness. Many investigators (Chodoff, 1972; Klerman, 1973; von Zerssen, 1977) have emphasized the role of personality in determining the clinical presentation of affective symptom patterns (especially in obsessive, dependent, or hysterical person-

ality types), the response to psychotherapy and medication, the tendency to become dependent on alcohol or other drugs, and adherence to prescribed treatment regimens. They have also identified personality as an important determinant of the nature and extent of interpersonal relationships. These relationships, in turn, can affect both precipitating events and the likelihood of emotional support during and after affective episodes. The ability to handle the enormous stress and complications of affective illness is assumed to be strongly influenced by premorbid personality and character structure.

- Personality is *altered* by affective illness. In this model, personality is assumed to be altered by the experience of affective illness. Various consequences of the illness—including changes in self-esteem and social interaction patterns; difficulties in sustaining meaningful relationships and employment; and frequent fluctuations in mood, energy, perception, and thinking—are all thought to both cause and reflect short- or long-term personality changes that may be reversible or irreversible. The obvious importance and impact on personality of such illness variables as frequency, duration, severity, and nature of episodes have not been well studied.

These models of the association between affective illness and personality are not mutually exclusive, and they may be difficult to disentangle in practice. Moreover, research has not tested all of the models with respect to bipolar disorder, leaving many questions unanswered. Recent research has generally addressed several largely descriptive issues. One such issue concerns the stability of personality traits and whether they vary by manic or depressed state. A related issue is whether there are unique personality characteristics of bipolar patients that differ from those of unipolar depressed or well individuals. Still another set of issues has to do with the predictive association between personality features and clinical course. Before turning to a review of studies that address these matters, however, a further caution concerning methodological issues is in order.

Methodological Issues

In addition to the conceptual issues raised above, many specific methodological problems are intrinsic to the study of personality and bipolar disorder. The most central of these is the problem of *trait and state*, or disentangling manifestations of illness from the more stable and lasting structures of personality. Specific problems include the substantial difficulties of separating the current clinical state from measured personality traits, of assessing the effects of medications on personality (independently of their effects on the underlying affective illness), of sorting through the personality effects of previous manic and

depressive episodes, and of delineating the effects of subclinical episodes on personality. Fundamental issues of measurement and philosophy emerge when two pivotal questions are posed. First, what aspects of personality are being studied when one is assessing the successfully treated person with bipolar illness—true premorbid ones or affectively changed and attenuated ones? Second, to what extent is personality a function of medication level or of the cumulative effects of disease?

Another set of problems concerns issues of *diagnostic and illness heterogeneity*. Heterogeneity is well recognized in the unipolar depressive disorders (in symptom patterns, etiology, severity, episodic patterning, and frequency). Although bipolar illness is more homogeneous, it, too, can be confusingly varied. Few investigations of personality distinguish between bipolar-I and bipolar-II, and fewer still consider other issues related to the full spectrum of bipolarity, such as the stage or severity of manic and depressive illness at the time of testing, the ratio of manic to depressive episodes, the age at illness onset, the frequency and nature of mixed states, the duration and patterning of episodes, and the characteristic nature of the manic episodes (euphoric and expansive, for example, rather than paranoid and dysphoric). All of these variables are likely to have both long- and short-term effects on the expression of personality. Other variables generally not controlled for in personality studies of affective illness include seasonal factors of importance to studies done during both remission and illness (see Chapter 4); the competence and sophistication of clinical care, including such common problems as prescribing incorrect medications or dosages; and selection factors intrinsic to the nature of remission studies—that is, a selection bias favoring healthier, more normal bipolar patients.

Measurement and design also are problematic. Until recently, comparison groups were inadequate. Early studies compared manic-depressive (predominantly bipolar) with schizophrenic patients; more recent studies have used unipolar depressed patients as controls. Studies using subjects from the general population as controls, although a clear improvement, too often have not controlled for family history of affective illness or for important demographic variables, such as age, IQ, socioeconomic status, and gender. Standard problems of measurement, such as the reliability and validity of the psychometric tests used, are well reviewed elsewhere. We note here, however, that much of the earlier research employed assessment methods based on questionable assumptions and validity (e.g., Rorschach), or on instruments that may no longer be widely used now that newer and more empirically and conceptually based approaches are available. In the sections to follow, older work is noted briefly, with greater emphasis on more contemporary methods.

Several study designs have been used to investigate personality and bipolar illness, including studies of patients across different mood states. In addition, comparisons have been made between affectively ill bipolar and unipolar patients, remitted bipolar and unipolar patients, and remitted bipolar patients and members of the general population. These design strategies are generally appropriate to address simple, descriptive questions, but more complex designs, including longitudinal studies, are greatly needed to pursue questions relating personality characteristics to the clinical and course features of bipolar disorder and social adjustment. Heterogeneity of comparison groups (for example, the tendency not to distinguish melancholic from nonmelancholic unipolar depression) is a significant problem (Parker et al., 2004).

Psychoanalytic Perspectives

Prior to the psychoanalytic era, most early clinical investigators assumed that personality structure in bipolar disorder reflected the underlying disease process.² Psychoanalytic theorists considered two major issues in their writings on manic-depressive illness: the etiology of mania and depression and the underlying personality structure of patients with bipolar illness. Most psychoanalysts focused primarily on the origins and nature of depression rather than mania. Their findings on this subject are well known and are not presented here. Instead, we briefly outline psychoanalytic concepts of mania and the manic-depressive personality. Although neither time nor research has supported the psychoanalytic perspective on bipolar illness, it is historically important, especially in the United States, because it deeply influenced generations of psychiatrists, psychologists, and social workers.

From a psychoanalytic perspective, mania can best be understood as a defense against underlying depressive affect. This fundamental concept has been stated in different ways by many authors.³ Although interesting, the psychoanalytic perspective suffers from the usual difficulties involved in analyzing open-ended, clinical observations: such observations are retrospective, interpretative, and highly speculative. Comparison groups are lacking, and there are few, if any, ways of subjecting the theory to test. Finally, as (Kotin and Goodwin, 1972, p. 684) concluded from their data-based studies of mania:

Our data suggest that if mania is a defense against depression, it is often an inadequate defense, since depressive symptoms remain prominent during the manic phase.

The manic-depressive personality has been viewed by psychoanalysts as narcissistic (Freud, 1917; Fenichel, 1945), masochistic (Gerö, 1936; Jacobson, 1953; Garma 1968), extraverted,⁴ and highly conventional.⁵ Rado (1928) discussed

at length the belief that manic-depressive individuals have an "obsessive need for the approval of others."⁶ Alexander (1948) described the manic-depressive individual as warm, outgoing, and practical—a person who prefers the concrete to the abstract. Not surprisingly, he noted a tendency for the emotions to rule reason. English (1949) characterized the manic-depressive patient as perfectionist, egocentric, logical, wise, talented, afraid to hate (except when manic), and rigid. Other writers (Dooley, 1921; Wilson, 1951; Cohen et al., 1954) highlighted somewhat different constellations of traits and the problems they pose for the therapist and others.⁷ Obviously inadequate as an etiological model, what psychoanalysts have historically viewed as "personality" often appears from our modern perspective to be the expression of symptoms of bipolar illness.

Personality during Mania and Depression

Studies contrasting personality functioning during manic or hypomanic and depressive states often—not surprisingly—reveal dramatic differences. Rather than a core, stable personality as assumed by psychoanalytically oriented theorists, observations made during episodes reflect the powerful influence of fluctuating mood and energy levels, as well as behavioral changes, brought about by the illness.

Comparisons between Manic/Depressive Episodes and Periods of Remission

Bipolar patients tested during remission show clear changes relative to personality profiles obtained during depressive episodes. Early studies focused in particular on neuroticism as measured by Eysenck's (1959) Maudsley Personality Inventory (MPI) (e.g., Perris, 1971; Liebowitz et al., 1979; Hirschfeld et al., 1983). The majority of studies showed significant decreases in neuroticism during remission, as well as increases in extraversion. A review of the stability of neuroticism scores during clinical states of depression and remission (mainly among unipolar depressed patients) suggested that neuroticism captures two elements: (1) a depressive-state influence and (2) an underlying vulnerability dimension that predicts the development and severity of depression (Clark et al., 1994). Neuroticism has also been conceptualized as a general factor termed *negative affectivity*, defined as a temperamental sensitivity to stimuli associated with a range of negative emotional states, negative perceptions and expectations, and low self-esteem (Clark et al., 1994).

In a combined sample of bipolar and unipolar patients, Hirschfeld and colleagues (1983) found that impulsivity scores were unchanged from depression to remission, and that no state-dependent changes occurred in measures of rigidity, obsessiveness, restraint, reflectiveness, demandingness, and dominance. They also found, however, that patients who had recovered from a depression scored lower

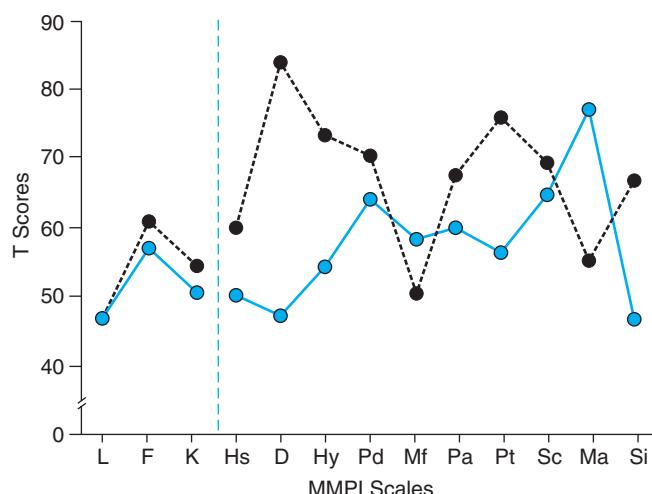

than when depressed on measures of emotional lability, neuroticism, passivity, hypersensitivity, and interpersonal dependency and higher on measures of emotional strength, resiliency, and extraversion. For a subgroup of patients who had not recovered from depression at the time of follow-up, scores on the personality tests did not change, lending credence to the authors' interpretation that "the changes recorded for the recovered patients reflect the influence of the depressed state" (Hirschfeld et al., 1983, p. 698).

A few studies have examined personality profiles across all three major affective states: mania, depression, and euthymia. Researchers (Lumry et al., 1982) administered the Minnesota Multiphasic Personality Inventory (MMPI) to a small sample of bipolar-I patients. The MMPI profiles obtained from 12 patients when manic or hypomanic and from 10 of these patients when depressed were classic manic and depressive profiles. The mean profile for the 12 euthymic patients was entirely within normal limits. The mean MMPI profiles obtained during hypomania or mania and depression are shown graphically in Figure 10-1. The authors concluded that the normal profile pattern obtained during euthymia in most of their lithium-stabilized patients indicated "complete restitution of normality."

Perceptions of Self across Affective States

Widely discrepant views of the self emerge during mania, depression, and normal functioning. Indeed, these differences in self-perception have been incorporated into the DSM-IV diagnostic criteria for mania and depression ("inflated self-esteem or grandiosity" and "feelings of

Figure 10-1. Mean Minnesota Multiphasic Personality Inventory (MMPI) profiles of bipolar probands during a hypomanic/manic phase (blue circles; $n=12$) and during a depressive phase (black circles; $n=10$); 5 cases overlap. (Source: Adapted from Lumry et al., 1982.)

worthlessness or excessive or inappropriate guilt," respectively). In an attempt to study alternating views of the self in depression and mania, Platman and colleagues (1969) administered the Emotions Profile Index weekly to 11 bipolar patients. This psychological measure was designed to assess eight primary emotions: fear, anger, acceptance, rejection, surprise, exploration, joy, and deprivation. Twelve staff members were asked to provide their conceptions of mania and depression. This collective profile was then compared with the profiles produced by patients while manic or depressed.

The staff's and patients' conceptions of depression were strikingly similar on all eight dimensions. For both groups, depression was characterized by decreases in sociability, in interest in new experiences, and in feelings of acceptance, as well as by increases in feelings of deprivation, in aggression, and in rejection of others. Mania, on the other hand, was perceived in very different ways by staff and patients, with seven of eight mean scores showing highly significant differences (at the $p < .01$ level). Patients while manic saw themselves as sociable, trusting, moderately impulsive, and cautious and not at all stubborn or aggressive. Staff members, however, saw them as only moderately sociable, somewhat distrustful, extremely impulsive and aggressive, quite rejecting of others, and completely incautious and unafraid. Response patterns from patients were far more variable than those from staff members, suggesting a more stereotypical (or accurate) view from the latter group.

Patients were asked, when normal, to recall their previous manic and depressive episodes. Their recalled depressive profiles were similar to those produced while actually depressed, and both resembled the staff-generated depressive profile. By contrast, profiles of recalled manic episodes did not resemble those actually obtained during mania. The patients' recall of mania was far more highly correlated with staff perceptions of mania ($r = .95$) than with their own ratings produced while manic ($r = .35$). The authors concluded:

These facts imply that the self-critical judgmental process is severely impaired in the manic state but not in the depressed state. This is consistent with the well-known fact that manic patients do not usually admit to any illness, or that they deny the maladaptive nature of their behavior. This is also why it is difficult to detect the presence of manic states by means of self-description type inventories; these usually show that the manic patient is normal.

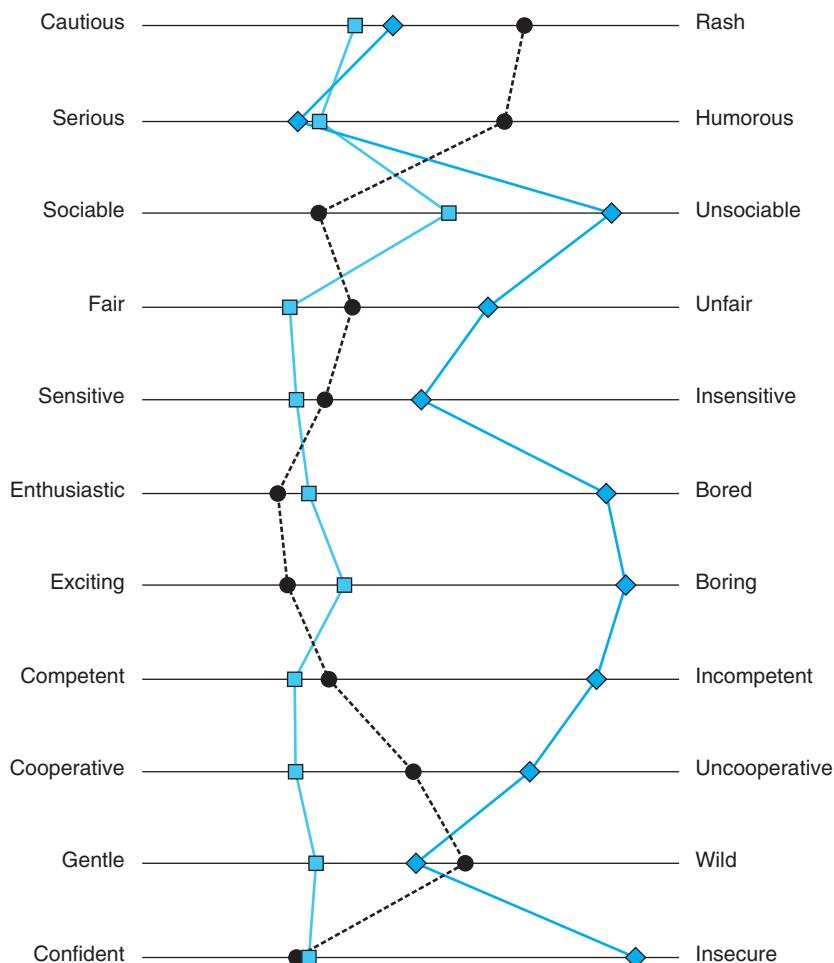

One interesting theoretical question posed by these findings is whether the manic patient is deliberately misrepresenting his feelings and behavior, or whether he is simply unable to discriminate the specific feelings and behaviors which are judged by an outside observer as pathognomonic of mania (Platman et al., 1969, p. 213).

Jamison and colleagues (unpublished data) examined self-perceptions across affective states in 69 euthymic bipolar patients using the Semantic Differential, a combination of associational and scaling procedures. Patients were tested with 22 pairs of opposite adjectives (e.g., good–bad, strong–weak, complex–simple), shown as the polar ends of a seven-point continuum. Patients indicated their perceptions of themselves when manic, hypomanic, depressed, and normal by marking the most descriptive point between each polar pair. Analyses of variance by gender, with repeated measures of mood phase, were performed on the adjective pairs. The phase of illness affected virtually all pairs, indicating that changes in self-perception across the affective states of bipolar illness were consistent and widespread (Fig. 10–2). Statistical comparisons, conducted to identify significant differences between each pair of different mood phases, revealed a number of consistent patterns, particularly for the adjective pairs reflecting a positive–negative, or evaluative, dimension.

For all these pairs, self-perceptions in the depressed phase were significantly more negative than those in the other phases. More interesting, for all except two pairs (serious–humorous and cautious–rash), the ratings for the hypomanic phase did not differ significantly from those for the euthymic phase. Compared with men, women rated themselves overall as less active and as more “cold” and “boring” during the depressed phase, and more “exciting” and “warm” during the manic phase. Women also perceived themselves as more changeable overall relative to men.

Of interest, men’s and women’s perceptions of their masculinity–femininity in various phases of illness also changed (not shown). Women felt less feminine and men less masculine in the depressed than in the euthymic phase; the opposite was true for the hypomanic and manic phases. In other words, depression had a neutering effect and hypomania or mania a polarizing or enhancing effect on sexual identity.

Figure 10–2. Perceptions of self in 69 bipolar patients as a function of affective state. Squares = normal state; diamonds = depressed state; circles = hypomanic state. (Source: Jamison et al., unpublished data.)

Throughout their bipolar cycles, patients underwent not only mood swings, but also substantial changes in their perception of self, self-esteem, energy expenditure, and interpersonal conduct. The study revealed that, as expected, bipolar patients had high self-esteem in the hypomanic or manic phase and low self-esteem in the depressive phase. Of more interest, self-esteem in the euthymic state did not differ substantially from that in the hypomanic phase. That is, bipolar patients generally held themselves in high regard; their apparently low self-esteem during the depressive phase was encapsulated, without perceived long-term adverse effects. Interpersonal conduct was perceived by patients to be less socially desirable in the hypomanic phase than during euthymia. Such findings are especially revealing in light of the common conception that bipolar patients are outgoing and socially engaging during their highs; this suggests that patients may have some insight into the one-sidedness of their social engagement in the manic and hypomanic phases.

Comparisons of Remitted Bipolar Patients and Normal Groups

Two major dimensions of personality—neuroticism and extraversion—have been compared between remitted bipolar patients and normal groups.

Neuroticism

Measures of neuroticism, typically using the MPI (or its later version, the Eysenck Personality Inventory [EPI]), identify significant differences between each pair of different mood phases (e.g., Clark et al., 1994). The neuroticism scale of the MPI/EPI is more likely to reflect changes in clinical state than is the extraversion scale. Several investigators have shown that neuroticism scores decrease following recovery in patients with endogenous depression (Crookes and Hutt, 1963; Coppen and Metcalfe, 1965; Ingham, 1966). In normal populations, neuroticism and extraversion are independent factors, but in psychiatric patients, the correlation between the two is usually quite high.

Eysenck and colleagues (Eysenck and Eysenck, 1963a,b) have defined neuroticism as “a largely inherited lability of the autonomic nervous system” and as a general measure of emotionality. Its principal components include mood swings, a sense of inferiority, poor emotional adjustment, lack of social responsibility, suspiciousness, lack of persistence, social shyness and hypochondriasis, and lack of relaxed composure. Moodiness, which has the single highest loading on the neuroticism factor in the EPI, is illustrated by positive answers to the following sample items: “Do you sometimes feel happy, sometimes depressed, without any apparent reason?” “Are you inclined to be moody?” and “Do you have frequent ups and downs

in mood, either with or without apparent cause?” Because of this measure of affective lability, the construct has frequently been investigated as a potential indicator of bipolar disorder.

Only one of several early studies⁸ comparing neuroticism scores on the MPI/EPI found significant differences between remitted bipolar patients and normal populations (Hirschfeld and colleagues [1986] found lower neuroticism among never-ill relatives of bipolar patients than among the patient group). This apparently anomalous finding was replicated in a more recent study conducted within the same program (the Collaborative Program on the Psychobiology of Depression). Solomon and colleagues (1996) compared 30 individuals diagnosed with bipolar-I disorder who were first-degree relatives or spouses of the patients in the Hirschfeld study and 974 never-ill relatives. They found that the bipolar patients, who were currently in remission, scored significantly higher on neuroticism than did the controls. Thus although most of the early studies indicated no stable traits of elevated neuroticism for remitted bipolar patients, results of more recent investigations suggest that some samples of such patients may in fact show elevated levels of the trait.

Extraversion–Introversion

As with neuroticism, the primary psychological measure of the extraversion–introversion dimension used in research on affective illness is the MPI/EPI. Extraversion was originally characterized in the MPI/EPI by impulsivity (typical item: “Are you inclined to be quick and sure in your actions?”) and sociability (typical item: “Would you be very unhappy if you were prevented from making numerous social contacts?”). In normal populations, impulsivity and sociability correlate at 0.5, producing a second-order factor of extraversion. More recently, impulsivity has been recognized as a separate factor, and it is not included in contemporary assessments of extraversion. Thus there may be some discrepancy between results of older and newer studies (Watson et al., 1994). Introversion can be further subdivided into social introversion (characteristic of those who prefer not to have much social contact with others) and neurotic introversion (characteristic of those who are afraid to have contact with others and are basically unsure of themselves and their interpersonal competence) (Eysenck, 1956). Just as neuroticism has been conceptualized as negative affectivity (as discussed earlier), extraversion has been conceptualized as positive affectivity—a stable, heritable, temperamental trait (Clark et al., 1994).

Based on the typical conceptualization of extraversion, many researchers have expected to find greater levels of this trait among bipolar patients. The authors of the MPI/

EPI (Eysenck, 1959; Eysenck and Eysenck, 1963a,b) described a typical extravert as one who:

[is] sociable, likes parties, has many friends, needs to have people to talk to . . . craves excitement, takes chances . . . is generally an impulsive individual . . . [is] easy going, optimistic . . . prefers to keep moving and doing things . . . and [loses] his temper quickly.

A typical introvert, on the other hand:

[is a] quiet, retiring sort of person, introspective, fond of books rather than people . . . reserved and distant except to intimate friends . . . tends to plan ahead . . . distrusts the impulse of the moment . . . does not like excitement . . . likes a well-ordered mode of life . . . keeps his feelings under close control . . . does not lose his temper easily . . . [and is] reliable, somewhat pessimistic.

As noted earlier, the extraversion–introversion scale of the MPI/EPI, unlike the neuroticism scale, is relatively impervious to the effects of mood or clinical state. Most studies comparing extraversion in remitted bipolar patients and normal individuals have found no significant differences between the two groups. One study of 45 bipolar patients, using the Cattell 16 Personality Factor Inventory, reported that remitted bipolar patients were more extraverted than the general population (Popescu et al., 1985). Two studies, however, found remitted female bipolar patients to be less extraverted (more introverted) than published norms or never-ill relatives (Hirschfeld, 1985; Hirschfeld et al., 1986). There was no significant difference for men (Hirschfeld et al., 1986).

Cyclothymia and Hyperthymia

Several investigators have found that an underlying cyclothymic temperament is particularly associated with bipolar-II disorder (Hartouche et al., 1998; Benazzi and Akiskal, 2005), as well as being elevated in healthy relatives of bipolar probands (Mendlowicz et al., 2005). Other investigators have confirmed Kraepelin's observation of a high rate of hyperthymic temperament in both bipolar-I and bipolar-II patients (Cassano et al., 1992; Perugi et al., 1998), although the interpretation of this observation is confounded by the fact that elevated rates of hyperthymic temperament have been demonstrated in control subjects as well (Evans et al., 2005; Matsumoto et al., 2005; Mendlowicz et al., 2005). Other researchers have found that individuals with bipolar disorder score significantly higher than controls on measures of novelty seeking (a tendency to seek out new situations, to be curious and impulsive, a trait discussed further in the next section) (Cronin and Zuckerman, 1992; Young et al., 1995; Nowakowska et al., 2005). A similar elevation in novelty-seeking behavior has been

shown to occur in pediatric bipolar patients and in the offspring of bipolar patients (Chang et al., 2003).

In summary, there are few significant differences between remitted bipolar patients and normal individuals on the two most frequently assessed personality dimensions, neuroticism and extraversion–introversion. Other studies that have included different measures of personality traits have also failed to find significant differences (e.g., Lepkifker et al., 1988). However, Solomon and colleagues (1996) found that the bipolar-I group scored significantly lower than never-ill controls on measures of emotional stability, ego resiliency, and ego control. They cautioned that their comparison group had been screened for absence of psychopathology, whereas prior disorders may not have been ruled out for control groups in other studies. They also noted that nearly 50 percent of their bipolar group had a history of substance abuse. The results of early studies require caution as well because their samples were small, and probably differed as to the extent of their predominance of mania and depression, as well as their social role functioning. Thus some samples of bipolar patients may indeed differ from normal controls during remission, perhaps depending on the composition and clinical features of the sample. In particular, it is likely that elevated neuroticism and introversion characterize those with prominent depressive episodes. (See Savitz and Ramesar, 2006, for an excellent review of personality research in bipolar disorder.)

Significant differences are found between bipolar patients and controls on measures of temperament. Several studies have found that cyclothymia and novelty seeking are more elevated in bipolar samples.

Comparisons of Bipolar and Unipolar Patients

Of historical interest in the pursuit and eventual recognition of the unipolar–bipolar distinction was a series of studies conducted in the 1970s comparing depressed unipolar and bipolar patients. Donnelly and colleagues (e.g., Donnelly and Murphy, 1973, 1974; Donnelly et al., 1976) found several differences between the groups: when acutely depressed, bipolar patients exhibited a greater social desirability response set with more “normal” profiles and less neuroticism, less impulse control, and less anxiety relative to unipolar patients. Many other studies found that unipolar patients scored higher in the direction of neuroticism and low self-esteem, or emotional instability.⁹ Two studies using alternative measures of neuroticism concluded that bipolar patients were more neurotic than unipolar patients (Abou-Saleh and Coppen, 1984; Popescu et al., 1985). However, many studies that specifically pursued comparisons of unipolar and bipolar patients in remission on neuroticism using the MPI/EPI failed to show differences between the groups.¹⁰

In several studies of extraversion using the MPI/EPI¹¹ and two using the extraversion factor from the Cattell 16 Personality Factor Questionnaire (Murray and Blackburn, 1974; Popescu et al., 1985), remitted bipolar patients scored higher on extraversion than did remitted unipolar patients. More recent and more tightly designed studies also found that remitted bipolar patients scored significantly higher on extraversion than remitted unipolar patients (e.g., Sauer et al., 1997; Janowsky et al., 1999). Preliminary findings suggest that not only bipolar–unipolar differences but also differences between bipolar subtypes may be associated with specific temperamental and personality profiles. Akiskal and colleagues (2006) administered a large battery of self-report personality scales to 78 bipolar-I, 64 bipolar-II, and 251 unipolar patients, all remitted. Most of the bipolar-I patients described themselves as essentially normal in emotional stability and extraversion, and they scored low on measures of neuroticism. In contrast, both the bipolar-II and unipolar patients scored high on neuroticism, although in the bipolar-II subgroup, the neuroticism scores were elevated as a result of mood lability, while in the unipolar group, the elevation was due to subdepressive traits. Two studies (Bech et al., 1980; Hirschfeld et al., 1986) found no significant differences in extraversion between the two groups. Hirschfeld and colleagues (1986) found no significant bipolar–unipolar differences in women, but they did find that bipolar men scored higher on extraversion measures than did unipolar men. Three studies of dominance, a closely related personality factor, found that bipolar patients were more dominant than unipolar patients (Strandman, 1978; Abou-Saleh and Coppen, 1984; Popescu et al., 1985).

A more recent comparison of depressed unipolar and bipolar patients failed to find greater “normality” in the bipolar group (Wetzler et al., 1995). In general, across testing with the MMPI and the Millon Clinical Multiaxial Inventory-II (MCMI) (Millon, 1987), few consistent differences were observed. Bipolar patients scored higher on indicators of narcissism, antisocial behaviors, and compulsive personality style, but Wetzler and colleagues (1995) noted that such elevated scores could be due to residual aspects of mania, such as grandiosity.

Cloninger (1987) developed a personality assessment system (the Tridimensional Personality Questionnaire [TPQ]) purporting to link heritable temperaments with underlying brain monoaminergic pathways. Three dimensions—harm avoidance (HA; pessimistic and shy versus carefree and outgoing), reward dependence (RD; sentimental and tenderhearted versus insensitive and practical), and novelty seeking (NS; curious and impulsive versus stoical and orderly) are presumed to relate to, and perhaps predict, forms of psychopathology.

A consistent finding in the literature, for example, is an association between elevated HA and unipolar depression (Strakowski et al., 1992), even during remission. Strakowski and colleagues (1993) found that bipolar patients, by contrast, scored significantly lower on HA than did unipolar depressed patients, and did not differ from controls. Young and colleagues (1995) suggested, however, that the patients in the Strakowski sample were not recovered from mania at the time of testing, and they therefore undertook a study of carefully defined “remitted” bipolar patients compared with recovered unipolar patients and controls. They found no significant differences between unipolar and bipolar patients on HA, and both patient groups had significantly higher HA than did the controls. Bipolar patients scored significantly higher on the NS scale than did unipolar and control subjects. The results suggest that HA may be a nonspecific indicator of mood disorders (perhaps like neuroticism), whereas NS may be more specific to bipolar disorder. The cross-sectional design of the Young et al. study makes it impossible to determine whether the traits result from manic episodes, are subsyndromal symptoms, or represent premorbid personality characteristics. There is suggestive evidence that bipolar patients with an earlier age at onset are more harm avoidant (Engström et al., 2003). A recent study of type A behavior in 23 bipolar-II and 42 unipolar patients found that the bipolar patients had significantly higher scores, largely attributable to greater impatience, time urgency, and irritability (Oedegaard et al., 2006).

Another study employing the TPQ compared 50 bipolar patients considered to be euthymic with U.S. norms. Like Young and colleagues (1995), Osher and colleagues (1996) found that the patients had significantly elevated scores on HA, as well as on RD, including the “persistence” subscale of RD. Unlike Young’s group, however, Osher and colleagues found no differences on NS.

Overall, few general conclusions can be drawn. Although bipolar patients in remission may differ from unipolar patients on extraversion, there is little indication that they are “healthier” than unipolar patients, and there is mixed evidence on normalcy during remission compared with well controls. Inconsistencies in study findings derive in part from heterogeneity among populations (due to use of differing diagnostic or inclusion criteria), variations in type and degree of illness (including manic/depressive states and response to treatment, as well as degree of recurrence within unipolar patients), inconsistent criteria for “remission,” and inclusion or exclusion of patients with “double depressions” (concurrent major depressive episode and dysthymia). The search for descriptive differences therefore appears unproductive, at least at this point in time, and more interesting questions of prediction and the implications of

various traits are increasingly the focus of research, as discussed in the next section.

Predictive Associations between Personality Features and Clinical Outcome

Premorbid Traits and Vulnerability

Although the topic of premorbid traits and vulnerability is a well-developed area of research in unipolar depression, it is rarely addressed in bipolar samples, perhaps because of the general assumption of a genetically based biological predisposition to bipolar disorder. Nevertheless, as suggested in Chapter 2, there may be early traits that portend the development of bipolar illness, or characteristics that might be viewed as risk factors given the appropriate biological vulnerability. An obvious research strategy would be assessment of premorbid characteristics, ideally in longitudinal studies involving subjects who are at high risk by virtue of having one or both parents with bipolar disorder. As indicated in Chapter 6, however, such work is in its infancy.

Although several studies have attempted to evaluate personality characteristics or subsyndromal symptoms of mood disorders,¹² there is little consensus on the best methods and instruments to use for the purpose. Several early studies identified personality traits associated with high-risk children: aggressiveness (e.g., Worland et al., 1979; Kron et al., 1982); extraversion, introversion, and impulsiveness (Kron et al., 1982); and sensation seeking (e.g., Nurnberger et al., 1988). Long-term follow-up studies are needed to determine whether such traits predict eventual bipolar disorder in high-risk populations. One such study of premorbid functioning was conducted by Clayton and colleagues (1994), who reviewed military records of performance on the Freiburg Personality Inventory of men who were later diagnosed with bipolar disorder. No differences in premorbid personality were observed as compared with controls who did not develop bipolar disorder.

Temperament and Vulnerability

As noted earlier, neuroticism may be conceptualized as a broad temperamental construct of negative affectivity, which has been linked empirically to general emotional distress (anxiety and depression) reflecting both current mood state and vulnerability to developing depression (Clark et al., 1994). Extraversion, conceptualized as positive affectivity, may be predictive of depression (with low positive affectivity being associated with depression and introversion). Persons with high positive affectivity/extraversion “feel joyful, enthusiastic, energetic, friendly, bold, assertive, proud, and confident,” whereas those with low positive affectivity/introversion “tend to feel dull, flat, disinterested, and unenthusiastic” (Clark et al., 1994, p. 107). While low positive affectivity/

introversion has been linked to depression, other theorists have recently proposed that high positive affectivity/extraversion may be linked to a biologically based approach system that activates behavior in response to signals for reward—also called the behavioral activation system (Gray, 1982). According to Depue and Iacono (1988), the behavioral activation system is similar to what they term the behavior facilitation system, which they believe underlies bipolar disorder. The latter system is believed to include locomotor behavior, incentive motivation, interest and alertness, and level of pleasure or excitement seeking. Poor regulation and the tonic level of the system have been speculated to predict mood disorders and their specific manifestations. Depue and colleagues (1994) also proposed a link between temperament and neurotransmitter functioning, and found preliminary evidence of an association between dopaminergic functioning and positive emotionality. The association among positive affectivity, bipolar temperament, and emotional resilience was addressed at length by Jamison (2004).

Johnson and colleagues developed a polarity-specific model of mood states and hypothesized that behaviors and traits consistent with the behavioral activation system may differentially predict manic symptoms (see, e.g., Johnson et al., in press). They specifically tested the hypothesis that extraversion and achievement striving would predict manic symptoms over time in bipolar-I patients, whereas neuroticism would predict increases in depressive symptoms (Lozano and Johnson, 2001). Using a version of the NEO Five-Factor Inventory (Costa and McCrae, 1992) that includes all of these constructs, Lozano and Johnson (2001) followed 39 bipolar patients over a 6-month period. Controlling for initial manic symptoms, they found that achievement striving predicted increased manic symptoms (although extraversion did not); likewise, controlling for initial depressive symptoms, they found that level of neuroticism predicted increases in depression. Thus their findings provided some support for their polarity-specific model.

Partially consistent data were obtained by Strakowski and colleagues (1993) in investigating their hypothesis regarding recovery from first-episode mania among 27 bipolar patients. They found that, although personality measures in the form of TPQ scores did not predict time to clinical recovery, *functional* recovery (which was uncorrelated with symptom status) was predicted by level of novelty seeking on the TPQ. Novelty seeking was significantly higher among those who failed to attain premorbid levels of adjustment, a finding consistent with the view that this dimension reflects impulsiveness and pleasure seeking. The authors noted, however, that they could not rule out the possibility that high scores on novelty seeking reflected subsyndromal symptoms. (Although bipolar patients score higher than unipolar patients on novelty seeking, Parker and colleagues

[2004] made the critical point that the heterogeneity among unipolar depressed patients is a confusing and confounding source of inconsistency in studies.)

An additional predictive study, by Carpenter and colleagues (1999), examined the association between neuroticism and affective symptoms, self-confidence, and marital satisfaction among a sample of married bipolar patients. Using the NEO Five-Factor Inventory of personality (Costa and McCrae, 1985), administered when the patients were not in an episode, they found that greater neuroticism predicted more severe illness during the 2 years before entry into the study and during the first year of treatment, worse Global Assessment Scale (GAS) scores during treatment, and lower self-confidence. Neuroticism also predicted Axis II (personality disorder) dimensional scores. Of interest, extraversion—but not neuroticism—predicted marital distress. The authors noted that in general, the personality scores were not especially deviant as a group, although there was considerable variability; they also observed that extremely high neuroticism scores could be indistinguishable from personality disorder.

Effects of Medication on Personality

Evidence for a strong effect of medication on personality functioning relates almost entirely to lithium and comes from several sources: studies of lithium's effects on normal subjects; *prima facie* evidence derived from both clinical and systematic observation of the drug's profound effects on behavior, mood, and personality in affectively ill patients; and comparisons of personality studies completed in the prelithium era with those completed after lithium treatment became widespread. Results of the latter studies indicate that personality differences between bipolar patients and other groups pale considerably, and often entirely, when lithium is used effectively.

We raise here several important philosophical and treatment issues. Does lithium make the personality of a bipolar individual revert to pre-illness levels, or does it decrease variability in mood and personality functioning beyond those levels? Does lithium create an abnormally stable personality and mood system? To what extent is personality in lithium-treated patients a function of blood level? Does a patient who is inadequately treated with or only partially responsive to lithium show premorbid personality or subsyndromal disease? How does lithium's influence on personality affect medication adherence?

Several authors have examined the effects of lithium on personality function in normal subjects. Schou (1968) was the first to describe systematically the cognitive, behavioral, and personality effects of the drug in normal people. At relatively low blood levels, lithium had minimal effects on personality functioning in medical student volunteers.

In three researchers taking lithium at higher levels, however, effects were more pronounced. They noted occasional hypersensitivity but also decreased responsiveness to their environment, increased indifference and malaise, greater passivity, and cognitive changes (discussed further in Chapters 12 and 21). Judd and colleagues (1977a), studying lithium's effects on normal male volunteers, found that in addition to reporting a mood-lowering effect, their subjects cited less inclination and desire to "deal with the demands of the environment." Normal men studied by Kropf and Müller-Oerlinghausen (1979) showed, while on lithium, decreased social involvement, activity, and concentration, as well as increased boredom and lethargy. When White and colleagues (1979) administered the Profile of Mood States (POMS) to 10 normal volunteers treated with lithium, the subjects reported a reduced sense of well-being and fewer social interactions; they also complained of fatigue, anxiety, lack of initiative, and decreased efficiency. In an indirect measure of lithium's ability to attenuate emotional responsiveness, Belmaker and colleagues (1979) found that, while taking lithium, neither normal subjects nor patients experienced the predicted increased heart rate generally caused by participation in cognitive tasks. Both of these studies, although intriguing, were relatively short-term trials (1–3 weeks and 2 weeks, respectively), and there is some indication that longer periods of time on lithium result in at least partial accommodation to some of these effects.

The most clear-cut influences of lithium on bipolar personality were evident in personality studies done on euthymic, lithium-stabilized patients. Additionally, a few studies have examined personality and mood stabilization over time in lithium-treated, affectively ill patients. Bonetti and colleagues (1977) administered the EPI and the Marke-Nyman Temperament Scale to 33 recurrent (minimally three episodes) unipolar and 28 bipolar patients at the end of the index episode and at least 3 months later. They found that personality changes were more pronounced in the bipolar patients, especially on measures of sociability, initiative, and impulsiveness. Neuroticism scores decreased most dramatically within the unipolar group (test-retest differences, $p < .001$). The authors speculated that lithium both reduced symptoms and altered habitual patterns of personality, such as high activity levels and impulsiveness in bipolar patients and anxious-neurotic traits in unipolar patients.

In an interesting and important study of the relationship between lithium blood level and personality change, Kropf and Müller-Oerlinghausen (1985) conducted a double-blind study of lithium dose reduction (20 percent) in 14 long-term lithium-treated patients (5 unipolar, 9 bipolar), all of whom were euthymic when tested. Eleven patients (3 unipolar, 8 bipolar) maintained at their regular lithium levels served as

controls. The patients receiving higher levels of lithium tended to be less active, less obsessive, and less elated. Specifically, those taking lower levels of lithium scored higher on Von Zerssen's measures of initiative and assertiveness ($p < .05$) and of social resonance (social acceptance and assertiveness), transparency (social openness and sensitivity), and social potency (sociability and "ability for devotion"). However, a significant proportion (29 percent) of the patients in the experimental group became affectively ill at a reduced lithium level.

Mood stability in lithium-treated patients, although not a direct measure of personality, clearly is related to personality functioning. Folstein and colleagues (1982) administered the Visual Analogue Mood Scale (VAMS) for 30 days to 65 euthymic bipolar patients on chronic lithium therapy and to 36 nonpatient control subjects. The mean mood ratings for the two groups were similar; the patients, however, reported significantly less mood variability. The authors attributed this unusual degree of mood stability to the effects of lithium treatment and suggested that euthymic patients might view this change as an undesirable aspect of lithium therapy. DePaulo and colleagues (1983) administered the VAMS to 17 euthymic bipolar patients and 21 nonpatient controls. Like Folstein and colleagues (1982), they found that the mean mood ratings were similar in the two groups and that the patients' moods were less variable than those of the controls. Three bipolar patients were studied separately, during and after lithium treatment. Two became manic, and the third, who remained euthymic while off lithium, showed markedly increased variability in daily mood ratings. The authors were uncertain whether these results reflected baseline differences in reporting between affectively ill patients and normal controls, lithium's therapeutic effects, or a medication effect.

PERSONALITY DISORDERS

Axis II (personality) disorders occur relatively frequently in clinical populations (with a range of about 5 to 40 percent, varying by personality disorder type) (Widiger and Rogers, 1989). Although epidemiologic studies of personality pathology in community samples have been infrequent and limited in scope, Weissman's (1993) review of such studies suggests that the population prevalence is 10 to 23 percent. Researchers have raised the question of the rates of personality disorders in bipolar samples and explored the correlates of Axis II pathology.

Early studies of the comorbidity of personality disorder with bipolar illness were hampered by methodological shortcomings, such as shifting diagnostic criteria for assessing Axis II disorders, assessment methods of uncertain validity, unclear or mixed samples of bipolar patients (e.g.,

comingling bipolar-I and -II), and small patient samples. A particularly serious problem was the failure to evaluate bipolar patients during euthymic states, so that reported "personality disorders" may have reflected largely mood state-related symptoms rather than stable underlying personality pathology.

Table 10-1 presents recent studies that attempted to verify bipolar-I diagnoses in patients while making an effort to control for mood state at the time of the assessment of Axis II disorders. For the most part, these studies used validated structured interview methods for assessing personality disorders. The samples included outpatients as well as inpatients, and those of varying ages and social/cultural circumstances. However, these studies employed relatively small samples, and some failed to control for other comorbid conditions, such as substance abuse. It is important to note that age at onset of bipolar disorder has not been explored (see Chapter 6), and early age at onset may be a significant predictor of Axis II symptomatology. Moreover, many of the studies were based on samples in tertiary care treatment, and may therefore reflect relatively more severe or complex cases of bipolar disorder.

Despite the significant variability in sample characteristics among these studies, however, they yield evidence of rates of comorbid personality disorders that, although relatively consistent with those of other diagnostic groups in clinical populations, exceed the rates in the general population. Several studies involved a unique sample not generalizable to the overall population of persons with bipolar-I disorder; for example Kutcher and colleagues (1990) included only adolescents, Carpenter and Hittner (1995) only married patients, and Kay and colleagues (1999) only male veterans. Overall, the rates of personality disorders across all the samples ranged from 22 to 62 percent, as listed in Table 10-1.

According to the studies reported in Table 10-1, somewhat higher rates of personality disorders were found among bipolar patients who had experienced more previous episodes and those who had a history of alcohol abuse, and when self-report questionnaires or informant reports (rather than clinician interviews) were used as the basis for symptom assessment. At least two studies found an association between greater levels of depressive symptoms and personality disorders (Brieger et al., 2003; George et al., 2003). One additional study—not included in the table because it appears to have combined bipolar-I, bipolar-II, and cyclothymic patients in unknown proportions—found that participants with dysthymia or bipolar disorder were more likely to have personality disorders (70 percent) than patients in treatment for other disorders, such as anxiety disorder (Flick et al., 1993). A recent study of young adults with affective illness found significantly higher median levels of

TABLE 10–1. Personality Disorders in Bipolar-I Patients

Study	Sample	Method	Clinical State	Comparison Group	Overall Rate ^a (%)	Most Common Diagnoses
Kutcher et al., 1990	20 adolescents/outpatients ^b	Personality Disorders Examination (PDE) (interview)	Euthymic		35	Borderline, narcissistic
Pica et al., 1990	26 inpatients (16 bipolar-I, 10 bipolar schizoaffective)	Structured Interview for DSM-III Personality Disorders (SIDP-III)	Current symptoms not controlled	33 patients with schizophrenia	62	Histrionic, antisocial, borderline
O'Connell et al., 1991	50 outpatients	Personality Diagnosis Questionnaire-Revised (PDQ-R)	Current symptoms not controlled but "stable"		58	Borderline, histrionic
Carpenter et al., 1995	23 outpatients (married or cohabiting)	PDE	Few or no current symptoms		22	Dependent, borderline, obsessive-compulsive
Peselow et al., 1995	66 patients	Structured Interview for DSM-III-R Personality Disorders (SIDP-III-R)	Interviewed when manic or hypomanic, then again when euthymic		53 manic or hypomanic, 45 euthymic	Borderline, schizoid, histrionic
Dunayevich et al., 1996	33 first-episode, 26 multiple-episode inpatients	Structured Clinical Interview for DSM (SCID-II)			48	Avoidant, Cluster B (mixed) ^c
Barbato and Hafner, 1998	42 outpatients	International Personality Disorders Examination (IPDE) (interview)	"In remission"		45	Histrionic, borderline, avoidant, compulsive
Ucok et al., 1998	90 outpatients	SCID-II	Euthymic	58 normal controls	48 bipolar patients, 16 controls	Histrionic, compulsive, paranoid
Kay et al., 1999	61 Veterans Affairs (VA) outpatients	SCID-II PDQ-R	Euthymic	Compared patients with and without history of alcohol abuse disorder	38 ^d	Cluster A, Cluster C ^c
Brieger et al., 2003	60 inpatients	SCID-II NEO Five Factor Personality Inventory	"Mostly in remission"	117 unipolar depressed inpatients	38 bipolar, 51 unipolar	Compulsive, narcissistic, borderline
George et al., 2003	52 outpatients	PDE	"In remission"		29	Histrionic, compulsive

^aEstimates of personality disorders in general clinical populations range from 5 to 40 percent (Widiger and Rogers, 1989), and in community samples from 10 to 23 percent (Weissman, 1993).

^bThere were no differences in rates of Axis II disorders between bipolar-I and schizoaffective patients, so the authors combined the groups in their analysis.

^cCluster A: paranoid, schizoid, schizotypal; Cluster B: antisocial, borderline, histrionic, narcissistic; Cluster C: avoidant, dependent, obsessive-compulsive.

^dHighest in patients with history of alcohol abuse.

borderline characteristics in the bipolar patients than in those with major depression (Smith et al., 2005). Three of the borderline characteristics differentiated bipolar from unipolar depression: "I've never threatened suicide or injured myself on purpose"; "I have tantrums or angry outbursts"; and "Giving in to some of my urges gets me into trouble." A study of 40 bipolar-II patients (Vieta et al., 1999) found that 33 percent met diagnostic criteria for a personality disorder. Overall, therefore, the typical bipolar patient sample appears to have relatively high rates of Axis II comorbidity.

Table 10-1 also indicates the most frequent individual personality disorder diagnoses. A number of studies found multiple disorders in bipolar patients, as is generally typical of diagnoses on Axis II. Viewed individually, however, the Cluster B disorders—especially borderline and histrionic—were most common among the bipolar samples. Rossi and colleagues (2001) also reported high rates of borderline as well as compulsive personality disorders; however, their bipolar sample included only those with recent depressive episodes, excluding those with recent mania.

Despite the general consistency in frequency and types of personality disorders observed across studies, the meaning of the results remains elusive. Conceptually, it is widely recognized that rates of comorbidity may be inflated because of the overlap of symptoms across disorders. Despite various efforts to assess for personality pathology during euthymic states, it is nonetheless possible that the personality disorders reported may reflect the symptoms of hypomania or depression. For instance, histrionic or borderline pathology may be difficult to distinguish from attention seeking, intense or exaggerated emotional expression, intense irritability, impulsive or provocative behaviors, and affective instability and rapidly changing mood. (See MacKinnon et al., 2006, for an excellent review of the centrality of affective instability to both bipolar illness and borderline personality disorder.) Peselow and colleagues (1995), comparing personality pathology assessed in the same patients during hypomania and euthymia, found a reduction in such pathology when the patients had recovered from the hypomanic state. Thus personality pathology may be inflated as a result of overlapping symptoms in Axis I and II categories containing manic, mixed, and depressive symptoms and behaviors.

A related conceptual question, noted previously, is the issue of whether personality pathology may be a consequence of bipolar disorder. Thus, for example, the unstable self-image or identity disturbance or the recurrent suicidal or parasuicidal behaviors of the borderline personality may be a reaction to the cumulative unpredictable and massively destructive mood swings of bipolar illness. It is possible that the onset of bipolar disorder in childhood or early adolescence may exacerbate identity difficulties

and impair the ability to form solid and sustaining relationships, thereby contributing to diffuse Axis II symptomatology. Thus the maladaptive behaviors reflected in personality disorders may in some cases be dysfunctional coping methods or adaptations to the illness.

A third conceptual consideration concerns sampling: patients included in the studies reported in Table 10-1 may reflect those who are most disturbed, and who are seen in research-oriented settings that may draw more difficult patients not readily managed in community or private care. As noted, clinical samples in general (compared with epidemiologic samples), and especially those in tertiary care settings, may not be representative in terms of comorbidity because they are likely to be sicker.

Finally, as discussed in Chapter 3, some would argue against conceptualizing Axis II disorders as conditions comorbid with bipolar disorder. Instead, it is argued, they may represent forms of disorder in the bipolar spectrum (e.g., Akiskal et al., 1985, 2000; Deltito et al., 2001). Gunderson and colleagues (2006) recently reported the results of a 4-year prospective investigation of 196 patients with bipolar disorder and 433 patients with personality disorders. They found that bipolar-I and bipolar-II disorders were significantly more common in patients with borderline personality disorder (19.4 percent) than in patients with other types of personality disorder (7.9 percent). The presence of co-occurring bipolar disorder had no significant effect on the course of the borderline personality disorder, as measured by remission rates, functional adjustment, or treatment utilization rates (hospitalization and medication usage). The investigators concluded that there was only a modest association between bipolar disorder and borderline personality disorder, "thereby making a strong spectrum relationship with bipolar disorder extremely unlikely" (p. 1177). We do not know enough at the present time to draw firm conclusions on this question.

Despite uncertainty about the conceptualization of personality disorder comorbidity, one meaning of comorbid Axis II pathology is not ambiguous: bipolar (or any psychiatric) patients who have personality pathology typically have worse outcomes. Kay and colleagues (2002) found significantly lower rates of employment, more complex medication regimens, and greater likelihood of substance and alcohol abuse among bipolar-I male veterans who had diagnosed personality disorders (but no differences between the groups in age at onset or duration of disorder). Over time, Carpenter and colleagues (1995) found that patients with personality disorder had significantly more symptoms and worse social adjustment scores than those without such disorder. Others have also found this to be the case (Bieling et al., 2003). Kutcher and colleagues (1990)

found that adolescent bipolar patients without personality disorder had a better response to lithium treatment.

Although Ucok and colleagues (1998) did not find differences in lithium responsiveness among their bipolar patients with and without personality disorder, they did find that patients with Axis II comorbidity had made more severe suicide attempts. Barbato and Hafner (1998) found that bipolar-I patients with personality disorder had significantly more lifetime days hospitalized and more severe symptomatology than those without personality disorder, and were more likely to report that their medications were “unhelpful.” Others (Dunayevich et al., 1996) have reported that patients with multiple episodes were more likely than first-episode patients to have personality disorder. Moreover, in a 12-month follow-up of these patients, those diagnosed with personality disorder were less likely to show syndrome or symptom recovery and had achieved significantly less functional recovery (Dunayevich et al., 2000). The authors speculated that poor medication adherence may mediate the link between personality disorder and poor outcome (see Chapter 21). Poor adherence, in turn, may reflect poorer response to treatment. Finally, Vieta and colleagues (1999) reported that those in their bipolar-II sample with personality disorder had earlier age at onset of bipolar disorder and more severe suicidal ideation. In general, these findings are consistent with those of research on other psychiatric populations, indicating that, whether true “comorbidity” is involved or mainly more severe general symptomatology, patients with Axis II disorders typically have worse illness course and are more difficult to treat effectively.

INTERPERSONAL FUNCTIONING

No one has the slightest idea of what I've been through with Cal [Robert Lowell]. In 4½ years, counting this present breakup, he has had four collapses! Three manic, and one depression. These things take time to come and long after he is out of the hospital there is a period which can only be called “nursing.” The long, difficult pull back—which does not show always to others. I knew the possibility of this when I married him, and I have always felt that the joy of his “normal” periods, the lovely time we had, all I've learned from him, the immeasurable things I've derived from our marriage made up for the bad periods. I consider it all a gain of the most precious kind. But he has torn down this time everything we've built up . . . how difficult these break-ups are for both of us. (Elizabeth Hardwick¹³)

Moods are by nature compelling, contagious, and profoundly interpersonal. Mania and depression alter the perceptions and behaviors not only of those who have them,

but also of those who are related or closely associated. Bipolar illness—marked as it is by extraordinary and confusing fluctuations in mood, personality, thinking, and behavior—inevitably has powerful and often painful effects on relationships. Violence, poor judgment, and indiscreet financial and sexual behavior are almost always destructive and embarrassing to spouses, children, family members, and friends. Trust is not easily restored in the wake of mania, nor are goodwill and love always regenerated after months of severe, depleting, and unremitting depression.

Mood-related changes in interpersonal functioning are not the whole story, however; increasing evidence points to persisting social, marital, and family difficulties even when individuals are not in the throes of an episode. Such impairments in interpersonal relationships may affect subsequent clinical functioning in a complex, reciprocal pattern. In this section, we review issues and studies concerned with bipolar patients and their relationships with other people. It should be emphasized that the studies reviewed focused exclusively on the impaired functioning associated with symptoms and episodes. As is typical of most psychopathology studies, little research has been conducted on aspects of marital and family functioning that may be associated with positive moods and behaviors, such as optimism, energy, and infectious enthusiasm (Jamison, 2004).

Social Functioning

Impairment during Mania and Depression

The complex, subtle, and potentially infuriating aspects of manic interpersonal behavior were observed by most early clinical investigators (see Chapter 1). Hypomanic behavior, especially, was noted for its powerful and confusing influence on others. The positive, engaging, and occasionally charismatic qualities of many individuals with bipolar illness are discussed at length in Chapters 2 and 12. Here we describe some of the more detrimental interpersonal features of bipolar illness.

Kraepelin (1921, p. 61) wrote of the skill of hypomanic patients in manipulating fellow patients:

It is just the peculiar mixture of sense and maniacal activity, frequently also an extensive experience of institutions, which makes them extremely ingenious in finding out means to satisfy their numerous desires, to deceive their surroundings, to procure for themselves all kinds of advantages, to secure the property of others for themselves. They usually soon domineer completely over their fellow-patients, use them for profit, report about them to the physician in technical terms, act as guardian to them, and hold them in check.

Psychoanalytic writers, with rare exceptions, regarded the interpersonal lives of bipolar patients as unstable and chaotic, narcissistically based, bereft of empathic regard for the rights of others, too dependent or independent, singularly rigid, and full of rage. These conclusions are not surprising given that they were based substantially on experiences with patients in the prepharmacotherapy era. Understandably, such perceptions led most psychoanalysts to be wary of and reluctant to treat these patients. Since the psychoanalytic relationship with bipolar patients was seen as superficial and distant, countertransference was the subject of considerable discussion and writing about such patients (see Chapter 22). Most psychoanalytic writers were interested primarily in the origins of the illness and the personality structure of bipolar patients, but we present here a brief review of their observations and interpretations of interpersonal behavior.

Abraham (1911, 1924), one of the earliest writers to formulate psychodynamic principles in bipolar illness, described what he perceived to be the patients' abnormal character development and inability to maintain good relationships. These features, he speculated, were coupled with an ongoing sense of impending loss of objects, which produced a "rageful" stance toward these objects and their inability to "gratify narcissistic demands." Freud (1917), for the most part, concurred: "Manic-depressives show simultaneously the tendency to too-strong fixations to their love-object and to a quick withdrawal of object cathexis. Object choice is on a narcissistic basis."

The attitude of bipolar individuals toward others was described by Blalock (1936, p. 342) as "a selfish one serving in its several aspects the narcissistic needs of the patient." Equally critical in his views, Fenichel (1945) regarded bipolar patients as "love addicts," narcissistic, and incapable of love. To English (1949, p. 131), the bipolar patient was egocentric, incapable of relating warmly to others, rigid, afraid to hate except when manic, and powerfully influenced by the intensity of feelings:

The manic-depressive is afraid of extremes of emotion, of great love, or of hostility, and yet these are the very things he may show in his illness. One patient . . . said, "To live is like opening all my pores on a cold day and subjecting myself to a catastrophe." The manic-depressive therefore has a defect in catching the feelings of others. He ignores what others feel and want as long as he can. Thus in trying to avoid being hurt he avoids the strengthening influence of friendship.

Fromm-Reichmann (1949), in a similar vein, described a "lack of subtlety," a "lack of any close interpersonal relatedness," and a tendency to exaggerate the intensity of interactions with other people. While describing manic-depressive

patients as manifesting a "particular kind of narcissistic dependency on their love objects," Jacobson (1953, p. 66) provided a perspective at variance with that of the earlier psychoanalytic writers:

We are also surprised to see that as long as they are not sick, they may be delightful companions or marital partners, a feature that Bleuler mentioned especially. In their sexual life they may show a full . . . response, and emotionally, in contradistinction to schizoid persons, a touching warmth and unusual, affectionate clinging to people they like . . . [they] are potentially able to function extraordinarily well.

Cohen and colleagues (1954, p. 119), however, commented on what they viewed as the illusion of normal relationships in manic-depressive patients:

The appearance of closeness is provided by the hypomanic's liveliness, talkativeness, wittiness, and social aggressiveness. Actually, there is little or no communicative exchange between the hypomanic and any one of his so-called friends. . . . The concept of reciprocity is missing; the needs of the other for similar experiences are not recognized.

Finally, Gibson and colleagues (1959, p. 1,102) stressed the dependent nature of the manic-depressive patient—the difficulties in dealing with feelings of envy and competition and the "common use of denial as a defense, there being a notable lack of subtlety, and of awareness of their own or the feelings of others in their interpersonal relations."

Janowsky and colleagues (1970, 1974), in an attempt to measure more objectively the interpersonal behavior of patients during the manic phase of their illness, assessed the interactional style of acutely manic patients with tape recordings of psychotherapy sessions (both group and individual), physician and social worker notes, observations of milieu therapy, and nurses' behavioral descriptions and ratings of patients. The manic person's interpersonal maneuvers are, according to these authors, "simultaneously cementing and distancing." Although their study presumes too much conscious control and manipulation on the part of the patient, it is one of the few clinical reports to describe in detail the interpersonal behavior of hospitalized manic patients. We quote, as an example, from their work on the manic patient's perceptiveness with regard to vulnerability and conflict (Janowsky et al., 1970, p. 254):

Intimately related to the manic's ability to appeal to the self-esteem systems of others is his extraordinary perceptiveness. In interpersonal encounters, the manic possesses a highly refined talent for sensing an individual's vulnerability or a group's area of conflict, and exploiting this in

a manipulative fashion. This sensitivity may be utilized in dealing directly with a given individual or in focusing on areas of conflict between others. In either case, the manic patient is able to make covert conflicts overt, causing the person or group with whom he is dealing to feel discomfort. . . . What he says cannot be dismissed as untrue or unreal, for the areas attacked truly do exist and, indeed, are areas of vulnerability.

The playful, high-energy, and extraverted behaviors associated with mania are often irritating. So, too, are the interpersonal qualities usually present during depression. Interviews with roommates of college students identified by clinical assessments as falling in the bipolar spectrum (cyclothymia as well as bipolar-I or -II) found that bipolar students were perceived as excessively excitable, showed poor judgment, were argumentative when hypomanic, and were irritable and socially withdrawn when depressed (Depue et al., 1981). It is not surprising, given the number of negative social behaviors exhibited by the bipolar students, that 58 percent of the roommates reported that they avoided the subject, finding him or her "noxious."

Fluctuations in levels of sociability almost define bipolar illness. Energetic seeking out of other people and uninhibited social behavior are common features of mania. Winokur and colleagues (1969, p. 63) described this in their monograph:

A most characteristic sight when the patient is brought to the hospital is a frightened and exhausted family, which has frequently been awake for 1 or more nights being lectured to by a bright-eyed and excited patient.

In their study of 30 bipolar patients, Murphy and colleagues (1974) found two distinctive behavioral characteristics of mania: noticeably increased psychomotor activity and, of relevance here, a need for increased interpersonal contact ("people seeking"). Akiskal and colleagues (1977) reported that half of their cyclothymic patients alternated periods of uninhibited people seeking with periods of introverted self-absorption.

During depressive episodes, maladaptive patterns of relating to others are common, including social withdrawal, loss of enjoyment and pleasure, irritability, increased criticism of and negativism toward others, and sensitivity to criticism or rejection by others (see Chapter 2; Benazzi, 2000). Depressed people are often highly dependent on others for reassurance and support, yet appear paradoxically to reject the support or view it as untrustworthy and insufficient. Friends and family may be frustrated by the exaggerated dependence of the depressed patient, especially when they seem unable to relieve his or her despondency. Moreover, the depressed person may be particularly

sensitive to perceived rejection or criticism, and minor or even nonexistent slights are exaggerated or interpreted inaccurately. All of these common symptoms of depression can thwart the best intentions and efforts of friends and family members.

Interpersonal tension may be further intensified by the depressed individual's marked guilt and feelings of worthlessness and self-blame for real or perceived negative social encounters. Indeed, when depressed, individuals may correctly perceive that they are a burden to others, a reality that may serve to heighten their depression (e.g., Coyne et al., 1987). Moreover, depression tends to elicit negative reactions even from strangers or acquaintances; many studies (reviewed in Gurtman, 1986) have demonstrated that others tend to reject depressed persons and express preferences for avoiding interactions with them.

Impairment despite Remission and Treatment

Compared with the clinical states and symptomatology of individuals with bipolar disorder, relatively little attention has been devoted to understanding social and interpersonal aspects of the disorder. Increasingly, however, research supports prior clinical observations of the extent to which social impairment persists even during stable, euthymic periods. For instance, Cooke and colleagues (1996) identified a sample of bipolar patients who were euthymic as well as free of recent substance abuse, personality disorder, or medical illness. The patients were administered the self-report functioning scales of the Medical Outcomes Study, and their results were compared with those previously obtained for a large number of individuals in treatment for a variety of chronic medical illnesses. Cooke and colleagues found that the bipolar patients scored lower on social functioning than did the medically ill patients. Similarly, Romans and McPherson (1992) interviewed remitted bipolar-I patients about their social functioning, and found that they scored significantly lower on availability and perceived adequacy of close relationships and had significantly fewer general social contacts and interactions than did a random community sample. A recent multicenter European study of 144 remitted bipolar patients found that, compared with normal subjects, patients were less well adjusted in general and, more specifically, in their leisure activities, relationships with extended family, marital relationships, and work activities (Blairy et al., 2004).

A study comparing outpatients in treatment for schizophrenia or bipolar disorder found that the two patient groups showed relatively similar levels of cognitive and social impairment on a battery of measures (Dickerson et al., 2001). Although the schizophrenic patients generally performed worse on most measures, the bipolar group was nearly as impaired. However, the clinical state of the bipolar patients at

the time of testing was not specifically noted. Coryell and colleagues (1993) reported on 5-year follow-ups of patients from the National Institute of Mental Health (NIMH) Psychobiology of Depression sample, including 148 bipolar patients. Both unipolar and bipolar probands showed deficits in their relationships with friends, children, and relatives, and they also displayed less involvement in and enjoyment of social and recreational activities compared with non-ill controls. Although Coryell and colleagues did not report on the clinical status of the bipolar probands during the follow-up period, they noted that the majority were being treated for their disorder. Thus despite treatment and variations in the course of the disorder, the bipolar patients fared relatively poorly compared with matched controls. It may be noted that several studies comparing unipolar and bipolar probands on social functioning have yielded inconsistent results, probably because of variability in clinical histories, mood states during assessment, premorbid functioning and temperament, age and demographic factors, and methods of measuring interpersonal functioning.¹⁴

Overall, therefore, it appears that bipolar disorder is associated with a variety of general indicators of social impairment. Even when the individual is not in an affective episode, these interpersonal difficulties appear to persist. The direction of causality remains unclear, however. Are the maladjustments in social functioning due to bipolar disorder, or might they be related to clinical variables such as comorbid substance abuse or early age at onset? In the following sections, we review research addressing the predictors of social functioning and the predictive relationship between social functioning and subsequent clinical status.

Clinical Predictors of Social Functioning

The relatively sparse literature aimed at understanding the conditions under which bipolar disorder is associated with good or poor interpersonal functioning is also limited by relatively small samples, varying definitions and methods of assessing functioning, and a narrow range of potentially key variables. Nevertheless, these studies provide intriguing glimpses of issues warranting further study.

O'Connell and colleagues (1991) evaluated predictors of general functioning in 248 bipolar patients using the GAS. Several variables correlated with outcome and were evaluated in a multiple-regression equation. Number of prior admissions was the strongest predictor, followed by family attitudes and social class. Family attitudes of hostility and criticism imply poor interpersonal relationships in the family, suggesting in turn poor general functioning associated with interpersonal difficulties. Bauwens and colleagues (1991) explored correlates of social adjustment in 27 remitted bipolar patients. They found that a composite overall measure of social adjustment was significantly related to

episode frequency, and poorer social/leisure activity was associated with more episodes and hospitalizations. Scores on depression symptomatology were also associated with lower levels of social/leisure activity.

Several studies have found that depression is more linked to difficulties in functioning than is mania. In a study aimed at exploring the mutual influence of social and clinical functioning, Gitlin and colleagues (1995) evaluated the impact of both past episode history and subclinical symptoms on indicators of social functioning in a sample of 82 bipolar patients followed for at least 2 years. Social (close relationships) and family functioning were significantly related to number of past and recent depressive episodes but not to manic or hypomanic episodes. In all the analyses, subclinical symptoms were more strongly predictive of poorer social functioning than was number of clinical episodes. The researchers also determined that depressive episodes were significantly more (negatively) predictive of the quality of relationships with family members than were manic episodes, with a similar trend toward a greater association of depression with social (close) relationships. In contrast, occupational functioning was negatively associated with both depressive and manic episodes.

A recent review and investigation of functional outcomes in bipolar patients revealed depression to be one of the few fairly consistent predictors of social, family, and marital (as well as occupational) functioning (Bauer et al., 2001). This study is noteworthy for its careful assessment of symptoms and functioning over 48 weeks in a sample of 43 male Veterans Affairs outpatients. The amount of time depressed and average depression symptom scores—but not mania scores—were significantly correlated with social and work functioning. Other researchers (Cooke et al., 1996) also found that bipolar patients' low scores on social functioning were associated with subclinical depressive symptoms (subclinical mania/hypomania was not assessed), and social functioning was lower in bipolar-II than in bipolar-I patients. Different investigators (Romans and McPherson, 1992), in contrast, found that a subgroup of patients with a predominantly manic course reported less adequate close relationships and less available social contacts than did those with depressive episodes, although the effect was not statistically significant. Perhaps consistent with the previously cited studies, Romans and McPherson found that patients with a longer history of illness reported fewer close and general social contacts.

A study of 40 bipolar-I patients' social functioning (Lam and Wong, 1997) included ratings of relationships with intimate partners and friends and "social presentation." The investigators evaluated recognition of prodromes of mania and depression and scored the patients' reports of how they coped with prodromal symptoms of depression

and mania. Generally, those with good awareness of prodromal symptoms and good coping methods had better overall social functioning. A multiple-regression analysis to predict overall social functioning indicated that lower current subclinical depression scores and good reported coping with prodromes of mania and depression significantly predicted good functioning, whereas number of past hospitalizations and current subsyndromal manic symptoms did not.

Social Predictors of Clinical Outcomes

The question of the origins of and contributors to social adjustment in those with bipolar disorder takes on particular urgency in view of studies now beginning to demonstrate a functional link between social and clinical outcomes. As evidence accumulates of enormous variability in the clinical course of bipolar disorder, even in those who are adequately or aggressively treated pharmacologically,¹⁵ studies have increasingly been exploring predictors of diverse clinical outcomes by including social variables.

Among recent longitudinal outcome studies, several indicate the importance of interpersonal functioning. Table 10–2 summarizes several studies of social predictors of clinical outcomes in patients with bipolar disorder. In all of these studies, patients were in treatment, and many of the studies controlled for medication adherence. The studies differ considerably in the social functioning variables assessed, but they are consistent in finding that indicators of interpersonal adjustment play an important role in clinical outcomes, independently of clinical history factors. Note that several of the studies found social impairment to be especially predictive of depressive symptoms. Coryell and colleagues (1998) hypothesized that a “prevailing depressive subtype” of bipolar patients may mark a particularly poor prognosis group with considerable social dysfunction.

Several of the studies listed in Table 10–2 identified family discord or negative family attitudes toward the patient with bipolar disorder as a predictor of worse clinical outcomes (Miklowitz et al., 1988; see also O’Connell et al., 1991). Research on the effect of family attitudes (particularly those of the caretaker or spouse) on the course of bipolar disorder, including “expressed emotion” and related constructs, is reviewed below in the section on marital functioning.

A particular focus of several of the studies in Table 10–2 is the role of the quality and availability of social support in predicting clinical outcomes among individuals with bipolar disorder. Generally, social support refers to individuals’ perceptions of the extent to which others are available to provide emotional and material assistance and to their satisfaction with the perceived supportiveness offered by others. O’Connell and colleagues (1985) found that a global measure of social support was the strongest correlate of clinical

outcome, social adjustment, and overall GAS score. Other researchers (Stefos et al., 1996) found that social support and social functioning variables predicted outcome, but clinical factors did not. They observed that 69 percent of patients with good social support, compared with 25 percent of those with low support, remained episode-free during a 4-year period of assessment. Similar results have been reported more recently.¹⁶ Of interest, several investigators¹⁷ have found the effects of social support to be polarity-specific, with lower social support at baseline predicting more increase in depressive symptoms over time, but no significant association with changes in manic symptoms was found. The relationship between social support and clinical outcome is complicated by the likelihood that support is more likely to be given to those who are less overtly or chronically ill. It may well be that patients who experience primarily euphoric manias or hypomanias garner more support than those who have predominantly mixed states. This issue has not been adequately addressed in the research conducted to date. Clearly, premorbid functioning and temperament are relevant, albeit poorly studied, factors in predicting how individuals will cope with their illnesses and maintain or develop personal relationships.

Conceptualization and Methodology

Although the studies discussed above generally indicate a link between clinical and interpersonal functioning, there is clearly a need for more exploration of the origins of poor or good social functioning. One promising pattern concerns the role of depression, with most studies indicating an association between depressive symptoms and social functioning. While several studies suggest that depressive symptoms may be especially impairing, however, the specific contributors and features of social functioning are not known. For instance, do symptoms prevent individuals from engaging in social relationships and activities, or do symptoms affect the quality (and eventually the availability) of such pursuits? Do symptoms emerge subclinically during developmentally important periods of life to an extent sufficient to impair normal acquisition of social skills and attributes, or are the social impairments consequences of repeated episodes that devastate the individual’s coping capacities?

There is a need to explore the origins of social impairments, as the question of whether they predate or follow bipolar episodes is unresolved. The topic of “premorbid social adjustment,” although well established in schizophrenia research and a potent predictor of disorder and functioning, is relatively less well studied in bipolar samples. An exception is the work of Cannon and colleagues (1997), who clearly demonstrated that the social functioning of bipolar patients when they were children and adolescents

TABLE 10–2. Social Predictors of Clinical Outcomes

Study	Sample	Significant Predictors of Poorer Outcome
O'Connell et al., 1985	60 bipolar-I outpatients	Episode intensity-duration score over a 1-yr period was correlated with less social support and worse social adjustment scores. Social factors were correlated more strongly with outcome than were demographic or clinical variables.
Miklowitz et al., 1988	23 bipolar inpatients	Relapse during a 9-mo follow-up was associated with family negative expressed emotion and negative interactions (affective style). Social variables predicted outcome independently of demographic and clinical factors.
Gitlin et al., 1995	52 bipolar-I outpatients	Relapse over a mean follow-up period of 4 yr was associated with both clinical features (prior episodes) and worse social adjustment. Strongest associations were between depressive symptoms and prior depressive episodes and poor family and social functioning.
Stefos et al., 1996	14 bipolar-I and 7 bipolar-II patients	A higher rate of major recurrences over a 4-yr follow-up period was associated with less social support, impaired social and leisure activities, and poor quality of relationships with the extended family, but clinical predictors were not significant.
Coryell et al., 1998	113 bipolar (with mania) inpatients and outpatients	Depression at 15-year follow-up was predicted by poor social (functional) adjustment before the study and persisting depression in the first 2 yr of follow-up. Earlier manic symptoms were generally unrelated to functional or clinical outcomes at 15-yr follow-up.
Kulhara et al., 1999	118 bipolar-I outpatients	A higher rate of recurrence over the follow-up period was associated with more depressive episodes before lithium treatment, more life events, and less social support.
Johnson et al., 2000	59 bipolar-I patients	Longer time to recovery over a 2-yr follow-up period was associated with lower social support. Depressive symptoms over time were predicted by life events and lower social support, but manic symptoms were not predicted by lower social support or stressors.
Johnson et al., 2003	94 bipolar patients	Those who relapsed over a 12-mo follow-up period had significantly lower perceived social support. Those with lower perceived support were also more likely to have partial rather than complete remission before relapse.
Cohen et al., 2004	52 bipolar-I outpatients	Episode recurrence over a 1-yr follow-up period, after controlling for clinical variables, was predicted by low social support and life events. Depressive episodes were more strongly predictive than manic episodes.

(continued)

TABLE 10–2. Social Predictors of Clinical Outcomes (*continued*)

Study	Sample	Significant Predictors of Poorer Outcome
Kim and Miklowitz, 2004	125 bipolar outpatients (116 bipolar-I, 9 bipolar-II)	Patients from families with high expressed emotion (EE) relatives did not experience higher rates of relapse over 2-yr follow-up, but they did experience higher levels of depression.
Yan et al., 2004	47 bipolar-I outpatients	High EE in collaterals (romantic partners, parents, friends) predicted depressive but not manic recurrence. After controlling for prior symptom severity, patients with high EE were five times more likely to have a depressive recurrence than those with low EE.

(as reported retrospectively by their mothers) was significantly worse than that of normal comparison subjects of similar age. Appropriate social behavior, quality of peer relations, and pursuit of interests appeared to be impaired in the prebipolar lives of patients. It is unclear, however, whether these individuals were actually symptomatic at young ages. Moreover, variability in reported adjustment suggests differing subgroups, including some with exceptionally good functioning. Such patterns warrant further study—as does clarification of the role of childhood disorders (see Chapter 7) in later social adjustment.

In view of the apparent impact of depressive symptoms on social adjustment, it may be noted that research on unipolar depression is focused increasingly on interpersonal functioning. Social variables are seen as playing a role in vulnerability to onset of the disorder and in the prediction of relapse, recurrence, and chronicity, and also as resulting from the impact of depression on the relationships of the depressed person with others. A large body of research has begun to document the role of social factors in depression, presumably operating both as cause and consequence of the disorder (e.g., reviews in Hammen and Brennan, 2002; see also Joiner and Coyne, 1999). This research may provide guidelines for further studies of bipolar samples.

There is a related need for further study of the specific effects of depression and mania on interpersonal relationships. Are there conditions under which manic and hypomanic symptoms portend decrements in social connections, as appears to be the case with depression? Or can they under some circumstances facilitate social contacts and friendships? Can the optimism and positive affectivity often associated with bipolar patients who have an underlying hyperthymic temperament lead to more opportunity for relationships that may prove to be sustaining and meaningful?

Marriage

I am tired of papering over the cracks and pretending to friends and relatives that life is wonderful. It is the nearest and dearest who come in for the bulk of the barrage.... It is the Jekyll and Hyde syndrome. I never know which is going to walk in through the door, and the unpredictability is most unnerving. It is like living on a knife-edge. You can never relax or take anything for granted and any thought of lapsing into "placid serenity" is completely out of the question. (Anonymous¹⁸)

To understand some of the important clinical as well as research issues that arise in addressing the topic of bipolar disorder and marital relationships, a brief discussion of research on unipolar depression and marital functioning is useful. This is followed by a review of descriptive studies of bipolar disorder and marital functioning and a consideration of the complex and reciprocal relationship between marital and clinical functioning. The section ends with a review of the literature on sexual behavior in bipolar illness, assortive mating among bipolar patients, and effects on marriage of treatment of bipolar spouses.

Unipolar Depression and Marital Functioning

There has been considerable research on depression and marital functioning in recent years, corresponding to a growing focus on the interpersonal causes and consequences of depression, as well as the development of effective psychotherapies aimed at treating interpersonal and marital dysfunction in depressed individuals. Two themes and sets of findings in particular are potentially relevant to bipolar disorder.

First, the phenomenology of depression may contribute to problematic marriages. Weissman and Paykel (1974) were among the first to characterize the marriages of depressed

women as fraught with friction, inadequate communication, dependency, overt hostility, resentment and guilt, poor sexual relationships, and a lack of affection. For both men and women, depressive symptoms such as irritability, loss of energy and enjoyment, heightened sensitivity to criticism, and defeatist and pessimistic attitudes all may erode the initial concern and patience of the spouse. The depressed person's exaggerated negative interpretations of self, the world, and the future may seem irrational and inexplicable, while an unwillingness to engage in typical or enjoyable pursuits and unresponsiveness to encouragement may be frustrating to the spouse and may even appear to reflect willfulness or resistance. Spouses and partners often are especially troubled by the restrictions on social and leisure activities and by the depressed person's withdrawal, worry, and suicidal thoughts (e.g., Coyne et al., 1987; Fadden et al., 1987).

As Coyne (1976) noted, there may be a deteriorating marital process in which initial concern and caring by the spouse is eventually replaced by resentment and impatience—reactions likely perceived by the depressed person as rejection and lack of sympathy, provoking further depression. As might be expected, observed communications between depressed individuals and their partners are characterized by relatively more negativity and fewer positive interactions than those of nondepressed couples (Johnson and Jacob, 1997). Such patterns have been found to be particularly pronounced among depressed women compared with depressed men (Gotlib and Whiffen, 1989; Johnson and Jacob, 1997). Over time, depression in a spouse may be perceived as a significant burden, and may even cause distress and symptoms in the nondepressed spouse (Coyne et al., 1987). Not surprisingly, depressed individuals are less likely than non-depressed controls to be married, and if they are married, they are more likely to divorce or to report the marriage as being of poor quality (Fadden et al., 1987; Coryell et al., 1993; Whisman, 2001).

A second set of findings in the unipolar field that is salient for bipolar disorder indicates that depressive episodes often result from environmental precipitants, among which marital conflict and difficulties may be especially common and potent. For example, Weissman (1987) noted a 25-fold increase in the relative risk for major depressive episodes among those in unhappy marriages, based on Epidemiological Catchment Area data for 3,000 respondents (see also Brown and Harris, 1986; Coryell et al., 1992; Anderson et al., 1999). Thus the consequences of depression for relationships may include the creation of a context that is stressful and unfulfilling, contributing to increased risk for further symptomatology.

The self-perpetuating cycle of depression and marital distress may be further complicated by some individuals' vulnerabilities in the form of maladaptive dependency or

the need for frequent reassurance, dysfunctional skills in resolving interpersonal problems and conflicts, and maladaptive mate selection (Hammen, 1997, 1999). Moreover, there is evidence that the impaired interpersonal relationships of depressed persons may not be confined to periods of depression. For instance, several studies have shown that even in remission, formerly depressed patients and community members continue to show social impairment, including marital dissatisfaction and conflict (Weissman and Paykel, 1974; Billings and Moos, 1985; Hammen and Brennan, 2002).

The link between depression and marital distress may be reciprocal: some individuals may be particularly vulnerable to developing depressive reactions because of dysfunctional needs and skills with regard to intimate relationships. As suggested earlier, increased recognition of the link between depression and marital distress has led to the development of several therapeutic approaches based on addressing marital difficulties as a way to treat depressive disorders. Interpersonal psychotherapy (Klerman et al., 1984; Weissman et al., 2000) and behavioral marital therapy (Beach and Jones, 2002), for example, have proven successful both in reducing depression and in improving marital functioning.

Bipolar Disorder and Marital Functioning

The marriages of untreated, inadequately treated, or treatment-nonresponsive bipolar patients tend to be turbulent, fluctuating, and uncertain. An overall clinical description was given by Janowsky and colleagues (1970, p. 259):

Diametrically opposed styles of marital relating, occurring during depressed or manic phases respectively, seem intolerable to the spouse. The depressive phase is usually viewed by the spouse as an illness over which the patient has little control. Here, spouses offer significant physical care and emotional support. The patient, during the depressive phase, often expresses much guilt and self-blame and sometimes speaks of the spouse in laudatory and absolving terms. . . .

In contrast, the attitude of the spouse undergoes a marked change when the patient is manic. The manic phase is perceived as a willful, spiteful act. Lip service only is given to seeing the mania as an illness. There is always an underlying feeling that the manic can control his actions, and does not do so out of maliciousness, selfishness, and lack of consideration. This impression is fostered by the fact that the manic often has periods of seeming reasonableness. . . .

Related to the issue of the spouse feeling betrayed and experiencing diminished self-esteem is the problem of marital infidelity. Often, manic patients speak of divorce, make sexual advances to other people, become engaged in affairs. . . .

In all these situations, the spouses felt trapped in what they perceived as an impossible situation. They felt caught in a whirlwind of activity, personally threatened, powerless to enforce limits. . . . Their moods and feelings were intimately related to the disease state of the sick partner.

Not all would agree with this characterization of spousal perceptions. Nevertheless, the turmoil associated with marriage to someone who undergoes unpredictable severe mood shifts clearly is highly stressful and challenges the coping capabilities of the partner. As we shall see, the attitudes expressed within the intimate relationship may also create conditions that may influence the course of bipolar illness.

At present, research on and conceptualization of marital functioning is less well developed for patients with bipolar disorder than for those with unipolar depression. Some of the earliest bipolar studies simply compared the marital functioning of unipolar and bipolar patients, yielding mixed findings as to which group had the "worse" outcomes (Janowsky et al., 1970; Brodie and Leff, 1971; Ruestow et al., 1978). The more crucial questions, however, concern marital functioning in treated patients, the impact of clinical features of bipolar disorder on intimate relationships, and effects of the quality of relationships on outcomes among bipolar patients.

Studies of treated patients provide ample but perhaps unsurprising evidence that marital functioning is often impaired among those with bipolar disorder. For instance, in one of the largest follow-up studies (5 years) of bipolar patients, Coryell and colleagues (1993) found that 148 such patients were only half as likely to be married by the end of the follow-up period as matched well controls (32 percent never married, compared with 15 percent of controls). Those who had married were twice as likely to be divorced as controls (45 percent divorced, compared with 18 percent of controls). Similarly, the Stanley Foundation Bipolar Network reported rates of divorced/separated or single status exceeding U.S. national norms (Suppes et al., 2001). It should be noted, however, that there is no evidence of higher divorce rates among those with bipolar disorder than among those with unipolar depression.

Corresponding to the high rates of divorce and reduced frequency of marriage among bipolar patients, couples in which one spouse is bipolar commonly report dissatisfaction. Several studies have obtained such information from the patient. For instance, Radke-Yarrow (1998) interviewed bipolar women in a study of offspring and family interactions. She found that women with bipolar disorder (a mix of bipolar-I and -II) reported higher rates of marital disorder at all follow-up assessments (62 to 76 percent) compared with non-ill women (7 to 13 percent) or women with

unipolar depression (53 to 59 percent). She speculated that psychiatric illness in many of the fathers of bipolar women may have contributed in part to the high rates of marital discord. Bauwens and colleagues (1991) collected Social Adjustment Scale information on 27 remitted bipolar, 24 remitted unipolar, and 25 control individuals. They found that bipolar patients scored midway between the unipolar (worst) and control (best) subjects in overall marital adjustment. Frequency of hospitalizations per year tended to be correlated with poorer marital adjustment, but there was no indication of the specific features of the course of illness that might have a particular association with marital difficulties.

A limited number of studies have examined the perceptions of spouses of bipolar patients. Hoover and Fitzgerald (1981) compared reported marital interactions of 42 bipolar and depressive inpatients and their spouses with those of 30 normal couples from the community. Using the 67-item Conflict in Marriage Scale (designed to measure resolution of conflicts, ways of dealing with anger, and content of disputes), they found that couples with an affectively ill spouse scored significantly higher on expressed conflict than did the community controls. Within the affectively ill group, couples with a bipolar-I member expressed more conflict than those with a unipolar or bipolar-II member, but the effects were not statistically significant. Of interest, there was low agreement between spouses in couples that included a member with mood disorder, with the ill member typically reporting much higher levels of conflict. Hoover and Fitzgerald (1981, p. 67) proposed several possible explanations for this discrepancy:

It may be that conflict with an ill partner is more difficult to acknowledge and express. . . . Another possibility is that the spouses of manic-depressive patients derive some personality reinforcement, a tested sense of ability or moral fulfillment, from caring for a recurrently sick partner. Or perhaps some spouses need to be a trifle oblivious and not too sensitive to remain with a manic-depressive patient through the years. . . . Finally, there remains the possibility that, in a complementary sense, mercurial persons seek out cheerful, denying persons to marry whereas stolid maintainers of the peace search for more spontaneous, mood-varying types.

Levkovitz and colleagues (2000) collected reports from 34 spouses of bipolar and unipolar patients during remission and from 34 non-ill control spouses. Unfortunately, results were not reported separately for the two diagnoses. Overall, however, patients' spouses perceived significantly more negative characteristics in their marriage, lower marital satisfaction, and more negative and fewer positive traits in their partner. There was some suggestion that these more negative views were associated with unemployment status

and prior history of suicide attempts on the part of the ill spouse, but generally there were no associations with clinical features of the disorder.

Few studies have attempted to shed light on the particular concerns of the spouse married to a bipolar patient. In a small-scale study, researchers administered the Family Attitudes Questionnaire to 19 bipolar patients and their well spouses to determine their attitudes and beliefs about the etiology, familial risk, and long-term burden of bipolar illness, as well as their attitudes toward marriage and childbearing (Targum et al., 1981). The reported long-term burdens of the illness included financial difficulties, home and child neglect, marital problems, loss of status and prestige, tension, and fears of recurrence of acute illness. The researchers concluded that the bipolar patients compared with their spouses tended to minimize problems associated with their illness and were more likely to deny the role of genetic factors in the disorder.

When the investigators asked the couples whether they would have married their spouses if they had known more about bipolar illness, 5 percent of the bipolar patients but fully 53 percent of their spouses said they would not have, a statistically significant difference. Similarly, when asked whether they would have had children, 5 percent of the bipolar patients and 47 percent of their spouses said they would not have. Both patients and spouses perceived violent behavior as the most troubling characteristic of mania. Patients also were especially worried by their poor judgment during mania. Spouses were particularly concerned about impulsive spending, overtalkativeness, and decreased need for sleep. Both groups saw suicide threats and attempts as the most troubling aspect of depression, and patients were also bothered by the hopelessness and poor concentration accompanying that state; spouses, on the other hand, were most disturbed by the patient's lowered self-esteem and withdrawal from others. Overall, the most troublesome long-term social problems resulting from bipolar illness were financial difficulties, unemployment, marital problems, recurrences of illness leading to rehospitalization, and social withdrawal due to depression. The researchers concluded:

Well spouses who have coped with affective illness for many years perceived bipolar illness as a profound burden that had seriously disrupted their lives. . . . The regrets of the well spouse are a most striking feature of this study. . . . Whereas affective episodes may not be directly associated with major persistent psychological deficits, the damaging effects of these episodes may still yield psychological and economic consequences, particularly for the spouse. The spouse is the person who bears the brunt of manic episodes. . . . In depression, the spouse is the

most frequent target of demands and hostility, and often feels inordinate responsibility for the mood state of the patient. (Targum et al., 1981, p. 568)

Targum and colleagues (1981) were the first to examine and compare systematically the attitudes of bipolar patients and their spouses and to highlight spousal distress. Yet other studies (e.g., Frank et al., 1981, in a study of 16 couples) have not found such negative effects. It should be noted that the study by Targum and colleagues did not employ a comparison group; moreover, most of the couples had been married for many years, increasing the chances that the bipolar spouse had not been treated with lithium or another mood stabilizer. In a study conducted in India, Chakrabarti and Gill (2002) found that caregivers (mainly spouses) of bipolar patients reported experiencing less of a burden than that reported by caregivers of people with schizophrenia; the burden they did experience involved mainly physical and mental health problems.

Perlick and colleagues (1999) studied perceived burden in a large sample of caregivers of 266 bipolar-I and -II and schizoaffective (manic) patients. Patients' depression was perceived as being associated with a greater burden relative to mania; caregiver distress was especially pronounced when the patient displayed symptoms of "misery, irritability, and withdrawal." The authors also found that the association between severity-of-illness factors and perceived burden was mediated by caregivers' beliefs and attitudes. Specifically, perceived burden was higher among those who believed the patient with bipolar disorder could control his or her symptoms whereas the caregiver could not, and among those with an accurate awareness of the nature and prognosis of the disorder.

Others have likewise speculated that a critical factor in attitudes toward partners with bipolar disorder is the extent to which the patient is perceived as willfully causing or controlling the symptoms. A study conducted by Hooley and colleagues (1987), which included both schizophrenic and bipolar patients and their spouses or family members, revealed that spouses or family of patients with florid, positive symptoms (auditory or visual hallucinations; grandiosity; agitation; speech disorganization; delusions; elated mood; silliness; or inappropriate affect, appearance, or behavior) reported significantly higher levels of marital satisfaction than spouses of patients with negative symptoms (social isolation, depression, lack of emotion, or routine or leisure-time impairment). The authors attributed this difference to the fact that the more bizarre and flagrant positive symptoms, unlike the negative ones, were perceived by the spouse as being caused by an illness and thus beyond the patient's volition. It is likely that milder symptoms of hypomania and depressive symptoms are especially likely to be attributed

erroneously to the patient's personality and behaviors. As discussed later, the attitudes of spouses and family members may play a significant role in clinical outcomes and therefore may be an important factor in treatment effectiveness.

A study of caregiver burden among spouses of bipolar patients was conducted in New Zealand (Dore and Romans, 2001). The caregivers were, for the most part, partners or parents of 41 bipolar patients. Virtually all reported that the patient was difficult and irritable or more distant during an affective episode, and that this caused the caregiver considerable distress. Nearly half reported experience with or concern about violence when the patient was in the midst of an episode. Marital difficulties were common and sometimes persistent. Fully 62 percent of the partners said they would probably not have entered into the relationship had they had more knowledge and understanding of the illness beforehand. Nevertheless, most caregivers felt that the relationship was good when the patient was in remission, and few were experiencing significant distress symptoms themselves at the time of the assessment.

Marital Functioning, Family Attitudes, and Predictors of Outcome

Clinical experience suggests that mood stabilizers have a positive effect on marriages involving bipolar individuals because the drugs partially or totally eliminate both highly volatile and disruptive manic episodes and frightening and depleting depressive episodes. These benefits appear to be corroborated by the few existing studies of marital interaction among adequately treated bipolar patients (McKnight et al., 1989). As the results of one early study suggest, however, improvements may be perceived differently by the spouse and the patient. Demers and Davis (1971) found that most of the well spouses participating in their study perceived improvements associated with lithium treatment, including enhanced marital satisfaction, as well as observed decreases in nervousness, violent or threatening behavior, withdrawn or demanding behavior, and sadness. Yet only a minority of the patients themselves perceived such positive changes—perhaps because they were still experiencing sub-syndromal episodes or, in some instances, because of their perceived loss of the positive experiences associated with hypomania.

Although the improved clinical status of a bipolar spouse may greatly relieve the patient's partner and family, there is, as noted earlier, a reciprocal impact: increasing evidence indicates that the quality of marital and family functioning may contribute to the patient's clinical outcome during treatment. Results of several studies suggest that good marital functioning or just being married may contribute to the effectiveness of treatment in reducing episodes. For instance, Yazici and colleagues (1999) found that being married was

associated with good response to lithium; 27 percent of good-response patients and 48 percent of poor-response patients were unmarried. Similar results have been reported by others (O'Connell et al., 1991). It is important to note, however, that these findings cannot clarify the direction of causality of effects, inasmuch as good response to lithium may be more likely among more well-functioning individuals, as well as those whose manic episodes are relatively more euphoric in nature (see Chapter 18). Likewise, medication adherence and stable sleep may be more likely in the context of a good marriage.

Several studies have found that the "expressed emotion" or "affective style" of partners (the overall negativity or positivity of attitudes toward the patient) may predict relapse and outcome in treated patients over time (Mundt et al., 2000). Miklowitz and colleagues (1988), for example, first demonstrated that bipolar patients whose spouses or parents expressed negative attitudes about them during hospitalization for mania were significantly more likely to have a relapse in the ensuing 9 months than were those patients whose spouses or parents expressed more benign or positive attitudes. O'Connell and colleagues (1991) also found that attitudes of family members, including those of spouses, were significantly related to outcome in a lithium treatment outpatient clinic. More negative attitudes were expressed by partners of patients with poor outcomes (40 percent) than by partners of patients with good outcomes (12 percent). Perlick and colleagues (2001) found that greater perceived caretaker burden, which, as noted, reflects in part attitudes toward the patient and the illness, predicted depressive relapse at follow-up, even after controlling for baseline symptoms. Furthermore, over a 15-month period of mood stabilization, those patients who had fewer symptoms but whose caretakers reported a high perceived burden were more likely to experience a recurrence of their illness. The investigators suggested that stressful family environments contribute to caretaker burden and possibly to depression, as well as to patient relapse.

A family-focused psychoeducational treatment program was devised by Miklowitz and Goldstein (1997) to improve the attitudes of spouses and family members toward the bipolar patient by increasing their knowledge and understanding of the disorder and improving their skills in communicating and solving family-related problems. An evaluation of the treatment suggested that it was effective in improving positive nonverbal communication, and that such improvements accounted in part for the progress seen in patients' symptoms over a 1-year period (Simoneau et al., 1999; Miklowitz et al., 2003) (see Chapter 22). The effectiveness of psychosocial treatments that include spouses is increasingly being demonstrated (e.g., Clarkin et al., 1998), including their potential role in helping to extend the duration

and quality of the beneficial effects of medication on the outcome of bipolar disorder (see Chapter 22).

Sexual Behavior

Again judging from my own experience, the sexual symptoms of the manic state seem to be the most powerful and important of all. . . . The normal inhibitions disappear, and sexual activity, instead of being placed, as in our Western Christian civilization, in opposition to religion, becomes associated with it. This release of the underlying sexual tension . . . seems to me to be the primary and governing factor of all the ecstasies and many other experiences of the manic state. (John Custance, 1952)

Changes in sexual desire, thought, and behavior during depression and mania were observed centuries ago. Aretaeus of Cappadocia (150 AD), for example, observed that “a period of lewdness and shamelessness exists with the highest type of [manic] delirium” (Jelliffe, 1931, p. 20). In the nineteenth and twentieth centuries, Tuke (1892), Kraepelin (1921), Bleuler (1924), Campbell (1953), and Mayer-Gross and colleagues (1955) also described heightened sexuality during mania and decreased sexuality during depression (see Chapter 2).

Fluctuations in sexual drive are sufficiently important in bipolar illness to warrant inclusion as diagnostic criteria in DSM-III and/or DSM-IV (“sexual indiscretions” for manic episodes and “decrease in sexual interest or drive” for depressive episodes). Items pertaining to sexual behavior are on most self- and observer-rating instruments for both mania and depression (see Chapter 12). Beigel and colleagues (1971), for example, required nurses to judge 26 items most characteristic of manic behavior, thought, and affect. Of those items, the 2 pertaining to sex (“talks about sex” and “is sexually preoccupied”) had high concordance with independent ratings on both a psychiatrists’ global mania scale and a nurses’ manic-symptom checklist.

The actual data on changes in sexual behavior and thinking during different phases of bipolar illness are relatively limited. Quantified observational data are presented in Chapter 2 and can be summarized here. Hypersexuality was observed or reported in 57 percent of manic patients (averaged across seven studies, with a range of values from 25 to 80 percent), and actual nudity or sexual exposure was reported in 29 percent (averaged across three studies, with a range of values from 23 to 33 percent). Akiskal and colleagues (1977) reported that 40 percent of their cyclothymic patients had “episodic or unexplained promiscuity or extramarital affairs.” Allison and Wilson (1960) studied the sexual behavior of 24 manic patients using data based on physician observations and on historical information from patients and their relatives. They found no relationship between

sexual display during mania and age, religion, duration of illness, previous episodes, or social class. Women were far more sexually provocative and seductive than men (58 and 0 percent, respectively) on a 5-point rating scale. However, women and men were equally likely to have both increased “libidinal drives” and increased frequency of sexual relations. In 78 percent of the patients, the frequency of sexual intercourse increased substantially during manic episodes.

A recent study of sexual satisfaction in 37 partners of bipolar patients found that partners were less satisfied when the patient was affectively ill (Lam et al., 2005). The investigators attributed this finding to illness-related changes in sexual interest, affection, and responsiveness.

Winokur and colleagues (1969) found that 65 percent of manic episodes were characterized by increased sexuality. In 32 percent of cases, the sexuality was of a socially approved type, that is, within marriage or a long-lasting relationship. In 10 percent of patients, the increased sexuality was in thought or discussion only, and in 11 percent it was manifested in socially disapproved behavior. In this latter group, patients were homosexually or heterosexually promiscuous or both; in all cases, the hypersexuality was clearly associated with being ill. Like those patients studied by Allison and Wilson (1960), the women (18 percent) in the study of Winokur and colleagues were more likely to have increased sexual contacts (noncoital) than the men (3 percent), but women and men were equally likely to have an increased frequency of intercourse (30 and 35 percent, respectively).

Spalt (1975) studied lifetime sexual behavior in 42 patients with unipolar depression, 19 with bipolar illness, 56 with secondary affective illness, and 38 with nonaffective illness. Extramarital sexual experiences were more frequent among bipolar patients (29 percent had more than 10 experiences) than among unipolar patients (12 percent). Bipolar patients (21 percent) also were more likely than unipolar patients (10 percent) to have had more than 10 sexual partners during their lifetime. These figures almost certainly reflect many other behavioral differences between the two groups, including hypersexuality and differences in sexual drive during normal periods, as well as differences in levels of gregariousness, sociability, and interpersonal turmoil.

Jamison and colleagues (1980) studied changes attributed to affective illness in 35 bipolar and 26 unipolar patients. Twice as many women (41 percent) as men (20 percent) reported that sexual intensity was “very much increased” during hypomania; 40 percent of the men and 18 percent of the women stated that sexual intensity during hypomania was “somewhat increased.” Women rated increased sexual intensity as the most important or enjoyable change they experienced during hypomania.¹⁹ Bipolar patients were significantly more likely than unipolar patients ($p < .01$) to feel that

increased sexual intensity was a lasting characteristic attributable to their mood disorder.

As noted, bipolar illness also can be associated with decreased sexual drive. For example, Winokur and colleagues (1969) reported that 63 percent of patients with bipolar mixed states reported decreased sexual interest. Indeed, approximately three-fourths of bipolar depressed patients have been found to experience a loss of sexual interest: 73 percent reported by Winokur and colleagues (1969) and 77 percent by Casper and colleagues (1985).

Sexual responsiveness can also be dampened in patients taking lithium.²⁰ Sheard (1971, 1975) and Lion (1975) attributed this phenomenon to a common effect on aggressive and sexual behaviors, both often occurring together in bipolar patients. Lorimy and colleagues (1977) reported that half of their patients taking prophylactic lithium experienced troublesome side effects affecting their sexual activities, including decreases in sexual intensity, frequency of sexual drive, and frequency of sexual intercourse. However, patients reported that once intercourse began, there was no decrement in enjoyment or orgasmic ability.

What accounts for these lithium-induced changes is unclear. Among the possible explanations are lithium-induced hypothyroidism, decreased frequency or intensity of hypomanic episodes, or the direct effect of lithium on the central mechanisms underlying sexual drive and behavior. Yet another possible reason for these changes is vacillation in interpersonal relationships brought about by lithium, with secondary manifestation in the sexual domain.

Assortative Mating among Bipolar Patients

An additional challenge to marital adjustment among individuals with bipolar disorder is the increased likelihood of nonrandom mate selection. Specifically, research, although limited, suggests that bipolar individuals have an increased likelihood of marrying a partner with affective illness (see Chapter 13). For instance, in a sample of 56 married inpatients with mood disorders, Merikangas and Spiker (1982) found a higher degree of assortative mating among bipolar than unipolar patients. They noted high diagnostic concordance between patients and spouses for both affective disorders and alcoholism. The effects could not be attributed to spouses' symptomatic reactions to marriage to an ill spouse because the spouses appeared to have a predisposition to the disorders based on elevated rates of psychiatric and mood disorders in their own relatives. Colombo and colleagues (1990) studied assortative mating in a large sample of more than 1,000 patients with mood or anxiety disorders. They observed that while patients with bipolar illness were less likely to marry overall than were those with unipolar disorder, there was a specific

assortative mating pattern such that bipolar men were more likely than controls to have wives with mood disorders.

Most of the few studies examining assortative mating have had methodological limitations, such as small sample sizes, lack of direct comparison groups, and differing diagnostic criteria. A meta-analysis approach is especially helpful for evaluating pooled effects across several small studies. One such analysis (Mathews and Reus, 2001), based on the six best-designed studies, confirmed the commonly reported finding of assortative mating for bipolar individuals, with higher rates than for those with unipolar depression. Specific analyses based on husbands and wives were inconclusive because of limited data, but suggested that data supporting the marriage of bipolar men to women with mood disorders are much more robust than is the case for the marriage of bipolar women to men with mood disorders. The authors also noted the paucity of evidence of mood disorders in mates before the marriage; thus depressive reactions to stress in marriage to a bipolar partner cannot be ruled out.

Although these studies raise a number of questions to be pursued in further research, they support the often-observed pattern of the marriage of bipolar individuals to those who also have mood disorders. Such dual-disorder pairings may promote shared understanding, but may also give rise to marital discord and instability by contributing to stressful home environments and potentially to limited skills for resolving interpersonal disputes. While not confined to bipolar disorder, such pairings may present a treatment challenge requiring family or couple interventions. Obviously if confirmed, assortative mating also has considerable genetic significance.

Effects on Marriage of Treatment of Bipolar Spouses

Clinical experience suggests that lithium, the only mood stabilizer that has been studied systematically for its effect on marital stability, has a highly stabilizing effect on the marriages of patients with bipolar illness because it partially or totally eliminates both highly volatile and disruptive manic episodes and frightening and depleting depressive ones. These benefits appear to be corroborated by the few marital studies of adequately treated bipolar patients,²¹ although they were not observed in the study by Targum and colleagues (1981).

Demers and Davis (1971) administered the Marital Partner Attribute Test to 14 married bipolar patients and their spouses. Lithium produced a highly significant decrease in spouses' negative ratings of the patients but no significant changes in patients' ratings of their spouses. In fact, 13 (93 percent) of 14 bipolar patients were rated by their spouses as improved and as having significantly fewer undesirable

attributes ($p < .01$) after lithium treatment. Spouses particularly noted decreases in nervousness; bizarre, threatening, and violent behavior; withdrawn or demanding behavior; guilt; sadness; and undue exaggeration of abilities. But they also reported missing the enthusiasm and heightened sexuality associated with hypomanic phases:

Hypomanic joviality, enthusiasm, and spontaneity are often regarded as social pluses; and manic-depressives and their spouses complain about the loss of these valued attributes. When pressed to discuss the sexual compatibility of the marriage, frequently they will say it is worse since lithium treatment started, as the lithium-treated spouse has less libidinal strivings. (Demers and Davis, 1971, p. 352)

Although 77 percent of the spouses rated the marriage as considerably improved, only 43 percent of the bipolar patients expressed this opinion. Patients may be more sensitive to the loss of positive experiences associated with bipolar illness, whereas their spouses may be more aware of lithium's beneficial effects. Such a possibility would be consistent with the discrepancies in perceptions reported by Targum and colleagues (1981). These results again underscore the importance of sophisticated clinical management and subtle titration of lithium to the lowest possible level consistent with efficacy.

O'Connell and Mayo (1981) studied the effects of lithium treatment on 12 bipolar patients and their families. They found that lithium increased the direct care of children by both patients and spouses, significantly alleviated marital friction, and resulted in increased cooperative planning, communication, and trust.

Holinger and Wolpert (1979) found that the majority (59 percent) of their 56 manic-depressive patients showed improvement in their relationships with spouses, families, or friends as a result of taking lithium; slightly more than one-third (39 percent) showed no change. The primary changes observed by the authors were decreases in impulsivity, fragility, and erratic behavior; confidence in relationships increased. The bipolar patients were far more likely than the lithium-treated unipolar patients to demonstrate a change in interpersonal behavior (59 and 11 percent, respectively). In a study by Lepkifker and colleagues (1988), psychiatrists' ratings of marital and other interpersonal relationships were significantly higher for the 50 bipolar and 50 unipolar patients (all of whom were euthymic and lithium-treated) than for 50 psychiatric controls with personality disorders. There were no significant bipolar-unipolar differences.

Finally, Ruestow and colleagues (1978), in a study cited earlier, suggested that bipolar manic-depressive patients, especially men, could have good marriages if stabilized by

lithium. While emphasizing the importance of adjunctive use of marital therapy, they also suggested "that patients be treated with medication . . . prior to the initiation of marital therapy and that the need for intensive marital therapy be reassessed after the patient's illness has been stabilized."

Bipolar Disorder and Family Functioning

In addition to the genetic risk imparted by bipolar parents to their children, there is a potential risk due to the children's exposure to parents' moods and maladaptive child rearing. This is an understudied research topic in bipolar samples; however, there is an important and well-developed literature linking the effects of parental depression and the commonly associated environmental conditions with diagnosable disorders in children and disturbances in their functioning.²² The vast majority of these studies involved mothers with diagnosed unipolar depression or nondiagnosed women who displayed elevated symptoms of depressed mood; the samples included children of all ages, from infancy to young adulthood. Across the wide array of samples with varying demographic characteristics in these studies, the results have been quite consistent. Infants display a variety of indicators of distress and discomfort while interacting with depressed mothers. School-age children with clinically depressed mothers show high rates of major depression, as well as anxiety and disruptive behavior disorders, with studies indicating that 50 percent or more of such children may have diagnosable disorders during childhood and adolescence (Hammen, 1991; Beardslee et al., 1998). The offspring of depressed parents have also been found to be impaired in academic and social functioning, and indicators of maladjustment and psychopathology appear to suggest further dysfunction over follow-up periods of several years (Anderson and Hammen, 1993; Weissman et al., 1997; NICHD Early Child Care Research Network, 1999).

While children's maladjustment may in part reflect genetically transmitted disorder, it has been widely speculated that depressed parents, particularly depressed mothers, are impaired in their parental roles in ways that have substantial negative impacts on their children, ways likely to be linked to the chronicity and severity of and perhaps the timing of the child's exposure to the parent's depression. Depressed women may be apathetic and withdrawn, display less physical affection, or be irritable and critical with their children. Not only do the symptoms of depression interfere with the kinds of warm, consistent, responsive, and available nurturing believed to be optimal for children's development, but the depressed parent may also be unable to assist the child in coping with stressful life events that befall the child or family and may fail to model

effective strategies for coping with interpersonal and stressful challenges. In addition, the lives of depressed women are commonly characterized by a variety of factors that may have a negative impact on the developing child, including marital conflict or divorce, as well as work and financial difficulties that create stressful conditions in the family.

As noted, far less research has been conducted on the parenting characteristics of women with bipolar disorder than on those of women with depression. Moreover, parenting behaviors are likely to differ as a function of mood state. While depressive symptoms may be associated with maladaptive parenting, it is less clear that bipolar parents who are euthymic or even hypomanic display dysfunctional behaviors. Additionally, significant changes in parenting style, perhaps resulting from mood shifts, may themselves have important effects on children. It is also important to distinguish the potentially detrimental effect on children of such cofactors of bipolar disorder as exposure to violence, psychosis, and substance abuse from outcomes associated with typical functioning while not in the midst of episodes. Thus parenting characteristics should be explored as a function of current, typical, and potentially changing clinical status, with attention to the considerable differences in outcomes that may be associated with each.

As noted in Chapter 7, relatively few studies addressing high risk for bipolar disorder have examined psychosocial mechanisms of children's risk in bipolar families. Radke-Yarrow (1998), reporting the results of an approximately 10-year follow-up of children of unipolar and bipolar mothers, summarized the results of several observational sessions involving mothers and their children. She and her colleagues attempted to characterize two mechanisms by which a mother's disorder affected her children—maternal symptomatology, and socialization and caregiving functions. Both unipolar and bipolar women were frequently observed to be irritable and angry with their youngsters (42 percent), and some of the bipolar women displayed an overall uninvolving or unavailable style (19 percent). Bipolar women also evidenced boundary issues, "unstable enthusiasms," and impulsive behavior in their interactions (61 to 69 percent). Overall, the maternal styles observed were fairly stable over the years of the study and were predictive of maladaptive outcomes in the children. It should be noted that because most of the bipolar women in the study had bipolar-II disorder, their symptoms were chiefly depressive, and the specific role of mania was not examined.

A study of the family environments of bipolar parents of 56 children aged 6 to 18 was conducted by Chang and colleagues (2001). They collected parents' reports on the Family Environment Scale, and found significantly lower

scores on the cohesion and organization subscales and higher scores on the conflict subscale compared with normative data. The scores were unrelated to whether the children had diagnoses of Axis I disorders, however, so child psychopathology was not directly associated with family functioning.

One of the rare studies of mother–infant behavior involving women with bipolar disorder compared ratings of mother–child interactions during hospitalization among unipolar, bipolar, and schizophrenic women (Hipwell and Kumar, 1996). All groups displayed erratic or dysfunctional interactions at first, but improved over time. While the scores of the bipolar women were initially similar to those of the schizophrenic women, they showed greater improvement over the course of hospitalization: by the time of discharge, 77 percent of bipolar and 86 percent of unipolar mothers fell within the normal range, compared with only 33 percent of schizophrenic women. It appeared that the impairments associated with bipolar disorder were symptom related and became normalized with clinical improvement.

The University of California-Los Angeles (UCLA) High Risk Study observed mother–child interactions among bipolar, unipolar, and medically ill and well women during discussions involving typical family disagreements. The researchers found that the bipolar women largely resembled the normal comparison women in their interaction styles, whereas the unipolar depressed women were significantly more negative, critical, and withdrawn from the discussion task with their children (Gordon et al., 1989). Analysis of the findings of this study revealed that overall, depressive mood was a strong predictor of maternal behavior, as well as of children's symptoms (Hammen, 1991). Regardless of diagnosis, women with more severe depressive symptoms had more disturbances in their interactions with their children, and their children were less well adjusted in various roles. Bipolar women had significantly fewer depressive episodes over the course of the study (3 years) than did unipolar women, and thus the phenomenology of the family experiences was quite different for the two groups. Anderson and Hammen (1993) reported that the offspring of bipolar mothers had better social adjustment and academic achievement relative to those of unipolar depressed mothers; indeed, their adjustment resembled that of children of normal community women. Similar results were reported by Klein and colleagues (1986), who found normal social adjustment in the adolescent offspring of parents with bipolar disorder. However, if the offspring themselves had cyclothymic behavior and mood disturbances, they tended to have impaired social adjustment. Thus the sparse evidence available suggests relatively good adjustment in children of bipolar parents (unless the children themselves are symptomatic) and provides little indication of significant

parenting impairment, except among those with chronic depression.

One hypothesis that should be pursued in future research is that the reactions of children and other family members to depression, mania, and mixed states are almost certainly quite different. As discussed earlier, a manic episode may be viewed as being more clearly beyond the individual's control than a depressive episode and therefore may be more likely to elicit alternative caretaking for children. The predominant mood state of the parent's mania—euphoric versus angry and highly volatile—is certainly relevant but has not been studied in this context. Also, of course, the parent's psychological and social functioning between episodes is likely to be a strong predictor of children's adjustment, inasmuch as stable and euthymic periods may help repair disruptions caused by periods of symptomatology. Not only the specific effects of depression and mania, but also the level of chronicity or recovery between major episodes, are of considerable predictive significance in understanding the overall effects of parenting behavior.

Clearly, further studies are needed to evaluate the parental functioning of adults with bipolar disorder. Of particular importance is the quality of parenting when the patient is not in the midst of a major episode. As in research on the effects of unipolar depression on children's risk, it is also important to measure and evaluate the environment in which families live, including parents' marital status, economic conditions, and the spouse's mental health and adjustment, as well as general resources for coping with the illness.

CONCLUSIONS

Personality

Contemporary research generally dispels the idea that the personalities of bipolar patients are fundamentally different from those of people without mood disorders. Descriptive studies comparing bipolar patients with other groups have yielded few consistent results and clearly suggest enormous variability, depending in part on the instruments used and individuals' current mood status. The major drawback of such studies is their limited utility. Nevertheless, the close and likely bidirectional association between personality and mood disorders suggests that many behaviors and attitudes we regard as personality may in fact be somewhat unstable and highly colored by affective experiences. The field now appears ready to proceed to more conceptually and practically challenging questions and prospective methods concerning the predictive utility of personality constructs: Do they tell us something important about the course of disorder, treatment responsiveness, and functional outcome

beyond that attributable to symptoms or psychosocial context? Are there premorbid signs of eventual bipolar disorder that might help in both understanding the risk for illness and altering its course? What are the underlying neurobiological processes of normal mood and temperament that may help us understand mood disorders?

Personality Disorders

Research on personality disorders—the enduring, pervasive, and dysfunctional styles measured on Axis II of the DSM—has increased in sophistication in the bipolar field. As with most Axis I disorders, studies of bipolar patients evaluated during remission indicate relatively high rates of personality disorders, and such disorders generally predict a relatively worse course of illness and functional adjustment. However, the overlap among bipolar symptoms, mood states, and personality pathology may obscure the question of whether a bipolar patient truly has an Axis II disorder.

Interpersonal Functioning

Interpersonal functioning is commonly a casualty of bipolar disorder, although there is tremendous variability in individuals' abilities to sustain close friendships and family relationships. It is unclear whether the effects of bipolar disorder on interpersonal functioning are the result of episodes or of underlying impairment of social skills. There is, however, ample evidence that poor social functioning may negatively affect clinical outcomes. Thus interventions targeting social and family relationships may potentiate the effects of psychopharmacology and, of course, benefit the loved ones greatly affected by their relative's disorder.

NOTES

1. These differences were well summarized by Hall and Lindzey (1970): the relative importance of the uniqueness of the individual (the idiographic-nomothetic controversy), whether man should be viewed as possessing purposive or teleological qualities, the importance of group membership, the relative importance of conscious and unconscious determinants of behavior, the number of motivational concepts, the importance of the principles of reward and association, the relative emphasis on stable structures or the process of change in personality, the functional independence of personality structure at any particular point in time, the relative importance of genetic factors in determining behavior, and the relative importance of early developmental experiences.
2. Thus Kraepelin (1921) delineated four fundamental types of temperament: *depressive*, *manic*, *irritable*, and *cyclothymic*. Kretschmer (1936) stressed the overlap among these personality types in the prepsychotic, *cycloid personality* of manic-depressive patients: "they form layers or patterns in individual cases, arranged in the most varied combinations." Campbell

(1953), too, described a cycloid personality, which could occur in one of three forms—*hypomanic*, *depressive*, and *cyclothymic*—“with innumerable gradations and mixtures between the three.” He, like Kraepelin, regarded all of these personality types as “part of the same disease process, and that any one of these may change into any other.” Leonhard (1957), who separated major affective illness into unipolar and bipolar types, also regarded many personality patterns in manic-depressive patients as subclinical, or “diluted,” forms of the primary illness itself. Mayer-Gross and colleagues (1955) derived personality topologies similar to those of Kraepelin (1921), Kretschmer (1936), and Campbell (1953): *cyclothymic* (social, good-hearted, kind, and easy-going), *hyperthymic* (elated, humorous, lively, and hot-tempered), and *hypothymic* (quiet, calm, serious, and gentle). Rowe and Daggett (1954) and Von Zerssen (1977) summarized premorbid personality traits of manic and depressed patients, which are quite consistent with the earlier clinical topologies.

3. Dooley (1921, p. 167) wrote:

The behavior found in the manic attack, in which the patient throws himself with almost equal vim into every possible avenue of expression, is in itself a defense reaction. By thus taking the offensive he keeps himself safe from the approach of the painful thought or feeling which is usually a realization of some failure or degradation, or fundamental inferiority of his own. When he is depressed his defense is no longer possible and he is weighed down by the pain of the acknowledged defect.

More specifically, Schwartz (1961, p. 244) described the dynamic purpose for hyperactive behavior and grandiose thought:

The hypermotility in mania may have a twofold purpose. First, it may serve as a method for distracting attention from the perception of deprivation; second, it is a diffuse and multidirectional effort to obtain pleasure, in which some realistic basis for the denial of deprivation may be grasped. . . . Grandiosity as a defense by denial against emptiness, however . . . may even represent, additionally, an intellectual attempt at a further regression, in the service of the ego, to the stage of omnipotence.

Grotstein (1986) described the manic mechanism of denial in terms of power and self-regulation:

The psychical state which is set up to regulate this primal state of powerlessness is that of a fraudulent state of power, including that of a severe superego and/or compulsive and/or hypomanic defenses which seek to create an artificial “floor” over a “floorless” psyche.

4. Dooley, 1921; Wilson, 1951; Arieti, 1959; Stone, 1978.
5. Cohen et al., 1954; Arieti, 1959; Gibson et al., 1959; Smith, 1960.
6. This concept was explained in a different way by Arieti (1959, p. 431):

The receptiveness to others and willingness to introject the others determines, at this early age, some aspects of the personality of the patient. He tends to become

an “extrovert”; at the same time he tends to become a conformist, willing to accept what he is given by his surroundings (not only in material things but also in terms of habits and values).

7. According to Dooley (1921, p. 39, 166):

The personality of the manic depressive individual also presents an obstacle. Those who manifest frequent manic attacks are likely to be headstrong, self-sufficient, know-it-all types of persons who will not take suggestions or yield to direction. They are “doers” and managers, and will get the upper hand of the analyst and everyone else around them if given the opportunity. . . . The manic-depressive character is extroverted, he tries always to relate himself to his environment, he minimizes the subjective element and makes use of every object in the range of his senses.

Wilson (1951, p. 362) further discussed the therapist’s problems in treating the manic-depressive patient:

From the psychiatrist’s point of view he is uninteresting because he is hard to get at. He is friendly and superficially cooperative, but soon personality investigation ceases because the patient refuses to be self analytical. When the patient is depressed or manic, his illness seems to explain his unapproachableness, and when he is well he will have nothing to do with you except in a very superficial way. This impenetrable shell is characteristic of persons with this illness and sets them apart from those having other forms of depression.

Cohen and colleagues (1954, p. 120) described the manic-depressive personality as dependent, even during states of normal functioning:

We see, then, in the adult cyclothymic, a person who is apparently well adjusted between attacks, although he may show minor mood swings or be chronically overactive or chronically mildly depressed. He is conventionally well-behaved and frequently successful, and he is hardworking and conscientious; indeed, at times his overconscientiousness and scrupulousness lead to his being called obsessional. He is typically involved in one or more relationships of extreme dependence, in which, however, he does not show the obsessional’s typical need to control the other person for the sake of power, but instead seeks to control the other person in the sense of swallowing him up. His inner feeling, when he allows himself to notice it, is one of emptiness and need. He is extremely stereotyped in his attitudes and opinions, tending to take over the opinions of the person in his environment whom he regards as an important authority. Again this contrasts with the outward conformity but subtle rebellion of the obsessional. It should be emphasized that the dependency feelings are largely out of awareness in states of well-being and also in the manic phase; in fact, these people frequently take pride in being independent.

Assessment

Our customary grouping into manic and melancholic attacks does not fit the facts, but requires substantial enlargement, if it is to reproduce nature.

—*Emil Kraepelin (1921, p. 191)*

Standardized measures of mania and depression provide the common language by which clinicians and researchers can communicate. By minimizing differences in the way clinicians record their observations, such instruments contribute to the widespread sharing of information and provide yardsticks for a variety of observers in very different settings. The measures discussed in this chapter vary in their goals and uses. Some help in determining the severity of episodes or symptom states, providing information about treatment response, and ascertaining the incidence of different types of affective states. Quantitative rating scales for mania and depression can be especially important in longitudinal studies (e.g., to describe the natural course of the illness and individual manic and depressive episodes) for identifying the progression and resolution of symptom patterns; studying euthymic states in bipolar patients; and correlating manic and depressive states with other aspects of behavior, cognition, personality, and neurobiology. The assessment literature focuses on bipolar disorder or major depression; there are no measures of depression that focus on the highly recurrent forms that, along with bipolar disorder, make up what we mean by manic-depressive illness. Accordingly the focus of this chapter is on the bipolar subgroup.

There are several additional uses of assessment instruments in the field of bipolar disorder. With the abundance of longitudinal studies of bipolar course, as well as treatment outcome studies, procedures for systematic mapping of the course of the disorder have been developed. Less focused on symptoms as such than measures of severity of mood states, such procedures have the primary aim of capturing changes in and patterns of mood episodes over time. Another relatively new development is the search for measures of risk for bipolar disorder. The potential utility of procedures that could be used to assess subsyndromal or

preclinical states lies in their ability to predict who will develop bipolar disorder over time. Because those with the disorder may be untreated and underdiagnosed, it would be useful to have screening measures to identify such individuals in general psychological, psychiatric, or medical settings. Also discussed in this chapter are measures of functional outcomes in work and social relationships; we note the paucity of such approaches relative to those with a clinical focus. Gaining a fuller understanding of bipolar disorder—as well as helping patients improve in key areas that affect the quality of their lives—requires attention to the development and application of such measures.

Several general types of measures have been developed to classify and quantify changes in affective states. The major categories, delineated by von Zerssen and Cording (1978), are (1) self-ratings, made by patients; (2) observer ratings, usually made by clinicians; (3) analyses of behavior (including linguistic analyses of speech or written productions); and (4) objective measurements, either of spontaneous activities (physical activity) or of reactions within a standardized situation (objective psychometric tests). This chapter necessarily is limited to an overview of self-rating and observer rating scales constructed to measure manic, depressive, mixed, and cyclothymic states. Measurement issues specific to particular topics are covered in the relevant chapters of this volume. For example, diagnostic evaluation is covered in Chapter 3, assessment of course and outcome in Chapter 4, assessment of neuropsychological functioning in Chapter 9, and measures of personality in Chapter 10. This chapter includes those generic rating scales that have been used or replicated most widely, as well as several instruments with potential utility for specific goals, such as screening for bipolar disorder.

We begin by describing conceptual and methodological issues involved in the assessment of manic and depressive

states. We then review in turn instruments used for assessment of the two states, and analyze and compare the scales used for both purposes. The following sections describe instruments used for combined assessment of manic and depressive states, assessment of bipolar risk and screening for bipolar disorder, charting of the course of bipolar disorder, assessment of psychosocial adjustment, and assessment of bipolar symptoms in children and adolescents.

CONCEPTUAL AND METHODOLOGICAL ISSUES

Conceptual Challenges

There are a number of difficulties associated with the measurement of manic and depressive conditions. Moods may be highly unstable, fluctuating rapidly over days or even hours. Bipolar conditions by definition include patterns over time, requiring longitudinal data gathering, which is fraught with its own pitfalls. Moods may be mixed, including both manic and depressive elements, and may include or reflect other emotional states and comorbid conditions, such as anxiety, substance abuse, and Axis II disorders (see Chapters 7 and 10). Bipolar conditions themselves are highly heterogeneous, including a wide range of syndromal and subsyndromal states, which vary in course and episode features. Continuing changes and refinements in diagnostic criteria and elucidation of potential subtypes suggest that no “gold standard” criteria currently exist against which to validate new instruments. Generally, there is reliance on convergent validation—agreement between the results of two instruments or of newer and older instruments. Additionally, most measures attempt to include a multitude of clinical symptoms of the syndromes of mania or depression. However, refinements of models of etiology and targeted treatment-related functional outcomes will likely require greater attention to specific clusters of symptoms—such as anhedonia, excessive activity, or distractibility—that are poorly conceptualized and lack adequate measures. Most of the instruments described in this chapter are used largely for clinical assessment and may not be sufficient for other research purposes. Finally, a further challenge, even for well-established measures, is the need for empirically derived endpoints that would be widely accepted and consistently employed as markers of meaningful clinical change in treatment outcome studies (Baldessarini, 2003).

Methodological Issues

Added to these conceptually challenging issues are numerous psychometric hurdles that must be overcome by any good measure, including establishment of various forms of reliability and validity. As discussed later, clinical activity and research in the field of bipolar disorder have brought

to light a number of gaps in existing tools for measuring manic and depressive states, indicating that much progress has yet to be made.

One methodological challenge is clarification of the goals of assessment. What do we mean, for example, by the measurement of “depression,” a term that variously denotes a mood state, a constellation of symptoms, and a diagnostic entity? Instruments designed to assess a constellation of symptoms of depression, such as the Beck Depression Inventory (BDI), are sometimes used erroneously as diagnostic tools, identifying “depression” if respondents score beyond a certain cutoff point. Yet a diagnostic instrument, such as the Structured Clinical Interview for DSM (SCID), used to identify major depressive episodes, may do a limited job of measuring the mood state “depression.” Numerous instruments, as we shall see, purport to assess syndromic features of depression or mania. Nonetheless, they may differ considerably in their item content, with varying emphases on cognitive, behavioral, mood, and somatic features (e.g., Snaith, 1993). The goals and limitations of each instrument must be clearly conceptualized so its uses will be appropriate to the purposes at hand, and conclusions based on a particular assessment strategy must be specific to that instrument.

Selection of appropriate instruments for specific purposes also requires determination of the validity of an assessment approach for a particular goal. Instruments appropriate for selecting patients for a treatment study or investigating an etiological mechanism may not be valid for measuring changes in mood state or evaluating outcomes over time. Thus different assessment procedures may be required to diagnose, measure severity, observe course features, and assess elements of a particular symptom.

In addition to such issues regarding the goals and meaning of various instruments, methodological challenges are inherent in the very assessment of manic and depressive mood states. Mood states color subjective reports of experiences and behavior, as well as memory of the past and expectations of the future; when depressed, for example, an individual may report having “always” been depressed and may exaggerate symptoms of past depressive episodes. Transient mood states may not only vary with clinical conditions, but also be affected by seasonal, diurnal, menstrual, and other cyclic variations. As noted, moreover, mixed states are more common than previously believed, and they confound the utility of bipolar scales—those constructed on the assumption that mania and depression are, in all respects, opposite states. Mood states also are often highly nonspecific across diverse clinical populations. It has been demonstrated that depressed patients, although distinguishable from normal populations on most scales, may not be readily distinguished by mood symptoms from other clinical populations, such as general medical patients,

schizophrenic patients, or other psychiatric patients (Mendels et al., 1972; Murphy et al., 1982). Similarly, certain manic symptoms, such as impulsivity, irritability, and distractibility, may occur in various diagnostic groups.

In the discussion that follows, these and related methodological problems are examined in greater detail. As a first step, we outline the advantages and disadvantages of the two major methods for measuring manic and depressive states: self-rating and observer rating.

Self-Rating of Affective States

There are obvious advantages to using self-ratings by affectively ill patients. Foremost, as Murphy and colleagues (1982) pointed out, patients are in a unique position to provide information about their feelings and moods—key symptoms in any assessment of mood disorders. The value of self-ratings was confirmed by Raskin and colleagues (1970), who found that a mood scale completed by patients was one of the best measures of significant treatment effects. The patient is also, for the most part, free of the theoretical biases that affect the development and use of observer ratings, and “has access to the totality of his experience, rather than only a subset of behavior that the observer views” (Murphy et al., 1982). For example, in an early study, Zealley and Aitken (1969) analyzed independent mood recordings made by patients and nursing staff; an example of the results of their analysis is shown in Figure 11–1, which illustrates the lag between a patient’s self-ratings and a nurse’s ratings of the patient. The results of this study indicate that patients’ mood symptoms changed from depressed to normal to hypomanic more rapidly than the staff detected, and suggest that the staff may have been unaware of patients’ mood states day to day. In addition to improved accuracy, there are several practical advantages to using patient self-report measures: they require relatively little professional time and expense, can be completed rapidly, and can be used for repeated measurement (Hamilton, 1976; Murphy et al., 1982).

Self-ratings have obvious disadvantages, however. Patients must be literate, cooperative, not too depressed or too manic, and able to concentrate (Hamilton, 1976; Snaith, 1981; Murphy et al., 1982). Other difficulties derive from patients’ idiosyncratic interpretations of the language of rating scales, their highly variable degrees of insight, and the scales’ inability to differentiate clearly between symptoms (e.g., mood and energy changes) when they occur simultaneously (Pinard and Tetreault, 1974; Snaith, 1981). Finally, there is some evidence that severely depressed patients tend to underestimate the severity of their psychopathology (see, e.g., Paykel et al., 1973). For instance, Prusoff and colleagues (1972b) assessed 200 depressed patients using semistructured clinical interviews and self-reports. They found that self-report ratings, although useful in measuring the presence or

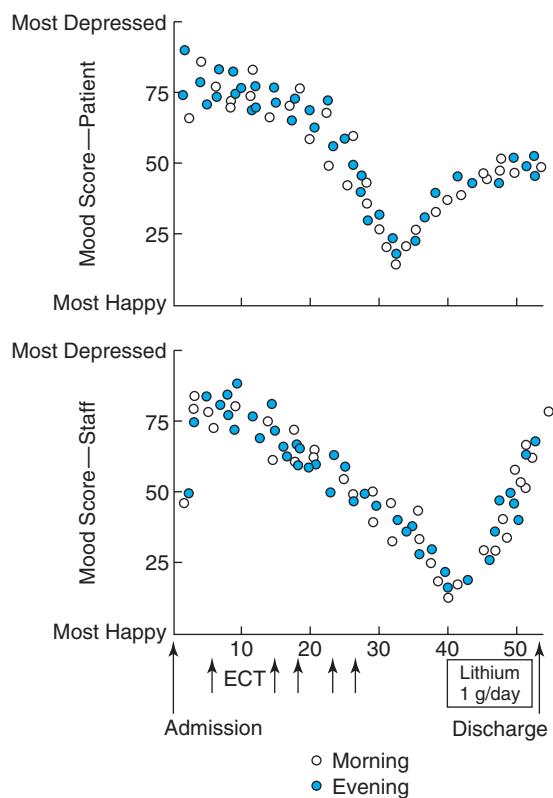

Figure 11-1. Visual analogue scale scores obtained from nursing staff and from a patient with manic-depressive illness. ECT=electroconvulsive therapy; open circles=morning observations; filled circles=evening observations. (Source: Adapted from Zealley and Aitken, 1969.)

absence of symptoms, were not a reliable index of symptom severity. Self-reports and clinically obtained measures were far more highly correlated at follow-up than during an acute episode. In a related study, Prusoff and colleagues (1972a) examined the nature of the discrepancy in scores derived from self- and clinician ratings. They found that patients whose ratings of symptoms were higher than those of clinicians tended to be younger, less severely depressed, and more histrionic. Conversely, those who minimized their symptoms tended to be older, more severely depressed, and obsessive. These results may reflect in part variations among patients with differing clinical and demographic characteristics, ranging from acute emotional turmoil with exaggerated subjective suffering to withdrawn, perhaps passive detachment and more physical manifestations.

Observer Rating of Affective States

In summarizing the advantages of observer ratings, Hamilton (1976, p. 158) cited the observer’s ability to:

evaluate the intensity of any one symptom by comparing it against the background of experience which he has . . .

penetrate the mask which the patient holds up, whether deliberately or unintentionally . . . [and] rate and assess certain manifestations of illness which the patient would find impossible or extremely difficult to do. [These include] loss of insight . . . mild retardation . . . [and] hypochondriasis and delusions. An observer can rate all grades of severity of an illness . . . whereas a patient can be too ill to complete a questionnaire.

At the same time, however, observer ratings have significant potential drawbacks, as discussed at length by both Lorr (1974) and Bech (1981). Lorr noted that variability in the degree of the patient's disturbance from one interview to another affects both self- and observer ratings. Furthermore, observers may differ in efficiency and their manner in relating to the patient, and rating scales may be worded ambiguously or require too much inference. Bech (1981) stressed sources of variance in observer ratings, including differences that occur because information is not gathered from the same sources, differences in multiple observers' perceptions of the same phenomena, and variations in the terminology used to report results of observations of the same phenomena. Variations in the mood of the observer also affect ratings for some items (Bunney and Hamburg, 1963); this is the case especially for anger and anxiety ratings, which may be distorted if the observer confuses his own feelings with those of the patient.

ASSESSMENT OF MANIC STATES

Self-Rating Scales

Self-rating scales have rarely been used to measure manic states. Poor judgment, uncooperativeness, cognitive impairment, distractibility, and denial combine to make meaningful measurement problematic. Platman and colleagues (1969), for instance, found a very low correlation (0.35) between self-ratings of patients during manic episodes and ratings by staff. After recovery, however, the patients' recall of mania was highly correlated (0.95) with staff perceptions. An early instrument designed to assess the less severe, hypomanic range of symptoms was the M-D Scale, developed by Plutchik and colleagues (1970). It had 16 items scored in a yes/no format (e.g., "Lately I feel like breaking things"; "I've been telephoning a lot of friends recently"). This instrument demonstrated discrimination of hypomania from normality, but little reliability or validity information is available.

Recently, renewed attempts have been made to develop and employ self-rating scales for mania because of their obvious advantages. Shugar and colleagues (1992; see also Braunig et al., 1996) reported on the development and

initial validation of a Self-Report Mania Inventory (SRMI). This instrument currently consists of 47 items rated true or false. Its developers based the scale on behavioral items indicative of severity and DSM-III-R criteria, on the assumption that these would be reported more accurately than would inferences about symptoms. Examples include the following: "I started things I didn't finish"; "I partied more"; "I was getting into arguments"; and "I thought I could change the world."

Braunig and colleagues (1996) found that manic patients were able to report reliably on such behaviors over various intervals on the SRMI. Self-report scores correlated highly with results of the Young Mania Rating Scale (YMRS) assessed by observers, and also reflected clinical improvement in hospitalized manic patients. In one study of 20 rapid-cycling bipolar patients, the SRMI results correlated with YMRS ratings, but the SRMI was found to be more sensitive than the latter scale to milder mood fluctuations in the euthymia to hypomania range (Cooke et al., 1996). A study of manic inpatients by Altman and colleagues (2001) found that the SRMI showed good sensitivity in detecting severe cases (86 percent) and was also sensitive to post-test treatment effects; however, its results did not correlate significantly with interviewer-based ratings at initial evaluation. The authors suggested as one possible explanation for this discrepancy that at least eight of the items on the SRMI refer to behaviors that would be prohibited in an inpatient setting (e.g., drinking alcoholic beverages), and thus the instrument might underestimate the severity of manic symptoms in such settings.

Altman and colleagues (1997) reported on the development and preliminary psychometric characteristics of the Altman Self-Rating Mania Scale (ASRM). Five content items based on DSM-IV criteria (cheerful, self-confident, sleep less, talk more, and activity) remained after specificity analyses, and each is presented with five response options. In a later study, Altman and colleagues (2001) compared the ASRM with the SRMI and a visual analogue scale (VAS) (the Internal State Scale [ISS], discussed later, used to record patients' subjective impressions of their mood states) in a sample of manic patients. The ASRM was found to have the highest sensitivity (93 percent) for detecting acute manic symptoms, showed good agreement with an interviewer-rated severity scale, and was also sensitive to treatment-related changes. The authors noted that further studies of patients with mixed states are needed.

Visual analogue scales are discussed later in the section on combined assessment of depression and mania. We note here, however, an application of the VAS methodology to self-reported manic symptoms in a French study using the Ahearn and Carroll (1996) Multiple Visual Analog

Scales of Bipolarity (MVAS-BP) (Akiskal et al., 2001). This instrument, based on a model of mania proposed by Carroll and Klein (Carroll, 1991), comprises 26 VAS items on global mood state; anger; and subscales of “consummatory reward,” “incentive reward,” “psychomotor pressure,” and “central pain.” A study of 104 hospitalized manic patients found that patient self-reports were especially likely to correlate with clinician reports on emotional factors of depression and elation. In a related analysis of the same sample, Hantouche and colleagues (2001) found that the MVAS-BP was particularly useful in detecting dysphoric mania, with such patients scoring significantly lower than euphoric manic patients on the psychometrically derived subtypes of symptoms.

The examples cited here provide evidence of the utility of self-reported manic symptoms. Further work is needed, however, to develop the psychometric features of the scales, as well as to identify their limitations.

Observer Rating Scales

Considerably more effort in assessment of manic states has focused on observer ratings, including methods based on patient interviews and behavioral observations. The following sections describe several of the more commonly used instruments and their historical predecessors. Readers are referred to a review by Livianos-Aldana and Rojo-Moreno (2001) for psychometric details and reproduction of various instruments. We begin by discussing observation-based scales (typically used by medical and nursing staff in inpatient settings) and then turn to clinician-administered interview-based scales (which may also include observations of the individual during the interview).

Early Efforts to Develop Rating Scales for Observations of Mania

One of the first systematic observer rating scales for the measurement of mania—the Manic State Rating Scale (MSRS)—was developed at the National Institute of Mental Health (NIMH) (Beigel et al., 1971; Murphy et al., 1974). The scale is made up of 26 items, rated from 0 to 5 on both frequency and intensity dimensions. It was designed to be used by trained research nursing staff in inpatient settings (Table 11-1). The nine superscripted items in Table 11-1 were found to be core features of mania—elements present in all patients and most characteristic of manic severity. The reliability and validity of the MSRS are generally good (Livianos-Aldana and Rojo-Moreno, 2001), and the evidence suggests that the scale can easily be taught to new nursing staff. On the other hand, the MSRS has been criticized as being too extensive to be practical. It is also thought to contain inadequately defined items and scale steps; to require too much time to complete; and to exclude certain

core features of mania, such as sleep changes (Petterson et al., 1973; Tyrer and Shopsin, 1982).

The Modified Manic Rating Scale (MMRS) (Blackburn et al., 1977; Loudon et al., 1977) was based largely on the MSRS. It comprises 28 items and uses a six-point rating scale for information derived from interviews and from nursing staff and case notes. The authors found good validity when using a global rating scale as an independent measure, and the scale was highly reliable when employed in a structured interview by several independent raters.

Attempting to develop a shorter but still reliable observation-based rating scale for mania, Petterson and colleagues (1973) devised a seven-item scale that uses a five-point severity system. The behaviors assessed are motor activity, pressured speech, flight of ideas, noisiness, aggressiveness, orientation, and elevated mood. As with the other scales that measure only mania, the Petterson Scale is flawed both theoretically and empirically in not assessing mixed (simultaneous manic and depressed) states. Although the scale rates fewer symptoms of mania than does the MSRS, its measures of severity are far more precisely defined, and because of its relative brevity, it can be re-administered easily to obtain serial ratings. Interrater reliability is good, and validity measures generally indicate good correspondence with other measures of mania and treatment outcome. However, several salient aspects of mania, such as sleep and work disturbances, are not assessed.

Young Mania Rating Scale

Presently, the YMRS is the most commonly used interviewer-based measure of severity of manic symptoms. Young and colleagues (1978) sought to develop a mania rating scale broader than the Petterson Scale but shorter and with more explicit ratings of severity than the MSRS. To this end, they devised an 11-item checklist, modeled on the Hamilton Rating Scale for Depression (HAM-D) (discussed later in the section on observer rating scales for depressive symptoms). They based their choice of items on published descriptions of the core symptoms of mania—those cutting across the entire spectrum of illness severity, although dysphoria is not included. Items assessed during the 15- to 30-minute interview are elevated mood, increased motor activity (energy), sexual interest, sleep changes, irritability, speech (rate and amount), language–thought disorder, language content, disruptive–aggressive behavior, appearance, and insight. Ratings are based on subjective reports by patients and on behavioral observations made by the clinician during the interview. Seven of the items are rated on an explicitly defined severity scale of 0 to 4. Four items (irritability, speech rate and amount, language content, and disruptive–aggressive behavior) are scored on a broader scale of 0 to 8. The authors reported that, based on their published results for relatively

TABLE 11-1. Manic State Rating Scale

Part A—Frequency (How much of time?)	The Patient	Part B—Intensity (How intense is it?)
0 to 5		0 to 5
—	1. Looks depressed	—

small samples, the scale is a reliable, valid, and sensitive measure of mania. More recent data showed that interrater reliability averaged .68 across items (Altman et al., 1994). The YMRS is increasingly being employed in bipolar clinical trials and treatment outcome studies because of its ease of use (e.g., Tohen et al., 2000; Leverich et al., 2001). The following is a sample from the YMRS developed to assess elevated mood:

Elevated Mood

0 = absent

1 = mildly or possibly increased on questioning

2 = definite subjective elevation; optimistic, self confident; cheerful; appropriate to content

3 = elevated, inappropriate to content; humorous

4 = euphoric; inappropriate laughter; singing

Bech-Rafaelsen Mania Scale

The main purpose of the Bech-Rafaelsen Mania Scale (MAS) (Bech et al., 1979; Bech, 2002) is to assess the severity of current manic symptoms. There are 11 items rated on a five-point scale, with highly specific ratings of severity; for example, a score of 1 on the sleep item represents a reduction of sleep by 25 percent, and a score of 2 represents a reduction by 50 percent. To control for diurnal variation in mood and behavior, the investigators specified that the 15- to 30-minute interview should always take place at a fixed hour. The scale items are motor activity, verbal activity, flight of thoughts, voice/noise level, hostility/destructiveness, mood (feelings of well-being), self-esteem, contact with others, sleep changes, sexual interest, and work activities. Data demonstrating the scale's adequate interrater reliability and

a high degree of item homogeneity were presented in an article by Bech and colleagues (1986). An example of the motor activity item follows:

- 0: Normal motor activity, adequate facial expression.
- 1: Slightly increased motor activity, lively facial expression.
- 2: Somewhat excessive motor activity, lively gestures.
- 3: Outright excessive motor activity, on the move most of the time. Rises one or several times during interview.
- 4: Constantly active, restless, energetic. Even if urged, patient cannot sit still.

The MAS is commonly used in treatment outcome trials. For instance, it is being used in ongoing trials of adjunctive interpersonal and social rhythm therapy for bipolar patients (Frank et al., 1999). Results of recent research also indicate the scale's validity and internal consistency (e.g., as reviewed by Bech [2002]), as well as its sensitivity to changes in bipolar patients participating in a drug trial (e.g., Licht and Jensen, 1997). It might be noted that Bech (2002; see also Rossi et al., 2001) has recommended using the MAS in conjunction with the Bech-Rafaelsen Melancholia Rating Scale (reviewed later) to capture the frequent co-occurrence of depressive and manic symptoms.

Clinician-Administered Rating Scale for Mania

The Clinician-Administered Rating Scale for Mania (CARS-M) (Altman et al., 1994) was derived from the Schedule for Affective Disorders and Schizophrenia (SADS) and DSM-III-R to characterize the severity of manic symptoms. The 15 items are each rated on a six-point severity scale ("insight" is rated on a five-point scale). Preliminary validity data were based on comparisons with the YMRS; the correlation with the latter was .94. Test-retest and internal consistency reliabilities were found to be adequate. Factor analyses revealed two subscales, mania and psychoticism, which are scored separately.

Additional Interviewer-Based Scales for Mania

Several additional scales for rating mania have been developed, but appear to be used relatively infrequently and may be limited in their testing of psychometric properties. The Manic Diagnostic and Severity Scale (MADS) was developed by Secunda and colleagues (1985) as part of the NIMH Collaborative Program on the Psychobiology of Depression-Clinical Studies. The authors aggregated previously developed items from physician- and nurse-rated instruments to create the MADS. Two subscales taken from physician-rated scales—the Schedule for Affective Disorders and Schizophrenia—Change (SADS-C) Scale 17 and the Global Severity Scale (Katz and Itil, 1974)—correspond, respectively, to the elated-grandiose

and paranoid-destructive indices proposed by Beigel and Murphy (1971). Two factors derived from the nurse-rated Affective Disorder Rating Scale (ADRS) (Murphy et al., 1982) also address items designed to measure these two major subtypes of manic symptoms. The MADS subscales measure elevated mood, sleep and energy changes, grandiosity, guardedness, anger, disturbances in insight and judgment, negativism, restlessness, impulsivity, and distractibility. Detailed reliability and validity data have not yet been published (see Livianos-Aldana and Rojo-Moreno [2001] for further discussion).

Several general rating scales measure features of mania even though they were not developed specifically for that purpose. These scales include the Inpatient Multidimensional Psychiatric Scale, the Brief Psychiatric Rating Scale, and the Clinical Global Inventory. The Differential Diagnostic Scale, Bellevue Differential Inventory, and SADS, devised for differentiating mania from schizophrenia and not directly relevant to the measurement of mania per se, are not reviewed here.

ASSESSMENT OF DEPRESSIVE STATES

Self-Rating Scales for Depressive Symptoms

Several self-report instruments are available for assessment of depressive symptoms, syndromes, and mood states. A few of those most widely used in clinical and research applications are discussed here. Further information on these and numerous other measures was provided by Ronan and colleagues (2000). Many additional instruments have been developed for use with specific populations, such as children and adolescents and the elderly, and for assessment of specialized content areas related to depression, such as hopelessness, suicidality, and self-esteem. These instruments are beyond the scope of the current discussion.

Beck Depression Inventory

The Beck Depression Inventory (BDI) is the most widely used self-rating scale for depression for both research and clinical purposes. Developed by Beck and colleagues (1961) and revised as the BDI-II for consistency with DSM-IV (1996), the scale consists of 21 items, each containing four response options with content ranging in severity from not depressed to severely depressed. Individuals select the one response per item that best corresponds to their current clinical state "over the past 2 weeks," and the options are scored on a scale of 0 to 3, yielding a total across all items. For the BDI-II, a score below 13 suggests minimal depression, a score of 14 to 19 mild depression, and so on. Like all self-report scales in which a cutoff is used to indicate significant symptoms, the scale is not a diagnostic

instrument, and scores may be elevated temporarily as a result of environmental, medical, or other difficulties. The items assessed include mood, guilt, irritability, social withdrawal, indecisiveness, fatigability, sleep and appetite changes, and loss of libido. The original BDI tended to emphasize the mood and cognitive features of depression, with less assessment of the more somatic symptoms, whereas the BDI-II includes modifications that permit individuals to indicate whether they have experienced an increase or decrease in sleep and appetite. The following sample item illustrates the range of severity assessed:

14. Worthlessness
 - o I do not feel that I am worthless.
 - 1 I don't consider myself as worthwhile and useful as I used to.
 - 2 I feel more worthless as compared to other people.
 - 3 I feel utterly worthless.

The original BDI had excellent psychometric properties, including internal consistency and test-retest reliability. It was shown to be a valid indicator of severity of depressed mood, having good correspondence with other measures and diagnostic criteria for depression (e.g., Beck et al., 1988). The BDI-II likewise has been well tested. It shows good correspondence with the HAM-D (Hamilton, 1960) and with other measures of depression-related constructs (Beck et al., 1996).

Zung Self-Rating Depression Scale

The Zung Self-Rating Depression Scale (Zung SDS), a 20-item scale with a four-point severity range, measures somatic, psychological, and mood aspects of depression. It is a modified version of the earlier Zung Depression Scale (Zung et al., 1965; Zung, 1974). For an item such as "I have trouble sleeping through the night," the patient is expected to indicate which of the following responses is most appropriate: "none or a little of the time," "some of the time," "good part of the time," or "most or all of the time." Note that the graded response to this question applies only to frequency, not to the extent of sleep loss. Further, the scale does not rate hypersomnia, a frequent symptom among patients with bipolar depression.

The Zung SDS does not show consistently high correlation with the HAM-D (Murphy et al., 1982). It has been criticized on the grounds that depressed patients have difficulty judging the degree and frequency of their symptoms, and endogenous symptoms are underrepresented (Rush et al., 1986). Hamilton (1988) also reported as a major shortcoming of the Zung SDS its relative insensitivity to clinical improvement after treatment (Rickels et al., 1968; Feighner et al., 1984). However, its brevity may enhance its value as a quick screen for severity of depressive symptoms.

Carroll Depression Rating Scale-Revised

The original Carroll Rating Scale was developed to parallel closely in item content the observer-scored HAM-D (Carroll et al., 1981; Feinberg et al., 1981; Smouse et al., 1981). The Carroll Depression Rating Scale-Revised (CDS-R) (Carroll, 1998) is a 61-item self-report questionnaire with items concerning 17 areas of depressive symptoms over the past few days, each rated yes or no. The revised version attempts to make the scale more compatible with DSM-IV. Examples include the following:

2. I have dropped many of my interests and activities.
7. I feel worthless and ashamed of myself.

Both the original and revised scales were based on Carroll's observation that neither existing self-report nor clinician-based scales were adequate for diagnosis of depressive symptoms (Carroll et al., 1981).

Most empirical evaluation of the Carroll scales has been based on the original version, but the author has indicated that the evaluation results are also applicable to the CDS-R. The scales appear to have excellent convergent validity with both self-report and clinician-based measures (e.g., correlation with the BDI, $r=.86$; correlation with the observer-rated HAM-D, $r=.71$ [Carroll, 1998]). Because it is similar in structure and content to the HAM-D and is less time-consuming and less expensive to administer, it may be a good alternative (see Smouse et al., 1981; Tandon et al., 1986). Correlations with other depression scales suggest that it is as sensitive to bipolar as to unipolar depression. Carroll and colleagues (1981) suggested that a cutoff of 10 can serve as a screen for the presence of significant depression.

Hamilton Depression Inventory

A different self-report instrument based on the observer-rated HAM-D was developed by Reynolds and Kobak (1995). The Hamilton Depression Inventory consists of 38 questions covering the original items of the HAM-D; there is also a melancholia subscale for evaluating the severity of DSM-IV melancholia symptoms. The instrument attempts to measure both the frequency and severity of symptomatology over the preceding 2 weeks. Its psychometric properties are promising, including a correlation of .94 with scores on the clinician-administered HAM-D in a sample of 403 adults (Reynolds and Kobak, 1995). It has not been extensively used in research or clinical settings, however, and its value therefore awaits confirmation.

A briefer version (19 items) of the same scale, the Reynolds Depression Screening Inventory (RDSI) (Reynolds and Kobak, 1998), is intended to take only 5 to 10 minutes to complete. Using a clinical cutoff score of 16, it has the potential to identify major depression among nonreferred

community adults with a high degree of sensitivity and specificity. Therefore, it may serve as a useful screening instrument. Its research uses have been limited to date, however.

Inventory of Depressive Symptomatology

Another recent addition to self-report measures of depression is the self-report version of the Inventory of Depressive Symptomatology (IDS-SR), devised by Rush and colleagues (1986, 1996b). It was based on the authors' clinician-rated scale (IDS-C, discussed later), which was developed to improve on the HAM-D and was recently revised to include symptoms compatible with DSM-IV. The IDS-SR includes 30 items assessed over the preceding week, rated 0 to 3, measuring three factors: a cognitive/mood factor; an anxiety/arousal factor; and a sleep, appetite, and leaden paralysis factor (confirmed by Corruble et al., 1999). Both the self-report and clinician-administered versions take approximately 30 to 45 minutes to complete. Excellent psychometric properties have been reported, including good convergent validation with other measures of self- and clinician-reported symptoms (Rush et al., 1996b; see also Trivedi et al., 2004). Research has demonstrated that the measures are sensitive to treatment-related changes. Recently, Rush and colleagues (2003) developed a shortened form of the two versions of the IDS, called the Quick IDS (QIDS, with self-report and clinician versions), consisting of 16 items from the original 30-item scale—those needed to assess DSM-IV criteria for major depression. Trivedi and colleagues (2004) reported on the use of these shorter versions with a large sample of outpatients with major depression or bipolar disorder. They concluded that the brief instruments corresponded closely to the longer IDS measures, had solid psychometric properties, and were sensitive to treatment-related change.

Additional Self-Report Scales

Several additional self-report scales for depressive symptoms merit mention. The Center for Epidemiologic Studies-Depression (CES-D) scale (Radloff, 1977) is used extensively in community surveys and as a screening measure for depression. It was designed to be administered quickly and easily in research and epidemiologic settings, but has limited clinical utility. Normative information on its use in various samples was reported by Weissman and colleagues (1977). Furukawa and colleagues (1997) reviewed studies of the CES-D and the limitations of its psychometric properties, and presented data on potential cutoff scores to be used in various settings to predict the probability of depressive disorder given a specific individual score.

The Inventory to Diagnose Depression (Zimmerman et al., 1986) was developed to serve as a self-report diagnostic

instrument for assessing the attainment of syndromic features of major depressive disorder based on DSM-III features; the authors presented initial evidence of its validity. Recently, noting changes in the DSM-IV criteria, Zimmerman and colleagues (2004a) developed a new 38-item self-report measure called the Diagnostic Inventory for Depression (DID), which includes symptoms, severity, duration, and impairment due to depressive symptoms. The authors reported on initial psychometric evaluation of the measure based on 626 psychiatric outpatients. The DID showed significant agreement with the SCID on diagnoses of depression, as well as convergent and discriminant validity. The instrument also showed sensitivity to change in symptom severity in follow-up assessments.

Bech and colleagues (2001) similarly developed a self-report scale for diagnosing major depressive episodes. A preliminary study based on 43 psychiatric patients and controls indicated a sensitivity of .1.0 and a specificity of .82 in comparison with DSM-IV/*International Classification of Diseases 10* (ICD-10) diagnoses. Further work is warranted to determine the validity of the procedure for screening and other clinical purposes.

Depressed Mood Self-Rating Scales

There are a number of scales for measuring depressed mood state, not including associated symptoms and syndromic features of depression. Such scales have been widely used in research on moods and emotions, may capture short-term changes in mood, and in some cases may be useful for limited clinical purposes.

- Visual analogue scales, mentioned earlier, are used to measure both manic and depressive states, and therefore are discussed in the section on combined measurement instruments (Hayes and Patterson, 1921; Zealley and Aitken, 1969).
- The Depression Adjective Check Lists (DACL) have both state and trait versions and have been studied extensively, including among clinical populations (Lubin, 1994).
- The Medical Care Outcomes Study (MOS) Screener (Burman et al., 1988) was developed as an eight-item scale to screen for symptoms of depression in the MOS, in order to identify those with likely depressive disorders. It is not suitable as a measure of severity, and its use for diagnosis requires application of a complex formula for weighting items. Nevertheless, it appears to have acceptable validity and has been used extensively in epidemiologic and health policy research.

Observer Rating Scales for Depressive Symptoms

It is often argued that, while self-report instruments are uniquely suited to capturing the subjective experiences of

depression, certain aspects of the depressive syndrome may be characterized more accurately by observers. As suggested earlier, self-reports may be biased not only by the cognitive capabilities or awareness, as well as mood-related perceptions, of depressed individuals, but also by their motives to present themselves in certain lights. Thus, for instance, evaluation of treatment outcomes may require objective ratings by trained clinicians. The drawback of such methods—and the reason for the relative paucity of such instruments compared with self-report questionnaires—is the requirement for training and the establishment of adequate expertise and reliability.

Hamilton Rating Scale for Depression

The HAM-D remains the most widely used observer-rated scale for depression. It was developed by Hamilton (1960) to measure severity and changes over time in the clinical state of depressed patients, and has been amended several times over the years. Although not developed as a diagnostic tool, it has been used with success in making retrospective diagnoses from chart reviews (Thase et al., 1983). It has been widely used as well to evaluate treatment response, correlate depression severity with biological parameters, and evaluate depression subtypes.

The HAM-D is focused much more on somatic and behavioral symptoms than on mood and cognitive symptoms. In its most commonly administered form, it consists of 17 items (9 on a five-point scale [0 to 4] and 8 on a three-point scale [0 to 2]) that measure mood, guilt, suicidal ideation, sleep disorders, changes in work and interests, psychomotor agitation and retardation, anxiety, somatic symptoms, hypochondriasis, loss of insight, and loss of weight. In later versions, additional items were added, so that it is essential to indicate which version is being reported. Note that, in contrast with most depression assessment instruments, the content includes several items pertaining to anxiety states. These features may be somewhat less relevant to bipolar than to unipolar depression.

Interobserver reliability is good, although various factor analyses have extracted inconsistent numbers and types of factors (see Hedlund and Vieweg, 1979). The HAM-D's high reliability, ease of administration (taking approximately 30 minutes), and emphasis on somatic symptoms have been cited as reasons for its enormous popularity (Murphy et al., 1982). On the other hand, critics believe that somatic symptoms are disproportionately represented in the HAM-D, that the differential weighting of symptoms is arbitrary, and that anchor points are ambiguous. Furthermore, certain symptoms, such as hypersomnia, increases in weight and appetite, and changes in quality of mood, are not assessed (Bech, 1981; Rush et al.,

1986). This last point may be an especially important limitation in the assessment of bipolar depression. As noted earlier, Rush and colleagues (1996a) developed a clinician-administered version of what they believe is an improved HAM-D addressing several of the shortcomings noted. The IDS-C is currently being used in the multisite NIMH-Stanley Foundation Bipolar Network study (Leverich et al., 2001), and its scores correlate highly with those on the HAM-D. A study of depressed inpatients reported by Corruble and colleagues (1999) confirmed the IDS-C's strong psychometric properties and suggested that it is more sensitive to treatment-related changes than the Montgomery-Asberg Depression Rating Scale (MADRS) (discussed later). The brief, 16-item clinician version of the QIDS was also found to have excellent psychometric properties in a large-scale study of unipolar depressed and bipolar outpatients (Trivedi et al., 2004). Finally, there is a Revised HAM-D (Warren, 1994). It remains to be seen whether alternatives to the HAM-D will flourish in clinical research over time.

Bech-Rafaelsen Melancholia Rating Scale

The Bech-Rafaelsen Melancholia Rating Scale, developed to combine the HAM-D and the Cronholm-Ottosson Depression Scale, comprises 11 items rated at five degrees of severity (Bech et al., 1979; Bech and Rafaelsen, 1980; Rafaelsen et al., 1980). Items are decreased motor activity, decreased verbal activity, intellectual and emotional retardation, psychic anxiety, suicidal impulses, lowered mood, self-depreciation, sleep disturbances, tiredness and pains, decreased motivation, and decreased productivity in work and interests. The interview is designed to be completed within 15 to 30 minutes, and to control for possible diurnal variation, is to be administered at approximately the same time of day each time. Guidelines for ratings are highly specific; for example, the guidelines for intellectual retardation are as follows:

- o Normal intellectual activity.
- 1 The patient has to make an effort to concentrate on his work.
- 2 Even with a major effort it is difficult for the patient to concentrate or make decisions. Less initiative than usual. The patient easily experiences "brain fatigue."
- 3 Marked difficulties with concentration, initiative and decision-making. For example, can hardly read a newspaper or watch television. Score 3 as long as the retardation has not clearly influenced the interview.
- 4 When the patient during the interview has shown marked difficulties in following normal conversation.

The interobserver reliability of the Bech-Rafaelsen Melancholia Rating Scale has been found to be as high as that of

the HAM-D (Rafaelsen et al., 1980), and the item–total score correlations are adequate (Bech and Rafaelsen, 1980).

Montgomery-Asberg Depression Rating Scale

Yet another observer rating scale for depression is the MADRS of Montgomery and Asberg (1979), developed to measure changes in depression after antidepressant treatment. Easily administered by clinicians, the scale's 10 items measure the major components of clinical depression: apparent sadness, reported sadness, inner tension, reduced sleep, reduced appetite, concentration difficulties, lassitude, inability to feel, pessimistic thoughts, and suicidal thoughts. Items are rated on a seven-point scale (0 to 6), with illustrative anchor points given for ratings of 0, 2, 4, and 6. For example, ratings for the item measuring pessimistic thoughts are as follows:

- Representing thoughts of guilt, inferiority, self-reproach, sinfulness, remorse and ruin*
- o No pessimistic thoughts.
 - 1
 - 2 Fluctuating ideas of a failure, self-reproach or self-depreciation.
 - 3
 - 4 Persistent self-accusations, or definite but still rational ideas of guilt or sin. Increasingly pessimistic about the future.
 - 5
 - 6 Delusions of ruin, remorse or unredeemable sin. Self-accusations which are absurd and unshakable.

The MADRS exhibits construct validity and concurrent validity relative to the HAM-D (Davidson et al., 1986; Khan et al., 2004). Further, it is easily and relatively quickly administered, has well-defined items, and provides for equal weighting of symptoms (Rush et al., 1986). The MADRS has been shown to demonstrate considerable clinical relevance as well (Williamson et al., 2006). On the other hand, its unidirectional rating of sleep change (i.e., decreased sleep) may be a disadvantage in rating bipolar patients. It may be noted that a self-report version of the MADRS (the MADRS-S) has been developed and shown to correlate highly with the BDI (Svanborg and Asberg, 2001).

Additional major observer rating scales for depression include the Cronholm-Ottosson Depression Scale (Cronholm and Ottosson, 1960); the Inpatient Multidimensional Psychiatric Scale (Lorr, 1974); the Physicians' Global Assessment Scale (GAS) (Carney et al., 1965; Endicott et al., 1976); and the Newcastle Rating Scales (Roth et al., 1983), which have been of special interest in biological studies because of their sensitivity to endogenous or melancholic items. As one might expect from the symptomatic differences

reviewed in Chapters 1 and 2, bipolar and unipolar depressed patients show different patterns of response to some of the same standard rating instruments (Paykel and Prusoff, 1973). In this light, it is unfortunate that there have been no systematic studies of the differential sensitivity of rating scales to bipolar depression. To our knowledge, the only scale designed specifically with bipolar patients in mind is the ADRS (Murphy et al., 1982), described later.

Instruments for assessment of depression are being refined and developed with increasing frequency and psychometric sophistication. The tension between having well-developed and empirically sound measures on the one hand and the capacity for widespread use and communicability on the other will doubtless grow. Most of today's instruments continue to be validated by comparison with older instruments (e.g., the HAM-D) without sufficient consideration of sources of invalidity of the latter. A further significant problem is the heterogeneity of the scales' contents, with some being far more focused on somatic or cognitive symptoms than others (see the later discussion). This variation leads to discrepancies in the results of treatment and clinical studies. Moreover, given the heterogeneity among clinical presentations of depressive syndromes, there have been calls for the development of more "narrow-band" instruments that can be used to assess individual or clusters of symptoms, such as energy and fatigability, sleep difficulties, and hopelessness. Such more narrowly focused assessments could potentially facilitate advances in treatment or in understanding of depressive subtypes.

Perhaps the greatest limitation of most well-established self-report and observer rating scales for depression is their failure to capture potentially unique aspects of bipolar depression. This shortcoming, discussed at length in Chapter 2, is of obvious concern to most researchers in the field (see Berk et al., 2004, for a review of the subject). Further research on the clinical features of bipolar depression is needed to help identify factors that should be developed or refined in assessment instruments.

ANALYSIS AND COMPARISON OF SCALES FOR MANIA AND DEPRESSION

There are many ways of comparing rating scales; here we focus primarily on differences in item content. Content profiles of the items included in observer rating scales for mania and in self-report and observer rating scales for depression are presented in Figures 11-2 through 11-5. The classification of items is, of necessity, occasionally arbitrary. For example, symptoms of mood and cognition (hopelessness and pessimism) often overlap, as do symptoms of behavior and activity level. Working within these and

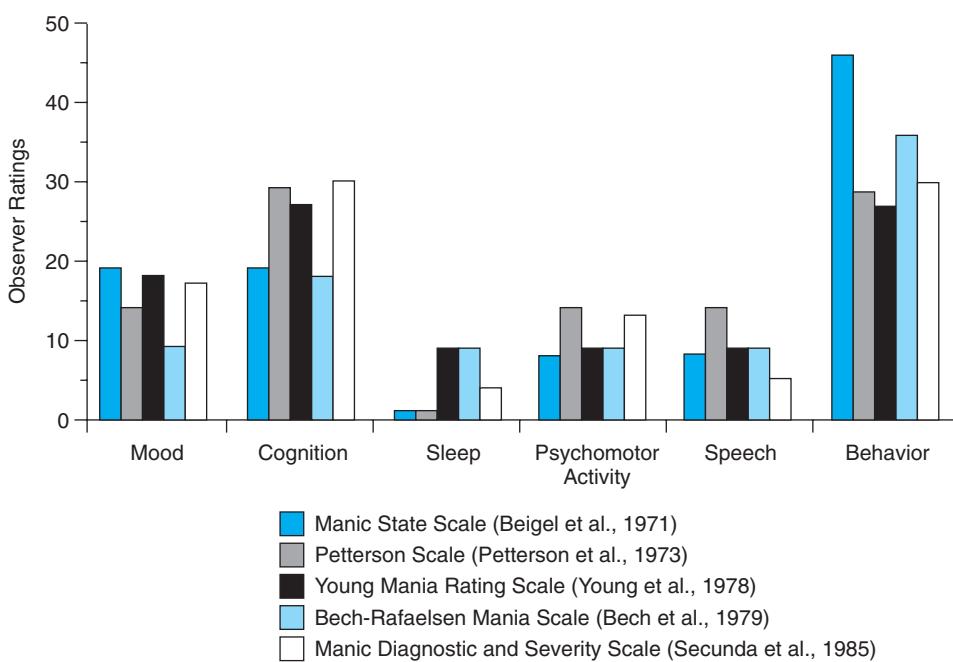

Figure 11–2. Relative weighting of item content: Observer rating measures of mania.

other constraints, it is possible to develop item-content profiles—that is, the items in each scale that are designed to assess a particular feature of mania or depression.

Content of Mania Scales

Figure 11–2 illustrates relative weightings for mood, cognition, sleep, psychomotor activity, speech, and behavior in observer rating scales for mania. The CARS-M (Altman et al., 1994) is not included; its 10 mania items are based on DSM-III-R and SADS criteria, with a separate psychoticism-insight subscale. Figure 11–3 portrays content profiles for more specific types of manic behavior—aggression and hostility, hypersexuality, impaired judgment, seeking out others, impulsivity, and appearance. Mood items represent approximately 15 percent of the total number of observer-rated mania items. The greatest emphasis is placed on euphoric and expansive mood, although all but two scales (the Petterson Scale and the Bech-Rafaelsen MAS) also include items measuring dysphoric, angry, irritable, or negativistic mood.

Despite the frequency of depression during mania (see Chapter 2), this mixed mood state is assessed in only one scale—the MSRS. The proportion of cognitive items is high on all scales, especially the MADS and the Petterson Scale. Sleep disorder symptoms, although integral to the diagnosis and pathophysiology of mania, are the least represented of all symptoms on the various scales; indeed, two scales do not inquire about sleep changes at all. Psychomotor activity and speech symptoms are measured by all of the mania scales. Behavior changes, like cognitive symptoms, are

widely represented, especially on the MSRS. The breakdown of behavior symptoms shown in Figure 11–3 reveals that the symptoms represented most widely and consistently are aggression and hostility, followed by hypersexuality and seeking out others. Impaired judgment, impulsivity, and appearance are assessed less consistently.

The decision to use a particular rating scale for mania is based not only on the item content, but also on the nature of the patient population and the training of the raters administering the scale. The YMRS and the MAS, for example, are more appropriate for less severely ill patients and require a less experienced rating staff, whereas the MSRS is more comprehensive, but also requires sophisticated nurse raters. If patients are only hypomanic rather than manic, additional useful subjective information may be obtained by using self-rating forms.

Content of Depression Scales

Relative weightings for item content in self-rating scales for depression are shown in Figure 11–4 and for item content in observer rating scales in Figure 11–5. Mood and cognitive symptoms are the best represented of symptom groups in both types of scales. The BDI is particularly weighted toward cognitive items, and the MADRS toward both mood and cognition. Somatic and sleep symptoms are represented most strongly on the HAM-D and on its self-rating parallel, the CDS-R. There are no other major differences in relative weightings of item content. Behavior items are not substantially represented on either self-rating

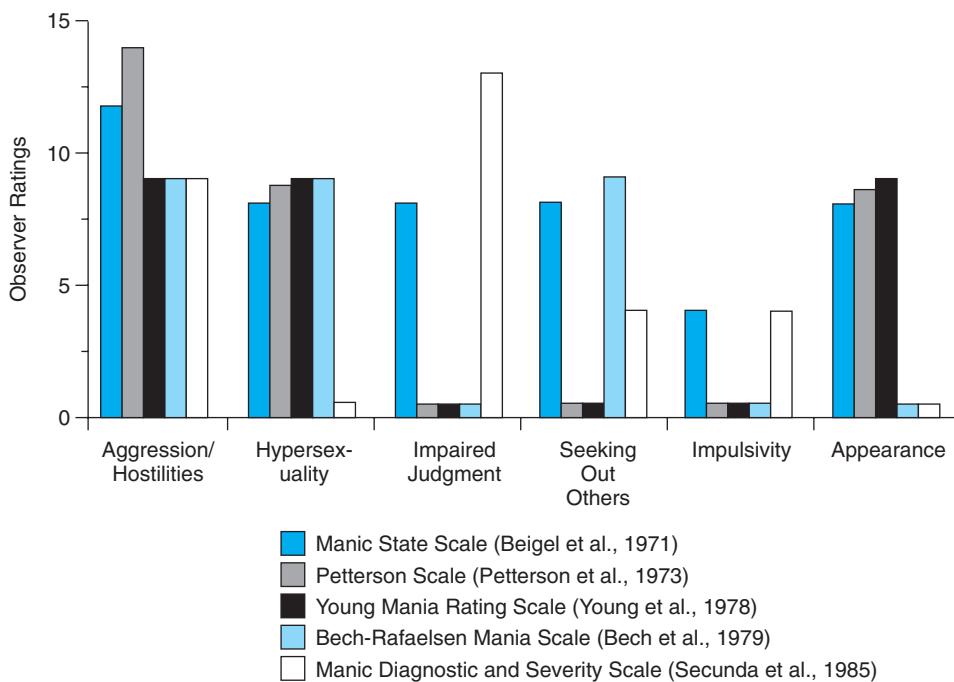

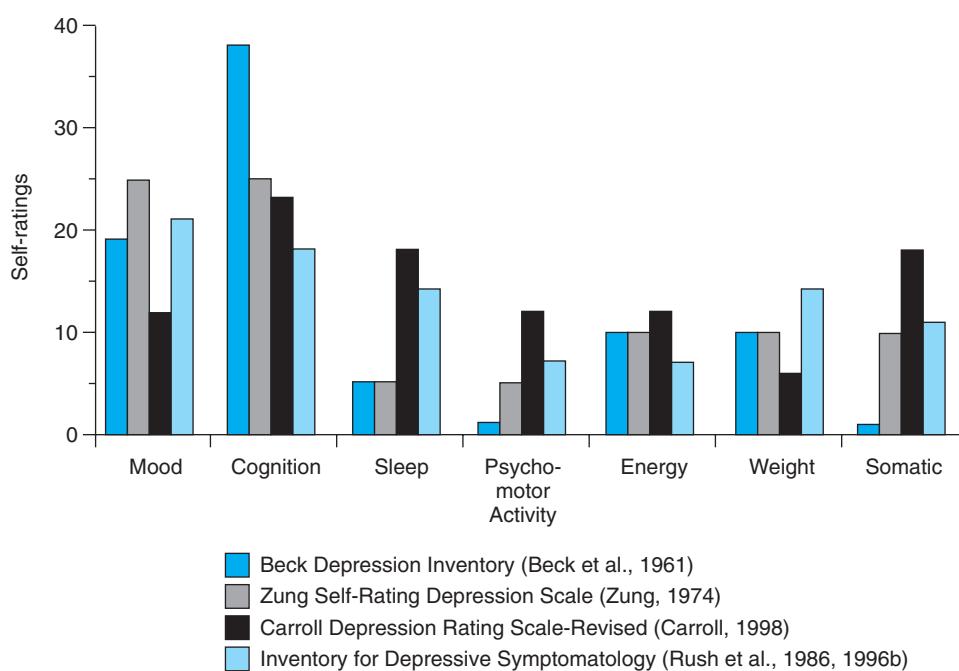

Figure 11–3. Relative weighting of item content for behavior items: Observer rating measures of mania.

Figure 11–4. Relative weighting of item content: Self-rating measures of depression.

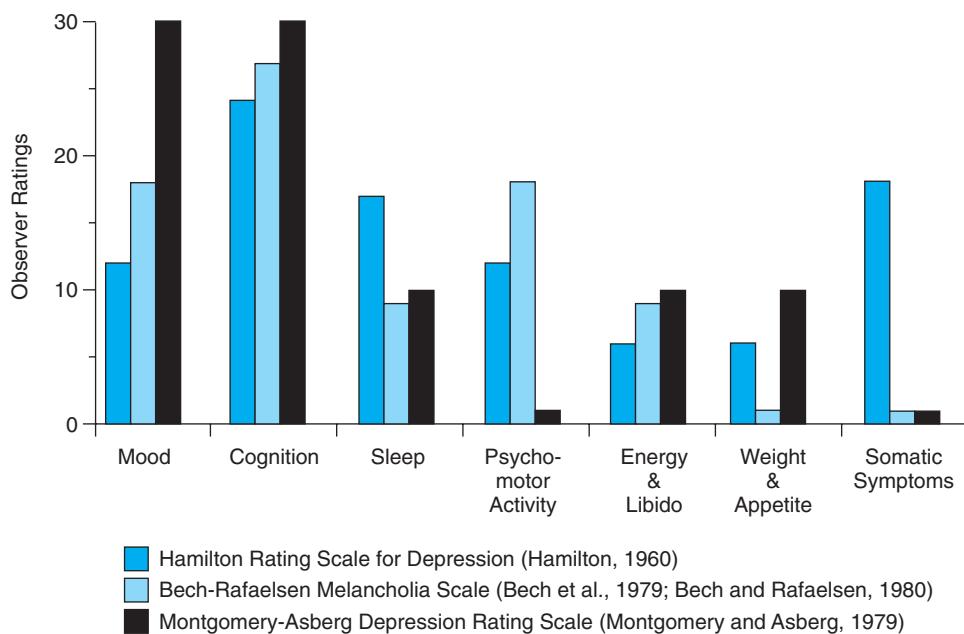

Figure 11–5. Relative weighting of item content: Observer-rating measures of depression.

or observer rating scales with the exception of work activities and interests, which together make up 7 percent of the total self-rating and 6 percent of the total observer rating items (all of the latter are on the HAM-D). As in the assessment of mania, the choice of instruments for assessment of depression depends on the patient population being evaluated, the level of interviewer training required, and the nature of the clinical or research issue being addressed. It is often useful to combine a self-rating with an observer rating measure.

COMBINED ASSESSMENT OF MANIC AND DEPRESSIVE STATES

A single rating scale that measures depression and mania along one continuum creates both theoretical and practical difficulties because it implies that depression and mania are opposite states—an assumption clearly contrary to what is known about the nature and expression of bipolar disorder (see Chapter 2). Monopolar scales (e.g., Bech, 1981) also generally preclude the measurement of mixed and transition states, rapid-cycling states, and diurnal or other cyclic variations in mood, behavior, and activity. A combination of individual measures of depression and mania or other combined measures, such as those discussed later, can be used to mitigate these problems.

Visual Analogue Scales

In their most commonly administered form, visual analogue scales (Hayes and Patterson, 1921; Zealley and

Aitken, 1969) are composed of a 100-mm line anchored at either end with opposite descriptors (e.g., “Worst I have ever felt” and “Best I have ever felt”). The patient is asked to place a mark or line across the point on the scale that best characterizes his or her mental state. Ratings are made frequently, typically once or twice a day, a characteristic that makes visual analogue scales especially appropriate for longitudinal studies of mood and treatment effects. Further advantages include the rapidity of assessment, economic feasibility, involvement of patients in their research and treatment protocols, a relative lack of cultural and educational bias, and good reliability and validity (Zealley and Aitken, 1969; Folstein and Luria, 1973; Luria, 1975). The simplicity of the test makes it ideal for depressed patients who are very ill or indecisive.

Moderately high correlations exist between visual analogue scales and the Zung SDS, the HAM-D, and global ratings by psychiatrists (Folstein and Luria, 1973; Luria, 1975), although correlations with clinical judgment tend to decrease after acute treatment (Zealley and Aitken, 1969). Moreover, such scales are not sensitive at lower levels of depression and other types of psychopathology. The most important limitation of the simple versions of these scales is that they are global measures not designed to assess specific psychopathological states or symptoms. As noted previously, however, Ahearn and Carroll’s bipolar scales use the VAS format for self-report across a variety of symptoms (e.g., Akiskal et al., 2001).

A more recent application of the VAS format, involving development and rescaling of the Internal State Scale (ISS),

was reported by Bauer and colleagues (2000). The 15-item self-report covers items from subscales called “activation,” “well-being,” a “depression index,” and “perceived conflict,” measuring patients’ subjective impressions of mood states. In a Veterans Affairs medical center study of bipolar patients, scores on the subscales were able to identify and distinguish among groups that were euthymic, manic/hypomanic, mixed, and depressed. Glick and colleagues (2003) recently developed a Likert-based scoring system that they believe is easier to use than the VAS method and results in characteristics similar to those of the original ISS. With respect to its use for self-rating of mania, however, Altman and colleagues (2001) found that the ISS well-being scale was not sensitive to treatment effects in manic inpatients, although the activation scale did show significant changes from pre- to post-treatment. Most important, the ISS had relatively poor sensitivity, detecting only 45 percent of patients with moderate or severe symptomatology at baseline.

Affective Disorder Rating Scale

The ADRS (Murphy et al., 1982) comprises 34 specific items assessing mania and depression, using a 6-point scale for the frequency and intensity of the behavior and global ratings (on a 15-point scale) of mania, depression, psychosis, anxiety, and anger. For the global ratings, specific guidelines for assigning scores are provided. For example, in the mild range (within normal limits), scores of 2 or 3 on the mania scale reflect “especially talkative, active, enthusiastic, gregarious or boisterous behavior,” while at the extreme end of the scale, scores of 13 to 15 reflect “nearly continuous manic activity and other symptoms, with uncontrolled, impulsive behavior requiring close supervision and often seclusion for the majority of the day.” Although preliminary psychometric data suggest good convergent validation with other scales of depressive and manic symptoms, little information exists about the properties and use of this instrument.

Comprehensive Psychopathological Rating Scale

The Comprehensive Psychopathological Rating Scale (CPRS) was developed in 1971 by the Swedish Medical Research Council to measure treatment effects (Asberg et al., 1978). Four scale steps, each described in detail, are allocated for each item. The scale, designed for use by all trained mental health workers, can be used to assess both reported and observed behaviors. Items include elevated and sad mood states, indecision, lassitude, fatigability, concentration difficulties, reduced or increased sexual interest, ideas of grandeur, and ecstatic experiences. Reliability studies among depressed patients in the United Kingdom (Montgomery et al., 1978a) and among cross-cultural populations

of Swedish and British depressed patients (Montgomery et al., 1978b) indicated that the CPRS is “highly reliable and highly sensitive [and] easily communicable” (Perris, 1979).

ASSESSMENT OF BIPOLAR RISK AND SCREENING INSTRUMENTS

Risk for Bipolar Disorder

There is considerable interest in detecting risk for bipolar disorder. The aim is to enable early intervention to alter the course of the illness and prevent the severe psychosocial consequences of the disruption of normal social development typically associated with the disorder. Several such instruments have been developed for use in research studies.

General Behavior Inventory

The General Behavior Inventory (GBI), a self-report inventory for nonpatients, was developed to identify individuals at high risk for developing bipolar disorder, particularly adolescents and young adults (Depue et al., 1981). Five dimensions of bipolarity are defined as characterizing the disorder: its core behaviors and symptoms; their intensity, frequency, and duration; and rapid shifts in mood and behavior. Sample questions (taken from a longitudinal mood-rating study), with their extreme polar descriptors, are presented in Table 11–2. Each item is rated on a four-point frequency scale.

The GBI, uniquely designed to measure subsyndromal variants of bipolar disorder (see Chapter 1), was validated in an initial series of studies through interview-derived diagnoses, interviews with college roommates, family histories of affective illness, clinical characteristics, and longitudinal mood-rating investigations (Depue et al., 1981). The GBI was originally viewed as a measure of subsyndromal cyclothymia or prodromal signs of bipolarity. Klein and colleagues (1986) predicted that it would identify youths at risk for bipolar disorder in a sample of offspring of bipolar-I parents; they found that half of the offspring had significant cyclothymic features identified by the GBI. The authors noted that offspring with cyclothymic features had significantly poorer social adjustment relative to noncyclothymic offspring and children of control parents. A follow-up study of 45 college students identified by the GBI as being at risk for bipolar disorder was conducted 19 months later (Klein and Depue, 1984); the investigators found that high scorers continued to exhibit significant impairment of functioning. Two patients had been hospitalized for major depressive episodes, and overall, the group reported higher suicidal ideation and treatment seeking.

TABLE 11–2. Sample Items from the General Behavior Inventory

Question Content	Extreme Polar Descriptions
Stimulus-seeking/excitement (receptivity toward and stimulation by the world)	<ul style="list-style-type: none"> Passionately absorbed in the world's excitement; my sensations and feelings incredibly intensified; I seek out novel stimulations. Life is too much trouble; sick of everything.
Flight of ideas/thought retardation (thought processes)	<ul style="list-style-type: none"> Brilliant penetrating ideas emerging spontaneously and with great rapidity. My mind is cold, dead; nothing moves.
Decisiveness/doubt	<ul style="list-style-type: none"> Supremely confident in my judgment and strength of mind; I can instantly see problems which confuse others and solve them. Utterly immobile, frozen by doubts; nothing is certain or solid for me.

Source: Depue et al., 1981. Reprinted with permission from the *American Journal of Psychiatry*. Copyright 1981, American Psychiatric Association.

Noting that the GBI appeared to identify those at risk for unipolar as well as bipolar depressive conditions, Depue and colleagues (1989) subsequently revised the GBI specifically to identify subgroups of unipolar (46 items) and bipolar (hypomanic/biphasic, 26 items) affective conditions. They reported that in a university sample, high scorers for the two conditions were identified and diagnosed by blind interviewers. The GBI's unipolar and bipolar scales showed adequate sensitivity (.78 and .76, respectively) and high specificity (.99 for both) for research use in nonclinical samples.

Hypomanic Personality Scale

Eckblad and Chapman (1986) developed the Hypomanic Personality Scale (HPS), a self-report scale for use in identifying those with gregarious and overactive behavior styles characteristic of episodes of hypomanic euphoria and hypothesized to indicate potential risk for developing bipolar disorder. The scale consists of 48 true-false items, such as "Sometimes ideas and insights come to me so fast that I cannot express them all" and "I would rather be an ordinary success in life than a spectacular failure" (scored in hypomania direction if false-rated). Internal consistency and test-retest reliabilities were shown to be high among a student population. The scale was validated among a university population against standardized diagnostic assessments; high scorers were significantly more likely to have experienced hypomanic episodes and depressive symptoms, drug and alcohol use, and psychotic-like symptoms. A longitudinal study of 36 high scorers on the HPS and 31 controls followed the groups for 13 years (Kwapil et al.,

2000). As predicted, significantly more high scorers than controls developed bipolar disorder (25 percent versus none) and experienced major depressive episodes (28 versus 19 percent); this was the case in particular for those who also scored high on the impulsive-nonconformity scale (Chapman et al., 1984). High scorers also had more severe psychotic-like symptoms, borderline personality disorder symptoms, and substance abuse disorders relative to the controls. A more recent study of 224 German university students found that the HPS was more effective in ascertaining individuals with a history of hypomanic or manic episodes than those with a history of depressive episodes (Meyer and Hautzinger, 2003).

An abbreviated version of the HPS was included in the Oregon Adolescent Depression Project (Klein et al., 1996), where it was found to be predictive of a wide range of psychosocial impairments; mood, disruptive, and substance abuse disorders; and suicide attempts. Among youths with a history of depressive disorders, the HPS appeared to predict for high scorers significantly more severe symptoms of depression and worse functional outcomes. Hofmann and Meyer (2006) studied three groups of young adults with high ($n=17$), medium ($n=19$), and low ($n=18$) scores on the Hypomanic Personality Scale. Those at elevated risk for bipolar disorder reported greater mood instability, as well as higher levels of both positive and negative affect. Although the sample has not yet been followed long enough to validate use of the HPS as a predictor of bipolar disorder, the scale appears to be valid for predicting mood and behavioral dysfunction that is potentially indicative of the disorder.

More recently, researchers have developed measures to assess bipolar spectrum disorder on the assumption that categorical measures are intrinsically limiting. These assessment systems—the Bipolar Affective Disorder Dimension Scale (Craddock et al., 2004) and the Bipolar Spectrum Diagnostic Scale (Ghaemi et al., 2005)—are promising but need further validation and replication. Also promising but preliminary are measures developed to assess dysfunctional beliefs that may predispose to bipolar disorder (Mansell and Jones, 2006) and positive self-dispositional appraisals linked to both hypomanic personality and bipolar disorder (Jones et al., 2006). Measures of temperament, beyond the scope of this chapter, have been studied by many groups¹ (see Chapter 10).

Screening for Bipolar Disorder

Noting that many cases of bipolar spectrum disorder may go undetected and undiagnosed, Hirschfeld and colleagues (2000, 2002) developed the Mood Disorder Questionnaire (MDQ), a brief self-report screening instrument for use in primary care, community agency, and psychiatric settings (Table 11-3). Based on DSM-IV criteria, it contains 13 yes–no items, as well as 2 additional questions designed to verify whether symptoms occurred during the same time period and caused significant problems. The questionnaire originated with a sample of 198 patients from five outpatient mood disorders clinics, who were then interviewed by telephone using the SCID for bipolar-I, bipolar-II, and bipolar—not otherwise specified (NOS) disorders. Using a threshold of seven or more yes responses, along with an indication that the symptoms occurred during the same time period and caused moderate or severe problems, the sensitivity was .73 and the specificity .90. This suggests a basis for the instrument's use in psychiatric settings, but how useful it will prove to be in general medical or community settings (where screening instruments should have the most utility) remains to be seen. When the same investigators conducted a population-based replication study, for example, the sensitivity of the MDQ (identification of true positive cases) was found to be .28, much lower than that found in the original study (Hirschfeld et al., 2003b). A recent study of 1,157 patients at a general medicine clinic found that although the specificity of the MDQ was lower than found in mood disorders clinics, the measure was helpful in identifying bipolar patients who would not otherwise have been recognized (Das et al., 2005). On the other hand, in a review of studies of screening instruments, Phelps and Ghaemi (2006) concluded that where there is likely to be a low prevalence of bipolar disorder, such as in community or primary care settings, screening measures such as the MDQ can rule out bipolarity but do not effectively rule it in.

As discussed, Hirschfeld's group reported on a population-based replication study in which the sensitivity of the MDQ was found to be much lower than that found in the original study (Hirschfeld et al., 2003b). Replication and further validation studies are well-warranted in view of the overlap of bipolar symptoms with those of other mood, substance, and behavioral disorders.

Despite ongoing concerns about its utility outside of mood disorders clinics, the MDQ has been widely disseminated, appearing in psychiatric publications and on Web sites, in the hope that it can facilitate the identification and treatment of bipolar disorder. It was tested in a French population of bipolar patients, with the investigators finding much greater sensitivity in bipolar-I than in bipolar-II patients (90 and 52 percent, respectively) (Rouget et al., 2005). It also served as the basis for an epidemiologic survey of bipolar spectrum disorder (see Chapter 5) (Hirschfeld et al., 2003a). But given the evidence to date that the MDQ appears to be insufficiently accurate to be used as a case-finding measure in community studies or as a screening scale in clinical practice, further research and refinement of the instrument are needed (Zimmerman et al., 2004b). Given that many bipolar patients lack insight into the hypomanic and manic phases of their illness, one helpful refinement might be a version of the instrument that could be filled out by family members. We recommend that the MDQ, while promising, be viewed with some skepticism until further validation and replication studies have been completed.

A somewhat similar scale, the Manic Depressiveness Scale, was documented by Thalbourne and colleagues (1994). The 19-item questionnaire, assessing manic and depressive experiences, was administered to normal college students and to a sample of bipolar patients. Despite significant mean differences between the groups and relatively good internal consistency and reliability, however, the scale showed overlapping distributions between the two populations, apparently precluding its use to identify bipolar disorder among nonpatient samples. A later revision (9 manic experience items and 9 depressive experience items) was found to correlate with severity of illness and number of hospitalizations for bipolar patients, but not for unipolar depressed patients (Thalbourne and Bassett, 1998).

Recently, Solomon and colleagues (2006) reported the development of a brief instrument to screen for bipolar disorder in patients acutely ill with major depression. The Screening Assessment of Depression-Polarity (SAD-P) consists of 3 items demonstrating the greatest disparity between bipolar-I and unipolar depression: presence of delusions during the current episode of major depression, number of prior episodes of major depression, and family

TABLE 11–3. Sample Items from the Mood Disorder Questionnaire

Question	Response	
1. Has there ever been a period of time when you were not your usual self and . . .	<input type="radio"/> yes	<input type="radio"/> no
• you felt so good or so hyper that other people thought you were not your normal self or you were so hyper that you got into trouble?	<input type="radio"/> yes	<input type="radio"/> no
• you were so irritable that you shouted at people or started fights or arguments?	<input type="radio"/> yes	<input type="radio"/> no
• you felt much more self-confident than usual?	<input type="radio"/> yes	<input type="radio"/> no
• you got much less sleep than usual and found you didn't really miss it?	<input type="radio"/> yes	<input type="radio"/> no
• you were much more talkative or spoke much faster than usual?	<input type="radio"/> yes	<input type="radio"/> no
• thoughts raced through your mind or you couldn't slow your mind down?	<input type="radio"/> yes	<input type="radio"/> no
• you were so easily distracted by things around you that you had trouble concentrating or staying on track?	<input type="radio"/> yes	<input type="radio"/> no
• you had much more energy than usual?	<input type="radio"/> yes	<input type="radio"/> no
• you were much more active or did many more things than usual?	<input type="radio"/> yes	<input type="radio"/> no
• you were much more social or outgoing than usual; for example, you telephoned friends in the middle of the night?	<input type="radio"/> yes	<input type="radio"/> no
• you were much more interested in sex than usual?	<input type="radio"/> yes	<input type="radio"/> no
• you did things that were unusual for you or that other people might have thought were excessive, foolish, or risky?	<input type="radio"/> yes	<input type="radio"/> no
• spending money got you or your family into trouble?	<input type="radio"/> yes	<input type="radio"/> no
2. If you checked YES to more than one of the above, have several of these ever happened during the same period of time?	<input type="radio"/> yes	<input type="radio"/> no
3. How much of a problem did any of these cause you—like being unable to work; having family, money, or legal troubles; getting into arguments or fights?		
• No problem		
• Minor problem		
• Moderate problem		
• Serious problem

history of major depression or mania. The investigators found that the screening instrument was easy to use and, in a cross-validation sample, correctly identified a substantial proportion of subjects with bipolar or unipolar illness (bipolar major depression was identified in the bipolar-I index sample with a sensitivity of 0.82 and in the cross-validation sample with a sensitivity of 0.72).

Screening for Bipolar Spectrum Disorders in Youths

As noted previously, the GBI (Depue et al., 1981) was initially developed for use with college-age young adults. Recently, it has been used in younger samples. A study of clinically diagnosed children and adolescents, for instance, found that both youth- and parent-reported symptoms on

the bipolar scale of the GBI were sensitive to the detection of actual bipolar disorder (Youngstrom et al., 2001; Findling et al., 2002). Results of various studies suggest that a cutoff score of 13 and higher for adults, and of 17 and higher for children and adolescents may be useful in screening for bipolar spectrum disorder or risk. Reichart and colleagues (2005) in the Netherlands used the GBI to assess psychopathology among 129 adolescent and young adult children of a bipolar parent over a 5-year follow-up period. They found that the depression scale of the GBI discriminated well between the development of new bipolar disorder and no disorder or unipolar disorder.

Also as noted previously, a version of the HPS (Eckblad and Chapman, 1986) was used in the Oregon Adolescent Depression Project (Klein et al., 1996), where it identified youths with clinical features and functional impairment who may have been in the bipolar spectrum. Further research is needed, however, to validate diagnostic status over time.

CHARTING THE COURSE OF BIPOLAR DISORDER

Because bipolar disorder is recurrent by definition, it is essential to have methods for capturing the phenomenology of the course of the illness to supplement methods used to characterize individual episodes. Indeed, Kraepelin (1921) used life charts with many of his patients and, from the study of these charts, made critical observations about the course of manic-depressive illness. Figure 11-6 is a case history used by Kraepelin to illustrate periodic mania with isolated episodes of depression. Such procedures yield charts of the past or recent history of changes in the illness, permitting examination of both clinical and research issues based on details of

those patterns. There are several methods for systematically assessing—either retrospectively or prospectively—the details of the topology and course of bipolar disorder.

Longitudinal Interval Follow-Up Evaluation

The contribution of the Longitudinal Interval Follow-up Evaluation (LIFE) to characterization of the course of bipolar disorder is noted only briefly here because this method is a procedure widely used for all DSM-related disorders. Developed by Keller and colleagues (1987), it is a semistructured interview procedure whose purpose is to provide a continual (e.g., weekly) charting of symptomatology, psychosocial functioning, and treatment based on regular follow-up evaluations. Severity of psychopathology is rated on a six-point Psychiatric Status Rating (PSR) scale tied to Research Diagnostic Criteria symptoms; several areas of psychosocial functioning (e.g., employment, relationships with family members) are also rated on five- or seven-point scales. The PSR scale and psychosocial ratings have been shown to have high interrater reliability (e.g., Keller et al., 1987). The LIFE charts provide an excellent basis for characterizing landmark clinical events, such as time to recovery or duration of episodes. The LIFE methods are widely used, especially in research on unipolar depression, as in the NIMH Collaborative Program on the Psychobiology of Depression-Clinical Studies (e.g., Judd et al., 2000; Solomon et al., 2000); they are also used to study anxiety disorders (e.g., Warshaw et al., 1994).

Life Chart Method

The Life Chart Method (LCM) was designed as a brief, easily administered, and flexible approach for mapping the course

Figure 11–6. Relapsing mania with isolated periods of depression. Light blue = depression; dark blue = manic excitement. (Source: Kraepelin, 1921, p. 143) Reprinted with permission.

The figure is a horizontal timeline visualization. It features a grid of 12 columns, each representing a month from January to December. The first column is labeled 'Alter' (Age). A vertical blue bar spans the entire height of the grid, starting from the 'Januar' column and ending at the 'Dez' column. This bar is divided into several segments of different widths, representing the duration of specific events. The segments are: Januar (wide), Febr (narrow), Marz (wide), April (narrow), Mai (wide), Juni (narrow), Juli (wide), August (narrow), Sept (wide), Okt (narrow), Nov (wide), and Dez (narrow). The year '1840' is printed vertically along the left side of the grid.

of bipolar disorder. In the original development of the approach, Post and colleagues (e.g., Squillace et al., 1984; Roy-Byrne et al., 1985) identified several goals for such a methodology: to systematize retrospective clinical history data; to capture meaningful episodes that might be missed because of incomplete memory; and, of course, to provide detailed phenomenological and descriptive information about the clinical course of mood disorders. The methodology bases the definition of an episode on functional impairment rather than symptomatic criteria, on the assumption that the former information is recalled more readily than whether a particular symptom occurred during a given time frame. Moreover, definitions based on functional impairment may capture a more detailed picture of variations in mood than can definitions based on strict adherence to DSM criteria. Accordingly, manic and depressive episodes are each measured on a three-point scale: mild, with only subjective distress and no or minimal functional impairment; moderate, with clear impairment in functioning in usual roles; and severe, involving incapacitation or resulting in hospitalization. Manic episodes are defined by any level of severity, and depressive episodes by moderate or severe ratings. The investigators noted that subjective reports were supplemented by the observations of others, especially for mild mania, a state often overlooked or denied by patients themselves.

The LCM has the advantage that it can be applied flexibly, so that different studies or contexts may involve different duration criteria (e.g., Kramlinger and Post, 1996; Denicoff et al., 1997), may be prospective or retrospective (or both), and may include staff ratings as well as patient reports. Denicoff and colleagues (1997) presented reliability and validity data on a prospective version of the LCM, developed during 2 years of a clinical trial on bipolar-I and -II outpatients. Daily ratings of mood severity based on functional impairment were provided by patients, supplemented by information from other sources (including spouses). Interrater reliabilities were very high. Validity was supported by significant associations with both self- and clinician-rated mood measures that included the BDI, YMRS, HAM-D, and GAS.

It may be noted that daily administration of the LCM using a palmtop handheld device is under investigation. Initial feasibility data indicate that this approach is useful and might greatly facilitate frequent monitoring of mood states and psychosocial functioning (Scharer et al., 2002). In a related development, Whybrow and colleagues (2003) devised the ChronoRecord, software patients can use on their home computers to record mood, sleep, life events, and medication intake. They found that 83 percent of the 96 patients they studied expressed high acceptance of the computer format.

Average Mood Symptom Score

The Average Mood Symptom Score (AMSS) is a somewhat similar method of prospective charting of mood patterns, adapted from the LCM (Gitlin et al., 1995). Hammen and colleagues (1989) first reported use of the procedure as a method for characterizing the timing and features of changes in symptoms of unipolar depression and bipolar disorder in relation to stressful life events. The goal is to systematize the severity and duration of mood states over time during ongoing follow-up. To this end, clinicians' chart notes of clinical status and dates of changes are translated into a time line, with dates on the horizontal axis and a vertical axis indicating nine levels of severity of mania or depression (where the zero midpoint is euthymia). Based on DSM criteria, manic states are rated as M₁ (only one or two symptoms) through M₄ (severe, hospitalized mania) above the zero point, or D₁ (only one or two symptoms) through D₄ (severe major depressive episode involving hospitalization or suicide attempt) below the zero point; mixed states can also be indicated. Figure 11-7 presents an example.

In addition to time lines that can be used to identify dates of onset or significant changes in severity or polarity of symptoms, the method yields a quantitative score of symptomatology per unit of time. A total mood score for a defined period may be calculated as level of symptoms multiplied by duration in days; the AMSS is the total mood score divided by days in the period of interest. A series of studies has employed such methods in samples of both unipolar and bipolar patients to characterize course of illness in relation to psychosocial factors, such as role functioning and episodic stressful life events (Ellicott et al., 1990; Hammen et al., 1992, 2000).

ASSESSMENT OF PSYCHOSOCIAL ADJUSTMENT

There has been increasing emphasis on the need for characterization of psychiatric patients' functional outcomes as a critical supplement to the relatively exclusive focus on clinical status. As Weissman (1997) noted, since the 1960s there has been a growing appreciation that for all disorders, it is necessary to understand individuals in their social contexts because family, social, and occupational adjustment all have an impact on clinical course. Moreover, social role functioning is a crucial marker by which individuals, their families, and the community at large judge the success of treatment in general and the effectiveness of specific interventions. Further impetus for studying functional outcomes in bipolar populations comes from the commonly noted discrepancy between clinical state and role functioning among people with mood disorders. For instance, many individuals who have recovered from

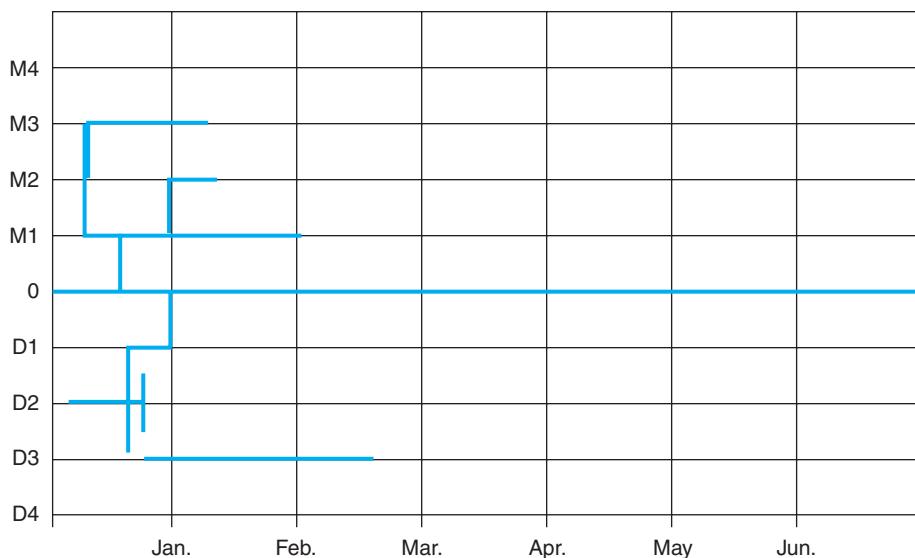

Figure 11–7. Example of time line for characterizing the timing and features of changes in symptoms of unipolar depression and bipolar disorder (see text for explanation).

episodes or have not experienced recurrences nonetheless display functional impairment,² especially in family and work adjustment. Maladjustment in important roles, moreover, may contribute—presumably as a stressor—to further clinical episodes and debility. Consequently, interest in the measurement of functioning in major roles and the use of such data to evaluate treatment outcomes has grown. In this section, we briefly review some of the methods used for these purposes and the resultant findings, noting that such issues are by no means specific to bipolar illness.

Unfortunately, actual progress in mapping social adjustment among those with mood disorders has been relatively limited, owing to the complexity of the constructs involved and the resulting problems in collecting reliable and valid information in relevant areas. The widely used GAS or its variant, the Global Assessment of Functioning (GAF) scale, employed as Axis V of DSM-IV, has been criticized for confounding clinical symptoms and psychosocial functioning (Williams, 2000). The single-item GAS and GAF scales provide no specificity in ratings for different areas of functioning. Similarly, the Clinical Global Impressions Scale for Bipolar Illness (CGI-BP) (Spearing et al., 1997), while providing clinician judgments specifically of illness severity and changes in mania, depression, and overall bipolar illness, does not yield information about functioning and changes in particular roles. Similar concerns may arise with regard to many “quality-of-life” scales, which provide general information about the adverse effects of clinical and medical states but less information about particular areas of discomfort (e.g., Vojta et al., 2001).

Weissman and colleagues (1981) reviewed a number of scales that specifically address social functioning and found

their quality and utility to be relatively poor. Thus although many such scales exist, few have provided the utility and psychometric qualities necessary for their survival (see Williams, 2000).

Currently, three patient-report scales are used relatively widely in research on quality-of-life issues for those with mood disorders. The Social Adjustment Scale-Self Report (SAS-SR) (Weissman and Bothwell, 1976; Weissman et al., 1978) assesses instrumental and emotional role functioning in six areas: work, social and leisure, marital-sexual, relationships with extended family, parenting, and family unit. It includes a total of 54 items and yields both subscale and overall adjustment scores. An example is the following:

How have you been getting along with the children during the last 2 weeks?

1. I had no arguments and got along very well.
2. I usually got along well but had minor arguments.
3. I had more than one argument.
4. I had many arguments.
5. I was constantly in arguments.

The SAS-SR has been shown to have excellent reliability and validity (reviewed by Williams, 2000). The initially developed clinician-rated version of the SAS employs a semi-structured interview format and is especially suitable for use when there is concern that patients’ mood status may distort their responses and perceptions.

The Social Adaptation Self-Evaluation Scale (SASS) (Bosc et al., 1997) was developed for use in clinical trials. It contains 21 self-report items covering current functioning in various psychosocial domains. As noted by Weissman (1997), its content emphasizes subjective aspects of

functioning, including motivation and self-perception, drive, and mastery, but focuses less on role performance. Instrumental functioning, such as work behavior and family and parental role functioning, is not specifically included. However, to the extent that the scale taps interest and enjoyment in functional roles, it adds an important dimension beyond clinical status.

The Short-Form Health Survey (SF-36) (Ware and Sherbourne, 1992) of the MOS includes several items specific to role functioning, such as loss of work functioning due to medical or depressive conditions. Data from the MOS have provided an important comparison between people with depressive conditions and those experiencing a variety of major medical syndromes (e.g., Wells et al., 1989; Hays, 1995). However, what is measured is largely global functioning, and the self-report format makes it difficult to disentangle actual psychosocial behavior and adjustment from depressive mood state.

Clinician-rated social adjustment scales include the Weissman Social Adjustment Scale (the precursor to the SAS-SR) and the social functioning scales of the LIFE method discussed previously (e.g., Keller et al., 1987). Both scales have solid psychometric properties but generally lack sufficient behavioral detail to fully characterize functioning in specific domains, such as work, parenting, and marital life.

ASSESSMENT OF BIPOLAR SYMPTOMS IN CHILDREN AND ADOLESCENTS

Measurement of Mania

As noted in Chapter 6, there is considerable controversy regarding the diagnosis of mania and manic symptoms in children (see also Chapter 3). The NIMH Bipolar Child Roundtable (2001) recommended the use of well-established interview diagnostic procedures for this purpose. One such instrument is the Kiddie Schedule for Affective Disorders and Schizophrenia (KSADS), specifically the Washington University version (WASH-U-KSADS), which contains items developed to assess childhood mania and other syndromes, including onset and offset of individual items and syndromes for current and lifetime disorders. Geller and colleagues (2001) reported excellent interrater reliability, including high kappa values between expert observers and off-site blind evaluators on ratings of mania and rapid cycling. At this time, the majority of NIMH-funded studies of bipolar disorder in children use the WASH-U-KSADS sections on mania and rapid cycling.

There is obviously a long way to go in developing an array of measures of mania symptoms in children that will parallel those available for adults. Considerable work is still

needed to assess individual manic symptoms in children validly and reliably; to establish developmentally appropriate indicators; and to distinguish them from those of other disorders, such as attention-deficit hyperactivity disorder (ADHD). For instance, it is necessary to address symptoms that occur in bipolar children but not in those with ADHD, including hypersexuality and grandiosity, while also distinguishing overlapping symptoms, such as distractibility and hyperactivity. Parents of 268 subjects (93 with a prepubertal or early-adolescent form of bipolar disorder, 81 with ADHD, and 94 healthy controls) completed the 10-item Conners' Abbreviated Parent Questionnaire before the WASH-U-KSADS was administered (Tillman and Geller, 2005). The results are shown in Table 11-4. Items 7, 8, 9, and 10 significantly distinguished between those children and adolescents with bipolar illness and those with ADHD. The authors concluded that the Conners' Abbreviated Parent Questionnaire (sensitivity = 0.73, specificity = 0.86) is a promising tool as a screen for early- and adolescent-onset bipolar disorder. The NIMH Research Roundtable on Prepubertal Bipolar Disorder (2001) recommended that researchers develop operational criteria for frequency and severity of various behaviors and symptoms potentially relevant to juvenile mania and the co-occurring disruptive behavior disorders and impairing symptoms.

To date, little information exists on the use of adult rating scales for manic symptoms with children. Gracious and colleagues (2002) reported on a parent-completed version of the YMRS, noting that it discriminated well among diagnostic groups aged 5 to 17, including those with ADHD. They found good psychometric properties for an eight-item version (eliminating three items, such as sexual interest, that did not contribute to the total scores) (see also Youngstrom et al., 2002, 2003). The agreement between the reports of children and adolescents and those of parents is problematic, however. Children, for example, are more likely than parents to report racing thoughts and decreased need for sleep (Tillman et al., 2004), and adolescents with bipolar disorder tend to underreport manic symptoms (Youngstrom et al., 2004).

Measurement of Depression

The assessment of depressive symptoms and syndromes in children and adolescents has been well described elsewhere (e.g., Nezu et al., 2000). In general, self-report questionnaires about symptoms and diagnostic interviews can be administered reliably and yield valid conclusions about symptom severity and the presence of depressive disorders. For example, a Children's Depression Inventory (CDI) was developed by Kovacs (1981); it has a three-response options format with content appropriate for those aged 7 to 17. The BDI, discussed earlier, is suitable for most patients aged 13 and older.

TABLE 11-4. Scores on Items of the Conners' Abbreviated Parent Questionnaire for Subjects with a Prepubertal and Early Adolescent Bipolar Disorder (BP) Phenotype, Subjects with Attention-Deficit Hyperactivity Disorder (ADHD), and Healthy Comparison Subjects

Questionnaire Item	SUBJECTS WITH A BP PHENOTYPE (n=92)		SUBJECTS WITH ADHD (n=80)		HEALTHY COMPARISON SUBJECTS (n=92)	
	Mean	Std. Dev.	Mean	Std. Dev.	Mean	Std. Dev.
1. Restless or overactive	2.9 ^a	0.9	3.0 ^a	0.8	1.2	0.5
2. Excitable, impulsive	3.2 ^a	0.8	3.1 ^a	0.8	1.3	0.5
3. Disturbs other children	2.7 ^a	1.0	2.5 ^a	0.8	1.1	0.3
4. Fails to finish things he or she starts—short attention span	2.9 ^a	1.0	2.9 ^a	0.9	1.2	0.4
5. Constantly fidgeting	2.7 ^a	1.0	3.1 ^a	0.8	1.2	0.4
6. Inattentive, easily distracted	3.2 ^a	0.9	3.3 ^a	0.7	1.2	0.4
7. Demands must be met immediately—easily frustrated	3.3 ^{a,b}	0.9	2.9 ^a	1.0	1.2	0.4
8. Cries often and easily	2.5 ^{a,c}	1.0	1.9 ^a	0.9	1.2	0.5
9. Mood changes quickly and drastically	3.2 ^{a,c}	0.9	2.3 ^a	1.0	1.2	0.4
10. Temper outbursts, explosive and unpredictable behavior	3.1 ^{a,c}	1.0	2.3 ^a	1.0	1.2	0.4

Note: See Tillman and Geller (2005) for a scoring algorithm and age-specific cutoffs for use of the Conners' Abbreviated Parent Questionnaire as a screening tool. Std. Dev. = standard deviation.

Two major issues are associated with assessment of depression in children. First, most diagnostic interview procedures assume that children's reports of their symptoms should be supplemented by information collected from caretakers. Most diagnostic methods for assessing depression, such as the clinician-administered KSADS (Ambrosini, 2000) or the Diagnostic Interview Schedule for Children (DISC), which is administered by trained laypersons (Shaffer et al., 2000), prescribe separate interviews for children and parents. KSADS commonly uses a "best clinical estimate" method, combining information from the child and the parent weighted by the type of information given, according to the clinician's judgment. For example, internal symptoms, such as depressed feelings and negative thoughts, cannot readily be detected by parents, and there-

fore the child's report on these symptoms might be given greater weight in a diagnosis of depression. The DISC is a highly structured interview, with a computer-based scoring algorithm often being used to combine information about diagnostic criteria.

A second, related issue concerns the relatively low agreement among informants (the child or adolescent, parents, and teachers). This problem occurs for all childhood disorders, not just depressive illnesses. It has been speculated, however, that reports of depression may be associated with systematic biases in the reports of certain informants. Specifically, some research has indicated that relatively depressed women may distort or exaggerate their children's behavior as more negative than it actually is. However, a review of 22 studies by Richters (1992) revealed that such

claims were based largely on inadequate designs, including simple associations between mothers' and children's symptoms that could be accurate given the common finding of disorders in offspring of depressed women. Subsequent studies using sophisticated methods, such as covariance structure analysis with latent variables formed from different informants, have supported the hypothesis that depressed mothers may report more negative behaviors. As these studies have shown, the fact that maternal depression truly is associated with more child disorder makes the conclusion of "bias" unclear (Fergusson et al., 1993; Boyle and Pickles, 1997). Other researchers who have evaluated parent-child concordance over time (Renouf and Kovacs, 1994; Boyle and Pickles, 1997) have suggested that maternal bias, if any, may be more pronounced for younger than for older children.

CONCLUSIONS

The status of assessment methods in bipolar disorder varies by topic:

- Diagnostic procedures, not specifically discussed in this chapter, are administered relatively reliably but are only as valid as our evolving conceptualization of bipolar disorder.
- Evaluation of states of depression has been a significant achievement in recent years, making use of a number of well-supported self-report and clinician-rated procedures that measure the presence and severity of various depressive symptoms. Instruments vary, however, in their coverage of particular symptoms.
- Measurement of states of mania is less well developed. The experience of manic symptoms interferes with obtaining valid self-reports by questionnaire, but even clinician-based measures are relatively sparse. Several self-report and clinician-rated instruments for measuring mania are currently available, but psychometric studies of their merits lag behind those used for depressive symptoms.
- There is a significant potential gap in measurement of particular symptoms or clusters. This gap is particularly pronounced in the assessment of mixed states. It might be anticipated that further developments in both conceptualization and instrumentation for specific symp-

toms would improve evaluation of the treatment of bipolar conditions (e.g., sleep disturbances, mixed states, cognitive–intellectual functioning).

- Several methods are for characterizing the course of bipolar disorder, based on symptom levels, episode status, and functional impairment. These methods of longitudinal or retrospective charting have proved valuable for understanding features of the course of the disorder, and potentially they can play an important role in treatment decision making.
- Preliminary steps have been taken to evaluate hypomanic personality, or risk for future bipolar disorder. Similarly, there have been some positive steps toward the development of screening instruments to help identify in nonclinical populations those who are at risk or have already experienced bipolar states.
- Initial steps have also been taken to describe functioning in important roles—areas of living that may be relatively independent of symptom levels. Further work is needed to provide scales that capture both objective features of how individuals live their lives and the contexts in which they struggle with their illness, as well as methods for capturing the motivations and perceptions of people with bipolar disorder.
- Research on the assessment of mania and manic symptoms in children is at a relatively preliminary stage. Diagnostic assessments require careful attention to clinical and course features, such as rapid cycling and mixed states, that differ between children and adults with bipolar disorder. There is a great need for developmentally appropriate indicators of symptoms, as well as for indicators that can distinguish among groups with overlapping disorders, such as ADHD.

NOTES

1. Many of these studies were reported in a special issue of the *Journal of Affective Disorders* in 2005: Akiskal et al., 2005a,b,c; Akiyama et al., 2005; Erfurth et al., 2005a,b; Matsumoto et al., 2005; Mendlowicz et al., 2005.
2. Paykel and Weissman, 1973; Harrow et al., 1990; Mintz et al., 1992; Gitlin et al., 1995.

[Edgar Allan Poe's alcoholism] was one of the methods by which he fought the intolerable morbidity of his manic-depressive state of mind . . . Had this been his only weapon to relieve the depressions that overtook him, he would, like thousands of others similarly affected, have lived his life unknown and gone unsung by posterity. But he had a second weapon—his pen.

—W. R. Bett (1952, pp. 74–75)

HISTORICAL BACKGROUND

The notion of a relationship between creativity and extremes in mood states is an ancient one, described in pre-Grecian myths and later by Plato and Socrates. Divine madness and inspiration were thought to be obtainable only during particular states of mind, such as loss of consciousness, affliction with illness, or fits of “possession.” In his speech on divine madness in *Phaedrus*, Socrates said:

Madness, provided it comes as the gift of heaven, is the channel by which we receive the greatest blessings . . . [T]he men of old who gave things their names saw no disgrace or reproach in madness; otherwise they would not have connected it with the name of the noblest of all arts, the art of discerning the future, and called it the manic art. (Plato, 1974, pp. 46–47)

He went on to discuss artistic “madness” in particular (p. 48): “If a man comes to the door of poetry untouched by the madness of the Muses, believing that technique alone will make him a good poet,” he proclaimed, “he and his sane compositions never reach perfection, but are utterly eclipsed by the performances of the inspired madman.”

Madness, as understood by Plato and Socrates, encompassed a wide range of states of thought and emotion, not just psychosis, but the emphasis was on a profoundly altered state of thinking, awareness, and feeling. Aristotle, writing in the 4th century BC, focused more specifically on the relationship among melancholia, madness, and inspiration. “Why is it,” he asked, “that all men who are outstanding in philosophy, poetry or the arts are melancholic?” This was true of Ajax and Bellerophon, he said: “The former went completely insane. . . . And many other heroes suffered in the same way as these. In later times also there have been

Empedocles, Plato, Socrates and many other well-known men. The same is true for most of those who have handled poetry” (1936, pp. 155–157).

The Renaissance saw a resurgence of interest in the relationship among genius, melancholy, and madness, but an important distinction was made between sane melancholics of high achievement and individuals whose insanity prevented them from using their gifts. The eighteenth century witnessed a sharp change in attitude, with rational thought seen as essential to genius, a view then sharply reversed by the nineteenth-century Romantics, who once again emphasized extremes in mood and experience as critical to artistic inspiration and expression. In 1812—the same year that Byron, the personification of Romantic, melancholic intensity, published *Childe Harold’s Pilgrimage*—physician Benjamin Rush, author of the first major psychiatric treatise in the United States, recorded his clinical observations about the relationship between acute manic and creative states (Rush, 1812, pp. 153–154):

From a part of the brain preternaturally elevated, but not diseased, the mind sometimes discovers not only unusual strength and acuteness, but certain talents it never exhibited before. . . . Talents for eloquence, poetry, music and painting, and uncommon ingenuity in several of the mechanical arts, are often involved in this state of madness. . . . The disease which thus evolves these new and wonderful talents and operations of the mind may be compared to an earthquake, which, by convulsing the upper strata of our globe, throws upon its surface precious and splendid fossils, the existence of which was unknown to the proprietors of the soil in which they were buried.

An ironic exception to the nineteenth-century writers who emphasized deep, mysterious, and irrational forces

giving rise to genius was the essayist Charles Lamb, himself institutionalized for what would now be called bipolar illness, and companion to a sister intermittently insane with the same illness. In *The Sanity of True Genius*, Lamb argued for a balance of faculties, much as the eighteenth-century writers had done (Lamb, 1987, pp. 212–213):

Far from the position holding true, that great wit (or genius, in our modern way of speaking), has a necessary alliance with insanity, the greatest wits, on the contrary, will ever be found in the sanest writers. It is impossible for the mind to conceive a mad Shakespeare. The greatness of wit, by which the poetic talent is here chiefly to be understood, manifests itself in the admirable balance of all faculties. Madness is the disproportionate straining or excess of any one of them. . . . The ground of the mistake is, that men, finding in the raptures of the higher poetry a condition of exaltation, to which they have no parallel in their own experience, besides the spurious resemblance of it in dreams and fevers, impute a state of dreaminess and fever to the poet. But the true poet dreams being awake. He is not possessed by his subject, but has dominion over it.

The late nineteenth and early twentieth centuries saw a moderation of earlier Romantic views, due in part to the inevitable swing from any extreme and in part to the more circumspect reasoning of academic psychologists and psychiatrists. William James and Emil Kraepelin, for example, emphasized positive features associated with certain kinds of madness, or “psychopathy,” and speculated on how these features might combine with other talents in some instances to produce an extraordinarily creative or accomplished person. They also stressed, however, the debilitating extremes of mental illness—psychosis or morbid depressions, for example—in addition to the milder, potentially productive hypomanias and more reflective, philosophical melancholias. These scholars underscored the need for sustained attention, discipline, and balance in the truly accomplished individual. This more moderate view has characterized most modern thinking about the relationship between psychopathology and genius.

Kraepelin, a contemporary of William James, was acutely aware of the dire consequences of untreated manic-depressive illness. But like many who had observed and studied it, he wrote of its occasional positive aspects as well (Kraepelin, [1921] 1976, p. 17):

The volitional excitement which accompanies the disease may under certain circumstances set free powers which otherwise are constrained by all kinds of inhibition. Artistic activity namely may, by the untroubled surrender to momentary fancies or moods, and especially poetical

activity by the facilitation of linguistic expression, experience a certain furtherance.

Swiss psychiatrist Eugen Bleuler concurred, and further drew the parallel between manic and artistic thought (Bleuler, 1924, pp. 466, 468):

The *thinking* of the manic is flighty. He jumps by by-paths from one subject to another, and cannot adhere to anything. With this the ideas run along very easily and involuntarily, even so freely that it may be felt as unpleasant by the patient. . . .

Because of the more rapid flow of ideas, and especially because of the falling off of inhibitions, artistic activities are facilitated even though something worthwhile is produced only in very mild cases and when the patient is otherwise talented in this direction. The heightened sensibilities naturally have the effect of furthering this.

William James, like his brother Henry and other members of their family, was subject to profound, debilitating depressions. Nonetheless, he wrote about the potentially valuable combination of an ardent, excitable temperament with talent (James, 1902):

The psychopathic temperament [by which James meant “border-line insanity, insane temperament, loss of mental balance”], whatever be the intellect with which it finds itself paired, often brings with it ardor and excitability of character. . . . His conceptions tend to pass immediately into belief and action . . . [W]hen a superior intellect and a psychopathic temperament coalesce—as in the endless permutations and combinations of human faculty, they are bound to coalesce often enough—in the same individual, we have the best possible condition for the kind of effective genius that gets into the biographical dictionaries. Such men do not remain mere critics and understanders with their intellect. Their ideas possess them, they inflict them, for better or worse, upon their companions or their age.

Myerson and Boyle, writing from Boston’s McLean Hospital in the 1940s, reiterated the basic position of William James; as Kraepelin and Rush had done, they focused on manic-depressive illness. In discussing affective psychosis in socially prominent families, they concluded (Myerson and Boyle, 1941):

It does not necessarily follow that the individuals who appear in these records were great because they had mental disease, although that proposition might be maintained with considerable cogency and relevance. It may be that the situation is more aptly expressed as follows. The manic drive in its controlled form and phase is of value *only* if joined to ability. A feeble-minded person of hypomanic temperament would simply be one who carried on

more activity at a feeble-minded level, and this is true also of mediocrity, so the bulk of manic-depressive temperaments are of no special value to the world, and certainly not of distinguished value. If however, the hypomanic temperament is joined to high ability, an independent characteristic, then the combination may well be more effective than the union of high ability with normal temperament and drive might be. The indefatigability, the pitch of enthusiasm, the geniality and warmth which one so often sees in the hypomanic state may well be a fortunate combination and socially and historically valuable.

EVIDENCE FOR A LINK BETWEEN MANIC-DEPRESSIVE ILLNESS AND CREATIVITY

Any relationship between manic-depressive illness and creativity would appear to be unlikely, especially in light of recent and overwhelming evidence that pervasive cognitive deficits mark many if not most individuals afflicted by the bipolar form of the disorder (see Chapter 9), although it should be noted that standard measures of intellectual functioning, such as IQ tests, show only a modest association with creativity (see, e.g., Ochse, 1990; Piirto, 1994; Simonton, 1994). (Anecdotally, it is of interest that scientists Richard Feynman and James Watson scored 120 on their respective IQ tests.) It is counterintuitive that such a destructive illness could be associated with imagination or great works of art. Yet the perceived association is a persistent cultural belief and one that is backed by data from many studies. All of these studies are limited by their methods, but as we shall see, their findings—converging as they do from across varied methodologies and different populations—are certainly suggestive. It may be, of course, that there is no relationship. Or there may be a link, but not a causal one. If there is a link, it may be that creativity or the creative lifestyle leads to instability (for example, through highly irregular sleep patterns, financial and other stresses, alcohol and drug abuse, or a social milieu with an excessive tolerance for erratic behavior), rather than the instability's facilitating creativity. Indeed, there may be a selection factor for those who choose a life within the arts.

We argue here that there is a causal link whereby the cognitive styles, temperaments, and intense, cyclic moods associated with bipolar spectrum disorders cause some who are already creative and productive to be even more so. The argument is not that manic-depressive illness and its related temperaments are essential to creative work; clearly they are not. Nor do we argue that most people who have bipolar or recurrent depressive illness are creative; they are not. The argument is, rather, that a *disproportionate* number of eminent writers and artists have suffered from bipolar spectrum disorders and that, under some

circumstances, creativity can be facilitated by such disorders. Indeed, great creative accomplishment is by definition a rare merging of temperament, intellect, imagination, happenstance, energy, and discipline.

While we focus here on mood, cognitive, and temperamental aspects of great achievement, the role of hard work and discipline cannot be overemphasized. Lord Byron is a good example of this point. There can be little question that his poetry was strongly affected by his extreme moods and indisputable mental anguish, but his personal discipline was extraordinary. Byron's extensive reworking of a single stanza from *Don Juan*, for example, is illustrated in Figure 12-1 and Box 12-1. "His reason was punctuated, even disturbed, by passion," wrote another poet, "but whatever he was in person he was not, as an artist, passion's slave. In the poetry Byron masks his passion and makes it into durable art" (Bold, 1983, p. 13). Byron himself wrote: "Yet, see, he mastereth himself, and makes / His torture tributary to his will."¹

Methodological Issues

There are several ways to examine the relationship between manic-depressive illness and creativity, but until recently, apocryphal speculation far outweighed systematic study. Criticism of work purporting to find a link has been justified. Biographical studies—while intrinsically fascinating, irreplaceable, and deeply instructive sources of information about moods, their extremes, and their roles in the lives of artists—are fraught with difficulties (Jamison, 1993).² This criticism has been discussed at length elsewhere (see, e.g., Jamison, 1993; Post, 1994; Ludwig, 1995).

Writers and artists, for example, however brutally honest they may be in some of their self-assessments, are of necessity subjective and biased as well. The reliability of letters, journals, and memoirs can be limited because they are written from a single perspective or because the writer was fully mindful of future biographers and posterity. Biographers, too, write with biases and under the influence of prevailing or idiosyncratic viewpoints. Historical context and existing social customs also determine which behaviors are culled or emphasized for comment. Certain lifestyles provide cover for deviant and bizarre behavior, and the arts, especially, have long given latitude to extremes in behavior and mood. The assumption is prevalent that within artistic circles, madness, melancholy, and suicide are somehow normal, making it difficult at times to distinguish truth from expectation.

Biographical or posthumous research poses other problems as well. Any historical perspective dictates that a listing of highly accomplished, affectively ill individuals will be illustrative, but by no means definitive. Always in the analysis of individual lives, problems arise. It is fairly easy

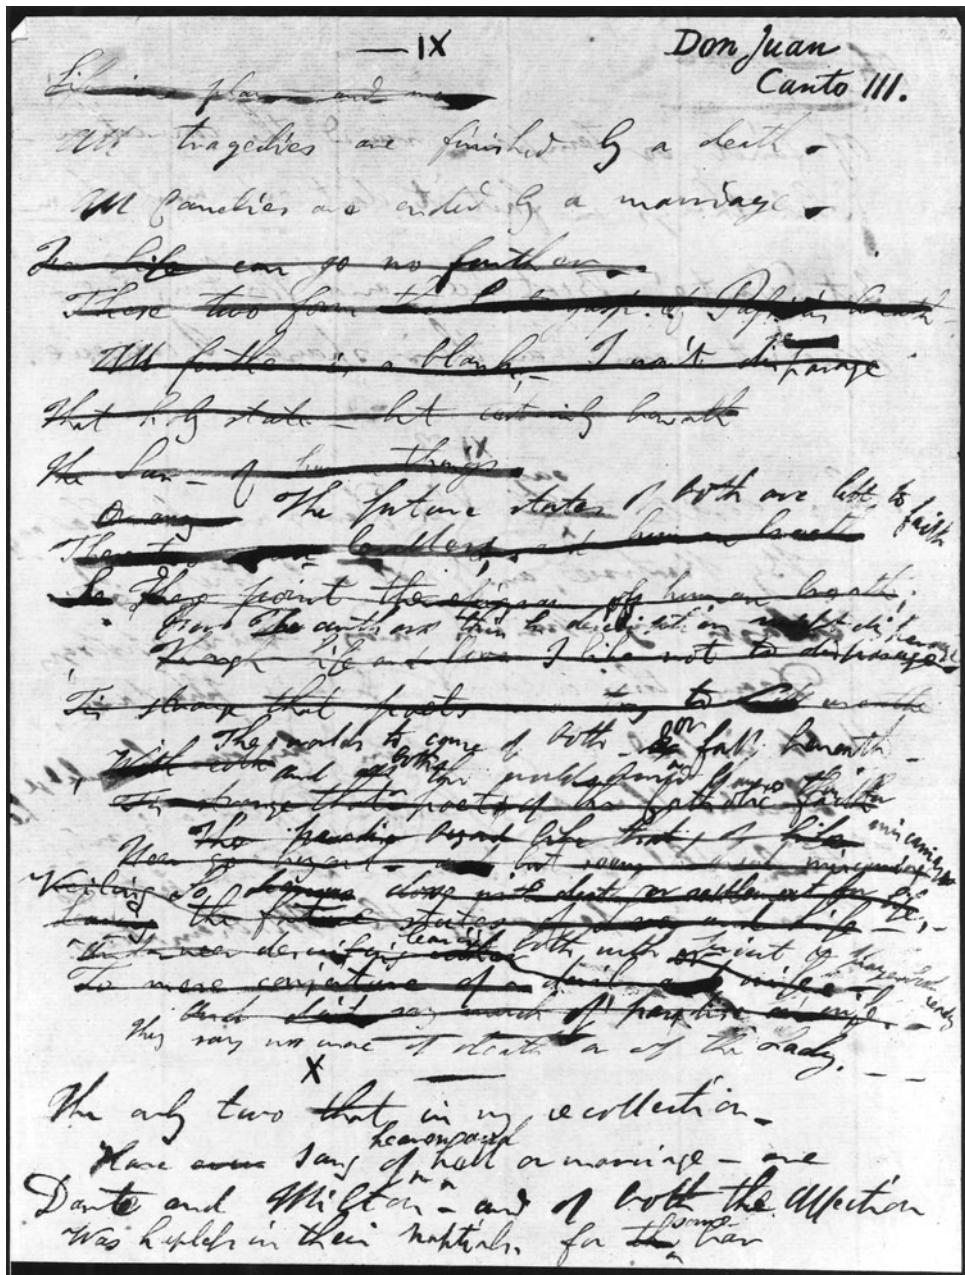

Figure 12-1. Autograph page from stanza 9, canto III, of Byron's *Don Juan* (reduced by one-third). (Source: Reproduced by permission of the Pierpont Morgan Library, New York. MA56-57.)

to identify any number of major nineteenth-century British or American poets who were manic-depressive, for example, but it is more difficult to determine what proportion of the total pool of "great poets" they represent. (In many instances, of course, the individuals under study are sufficiently important to be interesting in their own right, independently of any general grouping.) Also, more detailed information exists for some individuals than for others (for example, those more in the public eye, those living in relatively recent times, those institutionalized, or those writing more extensively about themselves).

The tendency for highly accomplished individuals to be, almost by definition, inordinately productive and energetic creates a problem of another sort—a bias toward underdiagnosis of the manic side of bipolar illness. Biographical studies indicate that writers, artists, and composers often describe their periods of melancholy or depression in great detail, but that other aspects of mood swings, such as hypomania and even at times overt psychosis, are subsumed under “eccentricity,” “creative inspiration,” or “artistic temperament.” Thus many individuals with clear histories of profound or debilitating depressions are

**BOX 12-1. Reworking by Byron of Stanza 9,
Canto III, from *Don Juan***

1. Life is a play and men
All tragedies are finished by a death,
2. All Comedies are ended by a marriage,
3. For Life can go no further
~~These two form the last gasp of Passion's breath~~
4. All further is a blank—I won't disparage
5. That holy state—but certainly beneath
6. The Sun—of human beings
7. These two are loveliers, and human breath
So These point the epigram of human breath,
Or any The future states of both are left to faith,
4. Though Life and love I like not to disparage
The For authors think description might disparage
fear
5. Tis strange that poets never try to wreath [sic?]
With either Tis strange that poets of the Catholic faith
6. Neer go beyond—and but seem to dread miscarriage
7. So dramas close with death or settlement for life
Veiling Leaving the future states of Love and Life
The paradise beyond like that of life
8. And neer describing either
To mere conjecture of a devil—and—or wife
5. The worlds to come of both & or fall beneath,
6. And all both the worlds would blame them for miscarriage
And then both worlds would punish their miscarriage—
7. So leaving both with priest & prayerbook ready
So leaving Clerg both a each their Priest and prayerbook
ready,
8. They say no more of death or of the Lady.

labeled "melancholic" rather than manic-depressive, despite their episodic (and often seasonal) histories of extremely high energy, irritability, enthusiasm, and increased productivity (periods often accompanied by costly lapses in financial, social, and sexual judgment). Paradoxically, the more chronically hypomanic the individual, the more noticeable and relatively pathological the depression will be. Diagnostic biases in the opposite direction also occur. Some researchers tend to overdiagnose bipolar illness because they observe patterns of behavior common to both hypomania and normal accomplishment (for example, enthusiasm, high energy, and the ability to function with little sleep) and then label as manic-depressive anyone displaying these "symptoms."

Despite the difficulty of conducting diagnostic studies based on biographical material, valid and useful research

can be carried out by using in a systematic way what is known about bipolar illness: its symptomatic presentation (for example, pronounced changes in mood, energy, sleep, thinking, and behavior); associated behavior patterns (such as alcohol and drug abuse, pathological gambling, violence, pronounced and repeated financial reversals, and chaotic interpersonal relationships); its association with suicide³; its natural course⁴; and a family history, especially in first-degree relatives (parents, siblings, or children), of depression, mania, psychosis, or suicide. Psychiatric and medical conditions that can have similar symptoms (for example, thyroid and other metabolic disturbances, drug-induced states, or complex partial seizures and related epileptic conditions) need to be considered, and ruled out, as well. Making a retrospective diagnosis is, in many ways, like putting together the pieces of a three-dimensional puzzle or solving a mystery by a complicated but careful marshaling of evidence. Biographical diagnoses must ultimately, of course, be more tentative than diagnoses made on living individuals, being circumstantial by nature, but they can be made, reliably and responsibly and with an appreciation for the complexities of anyone's life, especially that of an artist.

Studies of living artists, writers, and composers have had serious methodological flaws as well, including small sample sizes, inconsistent definitions of creativity and psychiatric illness, and nonrandom or nonspecified selection of subjects. These issues are discussed in greater detail later in the chapter.

Biographical Studies

Many case-history studies of psychopathology in eminent writers and artists were conducted during the late nineteenth and early twentieth centuries. Lombroso (1891) found an overrepresentation of manic-depressive illness in his study of geniuses and attributed it to his belief that those who suffered from the illness "feel and notice more things and with greater vivacity and tenacity than other men, their recollections are richer, and their mental combinations more fruitful" (p. 27). Babcock (1895), writing a few years later, observed that the geniuses he had studied were more likely to be emotionally unstable and given to extremes in moods. Jacobson (1912), White (1930), and Lange-Eichbaum (1932) found high general rates of insanity in their biographical studies of genius. The latter concluded that within the group defined as geniuses, artists and poets tended more to insanity than scientists and statesmen. Reid (1912) and Onuf (1918) found that manic-depressive illness was strongly overrepresented in their eminent subjects.

In a more quantitative analysis, Juda (1949) studied 113 German artists, writers, architects, and composers; she was one of the first to undertake an extensive, in-depth investigation of not only artists and writers but also their relatives.

TABLE 12–1. Biographical Studies of Depression, Mania, and Suicide in Eminent Writers, Composers, and Artists

Study	Subjects	Findings
Juda, 1949	113 German artists and writers	Two-thirds were “psychically normal”; more suicides and “insane and neurotic” individuals in artistic group than general population. Highest rates of psychiatric abnormalities in poets (50%), musicians (38%), painters (18%), and architects (17%). First-degree relatives of artists and writers were more likely to be cyclothymic, commit suicide, or have manic-depressive illness. Psychosis was much more common in grandchildren of artists and writers.
Martindale, 1972	21 eminent English poets (born 1670–1809); 21 eminent French poets (born 1770–1909)	55% of English poets and 40% of French poets had significant psychopathology (“nervous breakdown,” suicide, and/or alcoholism). One in 7 had been placed in asylum or had suffered from severe “recurring and unmistakable symptoms,” such as hallucinations or delusions.
Trethowan, 1977	60 eminent composers	Mood disorders “easily the commonest and most important of psychiatric illnesses” in composers; approximately 50% had a “melancholic temperament.”
Jamison, 1993	36 eminent/most anthologized British and Irish poets (born 1705–1805)	17% had been committed to insane asylum; 22% had a history of psychosis; 39% had a strong family history of psychosis, suicide, and/or melancholia; 6% committed suicide.
Schildkraut et al., 1994	15 abstract expressionist artists (New York School)	More than 50% had a depressive illness; 40% received treatment; 20% hospitalized; 13% committed suicide; 2 paternal suicides.
Post, 1994	100 eminent American and British writers	5% had history of bipolar psychosis; 2% unipolar psychosis; 16% severely disabled by depression; 8% committed suicide. Total of 82% with “affective abnormalities.”

(continued)

TABLE 12–1. Biographical Studies of Depression, Mania, and Suicide in Eminent Writers, Composers, and Artists (*continued*)

Study	Subjects	Findings
Ludwig, 1995	1,004 eminent individuals across all fields of accomplishment	Compared with other professions (business, science, public life), artistic group had 2–3 times the rate of psychosis, suicide attempts, mood disorders, and substance abuse. Those in the artistic group were 6–7 times more likely to have been involuntarily hospitalized.
Post, 1996	45 scientists, 52 composers, 48 artists, 50 writers	Severe depressive illness: scientists (18%); composers (15%); artists (8%); writers (36%).
Czeizel, 2001	21 eminent Hungarian poets (born 1554–1925)	Bipolar-I (14%); bipolar-II (53%); major depression (9%); committed suicide (9%).
Wills, 2003	40 eminent American modern jazz musicians	Psychotic illness (7.5%); major affective illness (28.5%); inpatient treatment for depression (10%); committed suicide (2.5%).

She found a high rate of what she called manic-depressive psychosis (4.3 percent) in her comparison sample of scientists (a broadly defined group), but no manic-depressive illness in the artists. (Not uncommon for the times, there was diagnostic confusion between schizophrenia and manic-depressive illness.) The artists, instead, showed a disproportionate rate of “undetermined psychoses” (2.7 percent) and schizophrenia (2.7 percent). First-degree relatives of the artists and writers, however, were disproportionately likely to be cyclothymic, to commit suicide, or to have manic-depressive illness. Juda’s findings, together with those from more recent systematic biographical studies, are presented in Table 12–1. The methods and populations used across these studies varied enormously, as did the selection criteria and means used for diagnostic ascertainment.

The inconsistencies and methodological flaws in these studies were substantial, but the individuals studied were of indisputable artistic ability, and most had made lasting contributions to their fields. What is of interest is the consistency of the findings—the strikingly increased rates of psychosis, institutionalization, and suicide in eminent artists and writers. The markedly elevated rates for depressive illnesses are particularly noteworthy given that the overwhelming majority of the subjects were men, who have a considerably lower rate of depression than women.

To study the occurrence of mood disorders and suicide in a consecutive sample of all of the most eminent British

and Irish poets born within a 100-year period (the most frequently represented poets in 15 anthologies of eighteenth- and nineteenth-century verse), Jamison (1993) examined autobiographical sources, contemporary accounts, and medical records (where available) for poets born between 1705 and 1805. She examined the available letters, journals, and medical records for symptoms of depression, mania, and mixed states; seasonal or other patterns in moods, behavior, and productivity; the nature of the course of the illness (for example, age at onset, duration, and patterns of recurrence); and evidence of other psychiatric or medical illnesses (for example, substance abuse or syphilis) that might confound the diagnostic picture. She placed a strong emphasis on both the severity and the recurrence of symptoms. In all cases it was the patterning of mood, cognitive, energy, sleep, and behavior symptoms that formed the focus of the study. The results are summarized in Table 12–2. Jamison’s findings—a disproportionately high rate of psychosis, manic-depressive illness, institutionalization, and suicide—are consistent with those of other biographical studies, such as Martin-dale’s (1972) of eminent English and French poets; Trethowan’s (1977) of composers; Schildkraut and colleagues’ (1994) of visual artists; Ludwig’s (1992) of artists, writers, composers, and eminent nonartists (see Table 12–3); Post’s (1994, 1996) of American and British writers and of scientists, composers, artists, and writers, respectively;

TABLE 12–2. Mood Disorders and Suicide in Eminent British and Irish Poets
Born 1705–1805

Poets	Comments
Samuel Johnson 1709–1784	Severe recurrent melancholia. Perceived himself as intermittently mad and had a terror of insanity. First serious breakdown at 20, lasting more than 2 years. Experienced tics, obsessions, and phobias as well. Felt he had inherited his “vile melancholy” from his father.
Thomas Gray 1716–1771	“Habitual melancholy” and attacks of depression that grew more frequent over time. Father “subject to intermittent fits of insanity”; extravagant, alcoholic, and violent.
Williams Collins 1721–1759	Psychotic melancholia and possible mania. First complete breakdown at 29. Confined to lunatic asylum; “accustomed to rave much and make great moanings.” Dissipation, intemperance, and excess while undergraduate at Cambridge. Little known about family history.
Christopher Smart 1722–1771	Ecstatic, grandiose, and religious mania. First confined to asylum in his early thirties, but financial extravagance, instability, and dissipation apparent while an undergraduate at Cambridge. Spent several years in “madhouse” on “incurable ward.”
Joseph Warton 1722–1800	No indication of a significant mood disorder.
Oliver Goldsmith 1730–1774	Violent temper, fitfully melancholic, financially extravagant, compulsive gambler. Increasingly irritable, melancholic, and subject to “violent alternations of mood” as he grew older. Little known about family history except that Goldsmiths were perceived as “strange” and “eccentric.”
William Cowper 1731–1800	Recurrent psychotic melancholia and repeated suicide attempts. Delusions and hallucinations. First signs of mental instability while in his twenties; confined to asylum in his early thirties. Family history of melancholia.
James Macpherson 1736–1796	No indication of a significant mood disorder.
Robert Fergusson 1750–1774	Cyclothymic temperament progressed to psychotic melancholia and then maniacal excitement (possibly exacerbated by head trauma). Died “furiously insane,” at age 24, in the Edinburgh Bedlam.
Thomas Chatterton 1752–1770	Committed suicide at age 17. Extremely moody even as a child. Subject to severe melancholia as well as periods of frenzied energies, occasionally incoherent enthusiasms, and extreme grandiosity. “Wild” fluctuations in mood. Sister confined to asylum, and niece suffered from unspecified psychiatric condition.
John Bampfylde 1754–1796	Confinement in private “madhouse” for 20 years. “Fell into dissipation” after Cambridge studies. Little known about nature of his psychiatric problems. “A disposition to insanity in the family,” including a sister who became insane.

(continued)

TABLE 12–2. Mood Disorders and Suicide in Eminent British and Irish Poets
Born 1705–1805 (*continued*)

Poets	Comments
George Crabbe 1754–1832	By age 24 described an “annual woe and dread”; suffered throughout his life from fits of depression. Daily opium use (initially prescribed for tic douloureux) for more than 40 years. Father, described as “a man of imperious temper and violent passions,” became increasingly and more irrationally violent as he became older.
William Blake 1757–1827	Hallucinations and delusions from an early age. Periods of exaltation and grandiosity, as well as periods he described as “a deep pit of melancholy—melancholy without any real reason.” Excessive irritability and attacks of rage, suspiciousness, and paranoia. Little information about family history although one brother, who spoke of visions of Moses and Abraham, was described as a “bit mad.”
Robert Burns 1759–1796	Severe, recurrent, often seasonal melancholia (described by Burns as “the miseries of a diseased nervous system” and a “deep incurable taint which poisons my existence”). Mercurial, agitated, and volatile temperament. Both parents described as “subject to strong passions,” fiery, and irascible.
Joanna Baillie 1762–1851	No indication of a significant mood disorder.
William Lisle Bowles 1762–1850	No indication of a significant mood disorder.
Samuel Rogers 1763–1855	No indication of a significant mood disorder.
William Wordsworth 1770–1850	Self-described as “of a moody and violent temper.” Subject to hypochondriacal aches and pains. Described by some biographers as suffering from severe depressions “to the verge of a mental breakdown,” but their nature and severity are unclear. Sister’s “insanity” likely to have been due to dementia rather than to a psychiatric illness.
Sir Walter Scott 1771–1832	At various times described himself as suffering from a “disposition to causeless alarm—much lassitude—and decay of vigor and intellect,” a <i>morbus eruditorum</i> , and a “black dog” of melancholy.
Samuel Taylor Coleridge 1772–1834	Extended and recurrent melancholia. Mercurial, restless, extravagant, grandiose, and agitated. Fitful enthusiasms and despairs. Opiate addiction. Visionary states. Family history of affective illness and suicide.
Robert Southey 1774–1843	Described as unduly excitable, with a history of “nervous fever” and an unbalanced state of “nerves”; however, unclear indication of recurrent mood disorder of any significant severity.
Walter Savage Landor 1775–1864	Violent, restless, and unstable temperament. Litigious and impulsive. “Very much disposed” to melancholy. Expelled from both Rugby and Oxford. Thought by others to have had “at least a touch of insanity.” “Ungovernable temper” and financially extravagant.

(*continued*)

TABLE 12–2. Mood Disorders and Suicide in Eminent British and Irish Poets Born 1705–1805 (*continued*)

Poets	Comments
Thomas Campbell 1777–1844	Recurrent and severe melancholia, “aggravated fits of despondency.” First attack when 18. Violently irritable, financially extravagant, and “alternately excited and depressed within short-periods of time.” Insanity in his and his wife’s families. Son placed in asylum, suffering from melancholia, “capricious fits of temper,” paranoia, and “leap-frog play of thoughts.”
Leigh Hunt 1784–1859	Autobiography describes a “nervous condition,” a “melancholy state,” which lasted, the first time, for several months. “I experienced it twice afterwards, each time more painfully than before, and for a much longer period . . . for upwards of four years, without intermission, and above six years in all.”
Thomas Love Peacock 1785–1866	No indication of a significant mood disorder.
George Gordon, Lord Byron 1788–1824	Recurrent, often agitated, melancholia. Volatile temperament with occasional “paroxysms of rage.” Mercurial and extravagant; worsening depressions over time. Strong family history of mental instability and suicide.
Percy Bysshe Shelley 1792–1822	Recurrent, agitated, and occasionally suicidal melancholia. “Hysterical attacks” followed by periods of listlessness; often seasonal. Ecstatic episodes and “violent paroxysms of rage.” Self-described as “tormented by visions,” the psychiatric nature of which remains unclear. Probable transient delusions. Intermittent laudanum use for “nerves.”
John Clare 1793–1864	Spent 25 years in insane asylum. Long periods of inertia and melancholia interspersed with episodes of frenzied, violent, and extravagant activity. Hallucinations, as well as delusions of persecution and grandeur. Cause of madness listed as “hereditary” by asylum physician.
John Keats 1795–1821	“Violent and ungovernable as a child”; described by brother as nervous, “morbid,” and suffering from “many a bitter fit of hypochondriasm” [melancholy]; periods of depression often followed by periods of intense activity and “exhilaration.” Described himself as having a “horrid Morbidity of Temperament.” Rapidly shifting moods predated symptoms and diagnosis of tuberculosis.
George Darley 1795–1846	Recurrent, occasionally suicidal melancholia. Increasing periods of depression and social withdrawal. Described extreme mood swings, ranging from “causeless and unreasonable” periods of “frolic, extravagance, and insane” actions to “crazed” periods of despair.
Hartley Coleridge 1796–1849	Recurrent melancholia; severe mood swings alternating between “depression and extravagant hilarity.” Lifelong struggles with alcoholism, “heavings of agony,” and “paroxysms of rage.” Expelled from Oxford for dissipation. Eccentric and visionary. Under conservatorship toward end of life. Insanity on both sides of his family.

TABLE 12–2. Mood Disorders and Suicide in Eminent British and Irish Poets Born 1705–1805 (*continued*)

Poets	Comments
Thomas Hood 1799–1845	Periods of morbidity, melancholia, and lethargy, but diagnosis complicated by severe, recurrent physical illness.
Thomas Lovell Beddoes 1803–1849	Committed suicide at 45 after at least one earlier attempt. Volatile, extravagant, eccentric, and subject to severe recurrent melancholia. Father, also a physician, was highly eccentric and of an “extremely ardent” temperament.
Robert Stephen Hawker 1803–1875	“Fits” of depression throughout his life. Deep depression and “brain fever” after wife’s death; possible psychosis. Volatile, extravagant, and eccentric. Intermittent opium habit. Physician had “never encountered in all his practice so excitable a tissue as that which held [his] Brain.” “My Grandfather and Father,” Hawker wrote, “were both of the same excitable temperament.”
James Clarence Mangan 1803–1849	Recurrent and prolonged psychotic depressions. Hallucinations, agitation, “great overcurtaining gloom.” Extreme eccentricity: “with one voice they all proclaimed me mad.” Probable opiate abuse. Father described as extravagant, financially dissolute, and of “quick and irascible temper.”

Note: Poets selected for inclusion were the most frequently represented in 15 anthologies of eighteenth- and nineteenth-century British and Irish verse.

Czeizel’s (2001) of Hungarian poets;⁵ and Wills’ (2003) of the lives of American jazz musicians. These studies are necessarily subjective in many respects—although suicide, psychosis, and institutionalization are relatively objective phenomena—but they are notable for the eminence of the subjects involved and for the consistency of their findings. Suicide rates were markedly elevated in all of the studies (see Fig. 12–2).

Studies of Living Writers and Artists

There have been fewer studies of psychopathology in living writers and artists. Andreasen and colleagues undertook the first such inquiries into the relationship between creativity and mental disorders (Andreasen and Canter, 1974; Andreasen and Powers, 1975; Andreasen, 1987). These studies, using structured interviews, the Research Diagnostic Criteria (RDC), and matched control groups,

represented significant methodological advances over prior, anecdotally based research. The size of the sample of writers was relatively small ($N=30$), however, and the subjects were of varying levels of creative accomplishment (all were participants in the University of Iowa Writers' workshop, but some were nationally acclaimed writers, while others were graduate students or teaching fellows not nationally or internationally recognized). Andreasen noted that because she studied only writers, her results could not be generalized to other groups of creative individuals, such as philosophers, scientists, or musicians. Although this is true, and writers may be disproportionately likely to have affective disorders, the homogeneity of the sample is valuable in its own right.

The results of the Iowa research are summarized in Table 12–4. Clearly, the writers had an exceptionally high rate of affective illness and alcoholism. Fully 80 percent of the study sample met standardized (RDC) diagnostic criteria for a major affective disorder. In contrast, 30 percent of the control sample (individuals outside the arts who were matched for age, education, and gender) met the same criteria ($p<.001$). Although this is a much lower figure relative to the study sample, it still represents a rate greater than that expected for the general population. It is unclear whether this discrepancy reflects an overrepresentation of affective illness in the control sample, or the diagnostic criteria were overly inclusive for both the

creative and control groups. Almost one-half (43 percent) of the creative sample met the diagnostic criteria for bipolar-I or bipolar-II disorder.

In a study of eminent British writers and artists, Jamison (1989) examined rates of treatment for affective illness within these groups and looked at seasonal patterns of moods and productivity, the nature of intense creative episodes and the similarities between such episodes and hypomania, and the perceived role of very intense moods in the writers' or artists' work. Subjects were chosen for the study on the basis of having won at least one of several specified top prizes or awards in their fields. Thus, all painters and sculptors were either Royal Academicians or Associates of the Royal Academy, and the work of 9 of the 18 poets in the study sample had already been anthologized in *The Oxford Book of Twentieth Century English Verse*. Six of the eight playwrights had won the New York Drama Critics Award and/or the Evening Standard Drama Award (the London Critics' award); several had won both or had won one of these awards more than once.

The artists and writers were asked whether they had ever received treatment for a mood disorder and, if so, what that treatment had consisted of. The results, shown in Figure 12–3, indicate that a large proportion of the total sample (38 percent) had been treated for an affective illness. Three-fourths of those treated had been given antidepressants or lithium or

had been hospitalized. Poets were most likely to have received medication for depression (33 percent) and were the only ones to have received medical intervention (hospitalization, electroconvulsive therapy, and/or lithium) for mania (17 percent). Thus, one-half of the poets had been treated with drugs or hospitalized for mood disorders. This rate is strikingly high when compared with rates in the general population (see Chapter 5). It is even higher when one considers the fact that the proportion of those in the general population so seriously ill as to actually seek and receive treatment is much lower, perhaps one-third to one-half the rates reported in prevalence studies using diagnostic criteria alone (Andreasen and Canter, 1974; Robins et al., 1984). A further probable underestimate of the total rate of affective illness in the study sample derives from the sample's being comprised largely of men, who, as noted, are less likely than women to suffer from depression, as well as less likely to seek treatment. The playwrights had the highest total rate of treatment for mood disorders (63 percent), but a very high percentage (38 percent) had been treated with psychotherapy alone; it is unclear whether this was due to a difference in illness severity or in treatment preference. Visual artists and biographers had relatively lower rates of treatment (13 and 20 percent, respectively); all treatment was with antidepressants.

Although, with the exception of the poets, the subjects reported being treated for depression, not mania or hypomania, the design of the study did not allow systematic inquiry into hypomanic or manic episodes. About one-third of the writers and artists reported histories of severe mood swings, however, and one-fourth reported histories of extended elated mood states. The novelists and poets most frequently reported elated mood states, whereas the playwrights and artists were the most likely to report severe mood swings. Biographers reported no history of severe mood swings or elated states, an interesting finding since of the five groups, they were the least likely to be associated with creativity and thus provide a natural comparison group (i.e., one highly proficient in writing but perhaps less outstandingly creative by the nature of their work).

One of the major purposes of the British study was to look at the similarities and dissimilarities between periods of intense creative activity and hypomania. Hypothesized similarities were based on the episodic nature of both; the overlapping nature of the behavioral, mood, and cognitive changes associated with both; and a possible link between the duration and frequencies of the two types of experiences. The vast majority of the subjects (89 percent) reported having had experienced intense creative episodes (100 percent of the poets, novelists, and artists; 88 percent

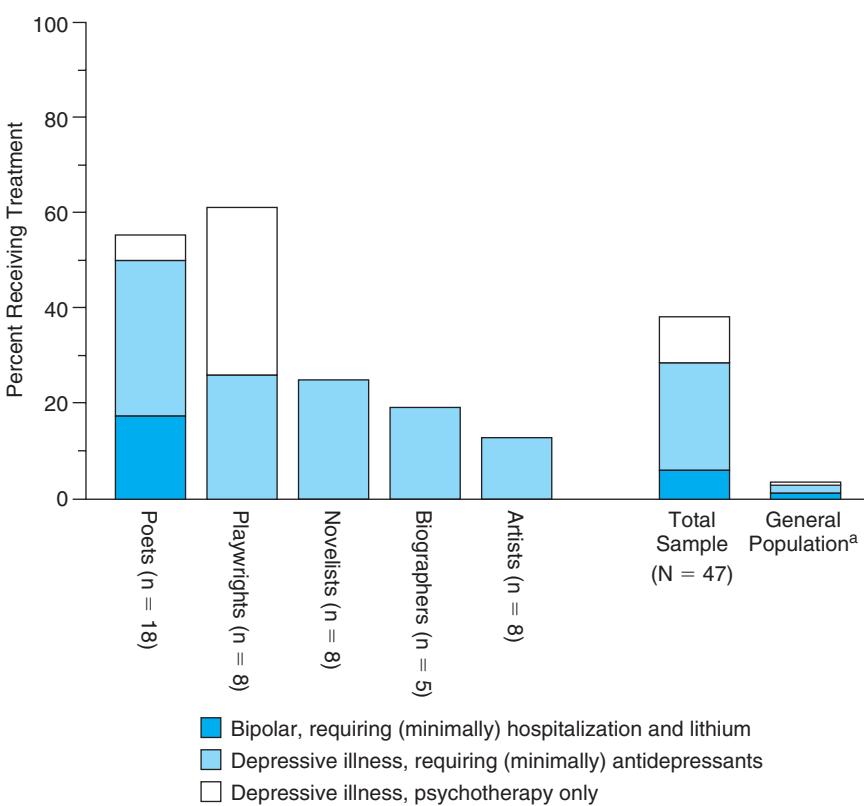

Figure 12–3. Rates of treatment for affective illness in a sample of British writers and artists. The percentages for the general population are based on Epidemiological Catchment Area data. They indicate that less than one-third of those individuals with bipolar or unipolar disorder receive treatment in any 6-month period. (Source: Jamison, 1989.)

of the playwrights; and, consistent with results reported earlier, only 20 percent of the biographers). The modal duration of these episodes was 2 weeks (35 percent); 55 percent of the episodes lasted 1 to 4 weeks, 20 percent 1 to 24 hours, and 25 percent longer than 1 month. The episodes were characterized by increases in enthusiasm, energy, self-confidence, speed of mental associations, fluency of thoughts, elevated mood, and a sense of well-being. Mood and cognitive changes showed the greatest degree of overlap with the episodes characterized as "intense creativity." Approximately half of the subjects described a decreased need for sleep and increased sensory awareness, but several of the more behavioral changes typically associated with hypomania (hypersexuality, increased talkativeness, and spending of money) were reported by only a minority of subjects.

When asked open-ended questions about changes before these intense creative episodes, 89 percent reported less need for sleep. (Coincident with the timing of the switch process in bipolar illness, 28 percent spontaneously reported waking abruptly at 3:00 or 4:00 AM and being unable to return to sleep.) Fifty percent of the subjects reported a sharp increase in mood just

before the beginning of an intensely creative period; for example, "I have a fever to write, and throw myself energetically into new projects"; "excited, anticipatory, energetic"; "more optimistic"; "elated"; "uplifted"; "euphoric"; and "ecstatic." Dysphoria preceded creativity in 28 percent of the subjects; that is, subjects reported feeling "more anxious"; "near suicide"; "increased irritability and tension"; "fearfulness, general mood of distress and slight paranoia"; and "irritable, antisocial." Finally, 22 percent reported mixed mood changes and psychomotor restlessness; for example, "mixture of elation together with some gloominess, feeling of isolation, sexual pressure, fast emotional responses"; "restlessness"; "low ebb bordering on despair often precedes good phase when work will flow almost as though one is a medium, rather than an originator"; "restless, dissatisfied." When asked specifically about the importance of very intense feelings and moods in their work, almost 90 percent stated that such feelings and moods were either integral and necessary (60 percent) or very important (30 percent). More poets than any other group regarded these intense moods as integral and necessary to what they did and how they did it.

Yet another link between creativity and affective illness may be the seasonal patterns underlying both moods and artistic productivity (as discussed more extensively by Jamison, 1993). Subjects rated their moods and productivity over a period of 36 months. Figures 12–4 and 12–5 show mood and productivity curves for the study sample (broken down by those writers and artists with a history of treatment for an affective illness and those with no such history). Very different seasonal patterns emerged. Those with a history of treatment demonstrated inversely related curves for summer productivity and moods, whereas those in the group with no history of treatment showed mood and productivity curves more directly covarying. In the treatment group, the peaks for productivity preceded and followed the mood peak by 3 to 4 months.

There are several possible explanations for these differences. First, increased productivity associated with elevated mood is almost certainly less likely to lead to treatment-seeking behavior than low productivity associated with elevated or any other mood. Second, the elevated mood of the treatment group may reflect more true hypomania (i.e., greater distractibility, increased stimulus and people seeking), which may well lead to less productivity in the acute phase. Indeed, Andreasen (1980, p. 381) found this in several of the writers in her study: "Some of their periods of hypomania were clearly counterproductive. The increased energy that they experienced could not be focused and controlled so that it could be expressed creatively, and so that energy was dissipated in social or personal outlets."

The British study of writers and artists revealed many overlapping mood, cognitive, and behavioral (especially sleep) changes between hypomania and intense creative

states. Cognitive and mood changes showed far more overlap than behavioral ones, indicating that the milder forms of hypomania may represent the more productive phase. The affective continuum that ranges from normal states through hypomania and then mania is very important, but poorly understood (Jamison, 2004). It remains unclear whether the overlap in cognitive and mood changes represents etiologically related syndromes or phenomenologically similar but causally unrelated patterns of expression. It also remains unclear to what extent writers and artists are simply more sensitive than the general population to their own mood states and are therefore more able, and perhaps also more willing, to articulate and report them.

In the no-treatment group, the periods of intensified mood and increased productivity may represent a milder form of hypomania, with cognitive and mood changes only. These milder forms of hypomania or intensified normal functioning may result in simultaneous peaks for mood and productivity. In the treatment group, the execution of work may have preceded and lagged behind the mood component.

In another study of psychiatric disorders in living writers, Ludwig (1994), using the *Diagnostic and Statistical Manual* (DSM)-III-R and the Lifetime Creativity Scales developed by Richards and colleagues (1988, discussed below), compared 59 female writers with 59 female nonwriters matched for age, educational level, and father's occupational status. The writers were far more likely to meet the diagnostic criteria for depression and mania, and five times more likely to have made a suicide attempt (see Fig. 12–6). They were also more likely to have had a history of panic attacks, drug abuse, or an eating disorder.

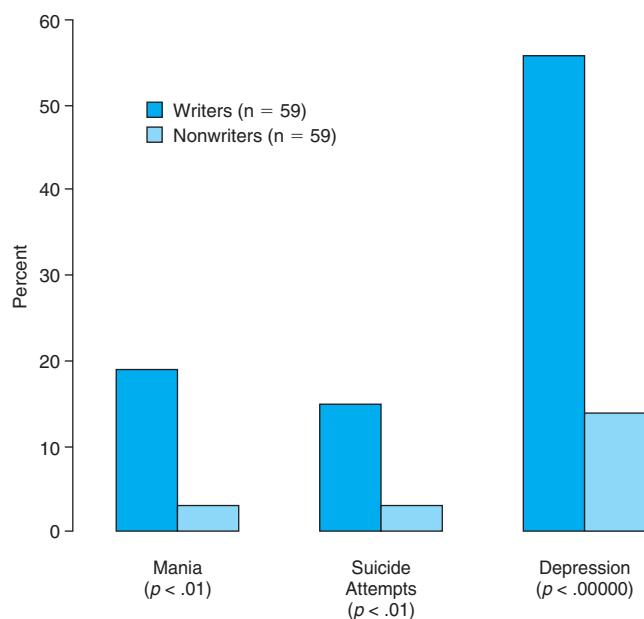

Figure 12-6. Lifetime rates of mood disorders in female writers and nonwriters. (Source: Adapted from Ludwig, 1994. Reprinted with permission from the *American Journal of Psychiatry*, American Psychiatric Association.)

tion to be eminent across many fields of artistic and intellectual endeavor. He also showed that there was a significantly increased risk of mental illness in distinguished Icelandic scholars and their relatives. Although Karlsson posited a familial relationship between schizophrenia and creativity, later investigators have concluded that his data actually show a very strong relationship between mood disorders, especially bipolar illness, and creativity (Richards, 1981; Andreasen and Glick, 1988; George et al., 1988).

Other researchers have looked at familial patterns of creativity and mood disorders in living artists and writers. Andreasen (1987) investigated the family histories of the University of Iowa Writers' Workshop writers and controls discussed earlier (see Table 12-5). Consistent with the elevated rate of affective illness in the writers, there was a significantly higher rate of affective illness in the primary relatives of the writers than in the primary relatives of the controls ($p < .001$). The overall prevalence for any type of psychiatric disorder was also much higher in the relatives of the writers (42 percent) than in the relatives of the controls (8 percent). Additionally, more first-degree relatives of writers than of controls showed histories of creative accomplishment (20 versus 8 percent).

Using a very different research design to study the relationship between creativity and psychopathology, Richards and colleagues (1988) at Harvard investigated creativity broadly defined in a sample of patients and their relatives. They hypothesized that a genetic vulnerability to manic-depressive illness may be accompanied by a predisposition to creativity, which may be more prominent among close relatives of patients with bipolar spectrum disorders than among the patients themselves. Such a compensatory advantage, they speculated, would be roughly analogous to the resistance to malaria found among unaffected carriers of the gene for sickle-cell anemia. To test their hypothesis, the researchers selected 17 bipolar and 16 cyclothymic patients, along with 11 of their normal first-degree relatives, using criteria that would ensure inclusion of a spectrum of disorders. These patients and their relatives were compared with 15 normal control subjects and with 18 controls who had a psychiatric diagnosis but no personal or family history of major affective disorder, schizophrenia, or suicide. Unlike other studies in the field, which limited the definition of creativity to significant, socially recognized accomplishment in the arts or sciences, these investigators attempted to measure the disposition toward originality manifested in a wide range of everyday endeavors. They administered the Lifetime Creativity Scales, a previously validated instrument that assesses the quality and quantity of "everyday" creative involvement in both work and leisure activities.

Family Studies

A familial association between psychopathology and creativity has been found in several studies. Early biographical work by Lombrosa (1891), Galton (1892), and Lange-Eichbaum (1932) suggested that both psychopathology and creative accomplishment ran in the families of eminent writers, artists, and composers. Juda (1949), as we have noted, found that first-degree relatives of artists and writers were more likely to have had manic-depressive illness, committed suicide, been cyclothymic, or been psychotic. This finding is supported by the results of Jamison's (1993) study of first-degree relatives of eminent British and Irish poets, as well as by the extensive family history (often multigenerational) of suicide, manic-depressive illness, and psychosis in the pedigrees of, among others, George Gordon, Lord Byron; Alfred Lord Tennyson; Robert Schumann; William and Henry James; Herman Melville; Samuel Taylor Coleridge; Virginia Woolf; Ernest Hemingway; Mary Shelley and Mary Wollstonecraft; James Boswell; Samuel Johnson; Vincent van Gogh; Théodore Géricault; Gustav Mahler; Robert Lowell; John Berryman; Anne Sexton; August Strindberg; Tennessee Williams; and Eugene O'Neill.

More systematic investigations have provided a valuable supplement to these case studies. Karlsson (1970), at the Institute of Genetics in Iceland, showed that first-degree relatives of psychotic patients, as well as the patients themselves, were far more likely than the general popula-

Richards and colleagues found significantly higher combined creativity scores among the bipolar and cyclothymic patients and their normal first-degree relatives than among the control subjects (see Fig. 12–7). The normal index relatives showed suggestively higher creativity relative to the bipolar patients, and the cyclothymic patients were close to the normal relatives. Modifying their original hypothesis, the authors concluded (p. 287):

Overall peak creativity may be enhanced, on the average, in subjects showing milder and, perhaps, subclinical expressions of potential bipolar liability (i.e., the cyclothymes and normal first-degree relatives) compared either with individuals who carry no bipolar liability (control subjects) or individuals with more severe manifestations of bipolar liability (manic-depressives).... There may be a positive compensatory advantage... to genes associated with greater liability for bipolar disorder. The possibility that normal relatives of manic-depressives and cyclothymes have heightened creativity may have been overlooked because of a medical-model orientation that focused on dysfunction rather than positive characteristics of individuals. Such a compensatory advantage among the relatives of a disorder affecting at least 1% of the population could affect a relatively large group of people.

Figure 12–7. Mean creativity in selected diagnostic groups. Mean overall peak creativity scores for controls with a diagnosis (DX), normal controls (N), normal first-degree biological relatives of cyclothymes and manic-depressives (NC Rel), cyclothymes (CYC), and manic-depressives (MDI). (Source: Richards et al., 1988.)

More recently, Simeonova and colleagues (2005) examined the potential familial connection between bipolar illness and creativity in a different way. They compared creativity in bipolar parents ($n=40$), their offspring with bipolar disorder ($n=20$), and bipolar offspring with attention-deficit hyperactivity disorder (ADHD) ($n=20$) with healthy control adults ($n=18$) and their healthy control children ($n=18$). The investigators found that parents with bipolar disorder and their bipolar offspring scored higher than healthy controls on measures of creativity. They suggested several interpretations for their findings, which are consistent with those of studies discussed earlier: bipolar disorder could "cause" creativity; bipolar disorder and creativity could be transmitted independently from parents to children; family environment may affect the putative familial cotransmission of creativity and bipolar disorder; or the genes for bipolar disorder and creativity may be "linked and co-segregate through generations, accounting for their co-occurrence in people with BD [bipolar disorder]" (p. 624). The study was unable to ascertain which of these hypotheses was the most viable, and its measure of creativity (the Barron-Welsh Art Scale) is not commonly used for that purpose, but the findings suggest that children with familial bipolar illness are more creative than healthy control children. The researchers also found that creativity in bipolar children was negatively correlated with duration of illness, which they attributed to the deleterious effects of prolonged illness and/or protracted exposure to medications.

In earlier, related research, Coryell and colleagues (1989) found that, although affectively ill groups (major depression, $n=442$; bipolar-I, $n=64$; bipolar-II, $n=88$) did not differ from one another in occupational or educational achievement, the first-degree relatives of the probands with bipolar disorder had significantly higher mean levels of achievement compared with the first-degree relatives of the probands with major depression. Earlier, Woodruff and colleagues (1971) had shown that bipolar probands and their brothers had higher status ratings than probands with major depression and their brothers.

The results of these studies suggest that creativity and mental illness, especially bipolar disorder, may tend to aggregate in certain families and not in others, but they do not show decisively that genetic factors are operating; that is, they demonstrate that there is a familial association, but not necessarily that the characteristics under discussion are heritable. It could be, for example, that the family and its environment, rather than the genetic inheritance itself, are exerting the primary influence. McNeil (1971), using an adopted-offspring research design, attempted to clarify this nature-versus-nurture problem. All of his subjects were adults who had been adopted shortly after birth and were part of a larger Danish psychiatric genetics study. They were classified as being "high creative" (most of the individuals in this group had achieved national prominence in the arts), "above average," or "low creative." Their rates of mental illness were then compared with those found in their biological and adoptive parents. The results are summarized in Table 12-6. The rates of mental illness were highest in the "high creative" group and their biological parents. The rates of psychopathology in the adoptive parents did not vary significantly from one level of adoptee creativity to another. Although the size of the sample was necessarily small, and the type of psychopathology was not rigorously ascertained, the study is both an interesting and an important one; its significance lies in the reasons given by McNeil in his summary remarks (p. 405):

Mental illness rates in the adoptees were positively and significantly related to their creative ability level, substantiating the hypothesized relationship between creative ability and mental illness. The mental illness rates of the biological parents were positively and significantly related to the creative ability of the adoptees. Mental illness rates among the adoptive parents and the adoptive and biological siblings were independent of the adoptees' creative ability level. The data were interpreted as evidence for the influence of prebirth factors on the relationship between creative ability and mental illness. No evidence of family-related postbirth influence was found.

TABLE 12-6. Rates of Mental Illness in Adoptees and their Biological and Adoptive Parents

Adoptee Group	Adoptees (%)	Biological Parents (%)	Adoptee Parents (%)

Hypothesized Relationships between Manic-Depressive Illness and Creativity

In hypothesizing possible relationships between manic-depressive illness and creative accomplishment, several general areas need to be explored: characteristics of the illness, such as acute and long-term cognitive, temperamental, and mood changes; experiences due to having the illness; and the relative importance of different aspects of the illness to various types of accomplishment.

Characteristics of the Illness

Profound changes in mood, cognition, personality, sleep, energy, and behavior can occur during all phases of manic-depressive illness. Even during normal states, many individuals experience subtle and not-so-subtle fluctuations in the intensity of their perceptions and feelings. All of these changes have potentially important effects on creativity and productivity, but perhaps most relevant to our discussion here are those changes that occur during the milder manic states. The DSM-IV-R criteria for hypomania are given in Chapter 3; even the most casual review suggests *prima facie* reasons for a possible connection between hypomania and accomplishment. There is some truth in the easy, glib question that often arises in clinical teaching situations: Who would not want an illness that numbers among its symptoms elevated and expansive mood, inflated self-esteem, more energy than usual, decreased need for sleep, and enhanced sexuality? (Notably, DSM-III criteria for hypomania also included “sharpened and unusually creative thinking” and “increased productivity” as diagnostic criteria.)

Many creative individuals describe their mood states during moments of greatest inspiration and productivity as elated, expansive, and, on occasion, ecstatic. Although it is unclear whether these mood changes precede or follow creative thought, there is some evidence that expansiveness of thought and grandiosity of both mood and thought—common features of mild mania—can result in an increased fluency and frequency of ideas that is highly conducive to creative achievement. The similarities between intense creative episodes and hypomania were discussed earlier; these are periods when many successful artists and writers report powerful mood and sleep changes, often just preceding times of intense creative activity. This period of elated and expansive mood is described by many individuals as a time of faster and more fluid thinking, new ideas, and novel connections between thoughts. The fluency of thought common to hypomania and creative activity was reported by Kraepelin (1921, p. 15) in his citation of the experimental work of Isserlin:

Isserlin has specially investigated the duration of ideas in manic patients. He found that their associations show

heightened distractibility in the tendency to “diffusiveness,” to spinning out the circle of ideas stimulated and jumping off to others, a phenomenon which in high degree is peculiar to mania.

The increase in speed of thoughts—ranging from a very mild quickening, to flight of ideas, to psychotic incoherence—may exert its influence on creative production in several ways. Speed per se, or the quantity of thoughts and associations, may be enhanced. Also significant, however, may be the effect of this increased quantity on the qualitative aspects of thought; that is, the sheer volume of thought may produce unique ideas and associations.

Guilford's (1957) systematic psychological studies of the nature of creativity led to the conclusion that creative thinking encompasses several components (many of which relate directly to cognitive changes that take place during mild manias as well). *Fluency of thinking* is defined operationally by Guilford through several related concepts, each with tests to measure it: (1) word fluency, or the ability to produce words each containing a specified letter or combination of letters; (2) associational fluency, or the production of as many synonyms as possible for a given word in a limited amount of time; (3) expressional fluency, or the production and rapid juxtaposition of phrases or sentences; and (4) ideational fluency, or the ability to produce ideas to fulfill certain requirements in a limited amount of time. In addition to fluency of thinking, Guilford developed two other concepts important to creativity: *spontaneous flexibility*, or the ability and disposition to produce a great variety of ideas, with freedom to switch from category to category, and *adaptive flexibility*, or the ability to devise unusual types of solutions (relative to the frequency of response occurrences in the general population). Guilford (1959) also concluded, as did Hudson (1966) in his later work, that creative individuals are far more characterized by “divergent” thinking (“a type of thinking in which considerable searching about is done and a number of answers will do”) than by “convergent” thinking (“thinking toward one right answer”).

More recently, several researchers have shown that manic patients, unlike normal individuals or patients with schizophrenia, tend to exhibit pronounced *combinatory thinking*. Characterized by the merging of “percepts, ideas, or images in an incongruous fashion,” the ideas formed in this way become “loosely strung together and extravagantly combined and elaborated” (Shenton et al., 1987; Solovay et al., 1987). Manic subjects show highly combinatory thought patterns—often characterized by humor, flippancy, and playfulness—in sharp contrast to the response patterns exhibited by normal subjects and by patients with schizophrenia (see Chapter 2, particularly Table 2-4).

Andreasen and Powers (1975) compared manic patients, schizophrenic patients, and writers from the University of Iowa Writers' Workshop on measures of conceptual overinclusiveness (the tendency to combine test objects into categories in a way that tends to "blur, broaden, or shift conceptual boundaries"). They hypothesized that creative writers might show thinking styles similar to those seen in schizophrenic individuals, but this notion was found to be groundless; instead, they observed that the writers showed conceptual styles quite like those of the manic patients: "Both writers and manics tend to sort in large groups, change dimensions while in the process of sorting, arbitrarily change starting points, or use vague distantly related concepts as categorizing principles" (p. 72). The subjects differed primarily in the degree of control they were able to exert over their patterns of thought, with the writers able to carry out "controlled flights of fancy during the process of sorting, while the manics tend to sort many objects for bizarre or personalized reasons" (p. 72).

Schulberg (1990) found that several hypomanic traits contributed to performance on tests measuring creativity; of particular relevance here, he found that creative cognition was far more similar to hypomanic flight of ideas than to the loose associations that are characteristic of schizophrenia. Relatedly, people having strong emotional responses in general, who also tend to score higher on measures of being at risk for developing bipolar illness, often have more elaborate and generalizing cognitive operations (Larsen et al., 1987). Early studies had found that rhymes, punning, and sound associations increase during mania, and that many patients spontaneously start writing poetry while manic (Kraepelin, 1921; Murphy, 1923). Welch and colleagues (1946), in an early study of associational fluency in 101 inpatients at the Payne Whitney Psychiatric Clinic, found that patient groups that would today be called bipolar scored higher when elated than other clinical groups; all patient groups scored higher when elated than when less elated (see Table 12-7).

Nearly 150 years ago, Richarz noted that "in mania thoughts tend to form strings of ideas . . . that link together by their content, alliteration, or assonance. In racing thoughts, the ideas come and go rapidly as if they were hunting each other or continuously overlapping without any link between them" (1858; quoted in Koukopoulos and Koukopoulos, 1999, pp. 557–558). The predominant difference between the two states described is mood; that is, the elated mood of mania probably is more likely to result in a linking of ideas than is the dysphoria associated with racing thoughts.

Likewise, in studies of word-associational patterns, researchers have found that the number of original responses

TABLE 12-7. Average Score on the Association Test for Elated and Nonelated Patients When Classified According to Clinical Groups

Clinical Group	Mean Score When Elated	Mean Score When Not Elated
Anxiety neurosis	—	3.5
Depression	—	2.3
Manic excitement	8.8	—
Manic-depressive	9.9	4.2
Manic-depressive, psychopathic	7.6	3.1
Paranoid reaction	—	5.4
Psychopathic personality	4.3	2.8
Schizophrenia	6.9	3.8
All groups	7.9	3.2

to a word-association task (in which an individual is asked to give as many associations as possible for a particular word) increases three-fold during mania; the number of statistically common, or predictable, responses falls by approximately one-third (Henry et al., 1971; Pons et al., 1985). Henry and colleagues (1971) found that the change in word-association patterns was directly proportional to the severity of manic symptoms. Other researchers have found that acutely manic patients score much higher on a word-association task than patients acutely ill with schizophrenia or control subjects (Levine et al., 1996) (see Fig. 12-8). Hypomania also has been found to increase intellectual functioning on the Wechsler Adult Intelligence Scale (Donnelly et al., 1982). Many mood-induction studies have shown that a strongly positive, or "up," mood facilitates creative problem solving⁶; relatedly, the majority of the British writers and artists in Jamison's (1989) study reported pronounced elevations in mood just prior to their periods of intensive creative activity. Richards and Kinney (1990) at Harvard found that the overwhelming majority of bipolar patients they studied reported being in a mildly or very elevated mood when experiencing their greatest periods of creativity. Several features closely linked to elevated mood states in their subjects clearly overlapped with those found in the British writers and artists; these included

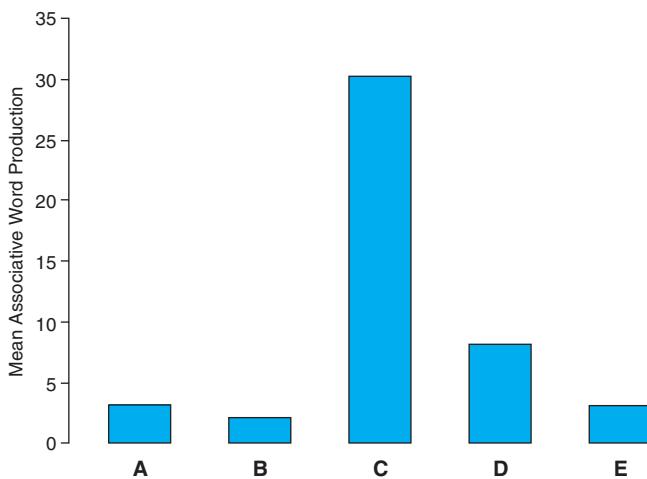

Figure 12-8. Mean associative word production—differential findings in acute manic versus acute schizophrenic patients. Given for each group are mean (\pm standard error [SE]) of associative words produced to 12 stimulus words. Mean associative word production by bipolar patients with acute mania (C) was higher in a statistically significant manner than in patients with acute schizophrenia (D) ($t=2.43$, $p<.05$). Both patients with mania and patients with acute schizophrenia showed significantly higher associative word production than control subjects (A) ($t=4.5$, $p<.001$; $t=4.5$, $p<0.001$, respectively). Patients with unipolar depression (B) or residual schizophrenia (E) showed mean associative word production similar to the control values. (Source: Levine et al., 1996. Reproduced with permission from Karger Publishing.)

increased speed of association, ease of thinking, new ideas, and expansiveness. Although the tendency has been to assume that creative periods lead to “high” or elevated moods and noncreative periods to depressed ones, the results of these studies suggest that the reverse may be true. It may be that elevations in mood such as those caused by hypomania result in more creative thought; likewise, depressed mood and thinking usually lead to periods relatively bereft of creative work.

In all these facets of creative thought, the elements of fluency and flexibility of cognitive processing are emphasized. Clearly, the mere quickening and opening up of thought in an otherwise unimaginative person will not result in creative achievement. If the cognitive processes of an otherwise creative individual are hastened and loosened by hypomania, however, a qualitatively different result may well emerge. Hyperacusis, so often experienced during manic states, may contribute to creativity as well. Characteristics of a noncognitive nature—such as boldness, grandiosity of spirit and vision, disinhibition, impatience, abandonment of normal judgment and restraint, and recklessness—also link bipolar illness and creative accomplishment. The temperamental characteristics observed to be common in highly creative individuals—persistence, wit, self-confidence, a

pleasure in taking risk, high energy, independence, exuberance, rebelliousness, and playfulness⁷ are also characteristic of many who have hypomanic and cyclothymic temperaments. Stanford researchers, for example, found that bipolar patients and highly creative individuals have more personality traits in common than do healthy normal controls and creative individuals (Nowakowska et al., 2005; see also Jamison, 2004).

It may be that the combination of experience, potentiating personality characteristics (see Chapter 10), and cognitive changes that occur during hypomania and may facilitate original thought gives rise to a subgroup of individuals with bipolar illness that is unusually creative. Two critical components of creativity—an independent, risk-taking, restless, and enthusiastic personality, and a fluent, disinhibited cognitive style—are found at an increased frequency in the bipolar population, thus producing some of the conditions that may lead to a disproportionate rate of creativity in a group otherwise characterized by damaging moods and behavior. Recent research lends credence to the importance of disinhibition, or an openness to incoming stimuli from the surrounding environment, to creativity. Carson and colleagues (2003), for example, found that highly creative Harvard students were seven times more likely to have low inhibition scores than less creative Harvard students. The investigators hypothesized that low inhibition, when coupled with extreme flexibility of thought, may lead to mental illness in some individuals and to creative accomplishment in others. Presumably it could also lead to the coexistence of creativity and mental illness in yet others. Likewise, the ability to function well on a few hours of sleep and to work at a high energy level are integral to most hypomanic states; they are also integral to putting ideas into action. In her studies of outstanding artists and scientists, for example, Anne Roe (1946, 1951, 1952) found one trait that stood out: the willingness and ability to work hard and to work long hours.

Throughout this book, we stress the recurrent, cyclic nature of manic-depressive illness—its natural course, pathophysiology, subjective experience, and seasonal and diurnal patterns. Integrally linked to this conception and of particular consequence here is the significance of contrasting, recurrent mood states. Cyclic patterns are common to both mood disorders and the nature of creative work. The ebbing and flowing character of inspiration, described so often, bears a striking resemblance to changes from the vitality to nonvitality of different seasons, death and rebirth, and the antithetical qualities of the bipolar mood states.

Clinical characteristics such as changes in mood, thinking, energy, and behavior are usually opposite in mania and depression. This is true for linguistic and artistic patterns as

well. Manic patients, for example, tend not only to speak more and more rapidly, but also to use more colorful and powerful speech, including more action verbs and adjectives (see Chapter 2). Artistic expression also changes across mood states (see Table 12–8 and Plates 15–18). Manic patients tend to use vivid and highly contrasting colors; depressed patients, on the other hand, use primarily black and cold, darker colors (when the depression begins to clear, the palette tends to lighten accordingly). The content of paintings produced during mania tends to be more sexual, filled with motion and bright portrayals of natural phenomena such as fires, waterfalls, and landscapes; in contrast, paintings done during the depressed phase tend

to show a paucity of ideas, a lack of motion, and themes of death and decay. Paintings produced by manic patients are usually done rapidly and impulsively and often have an agitated or swirling quality; paintings produced by depressed patients are relatively barren, are painted slowly, and exhibit less imagination. The contrasting nature of the elated and depressive states provides, for those with artistic or literary ability, a rich variety of experiences and sensations from which to create.

The ability to reconcile opposite states, whether they are of mood, thought, or vitality, is critical to any creative act.⁸ Thomas Moore (1832), himself a poet, described this ability in his friend Byron:

TABLE 12–8. Artistic Expression during Mania and Depression

Feature	Mania	Depression
Color	Vivid, hot, sharply contrasting (Zimmerman and Garfinckle, 1942); wild (Reitman, 1950); highly colored, without the time to use a variety of colors (Dax, 1953); vivid (Plokker, 1965); bright, warm, optimistic (Enâchescu, 1971); color did not differentiate manic patients as a diagnostic group (Wadeson and Carpenter, 1976).	Somber (Reitman, 1950); somber, usually black with upper portion darkest (Dax, 1953); dark colors, upper portion of picture generally darker than lower, lightening of palette as depression begins to clear (Plokker, 1965); dark, dirty, cold, somber (Enâchescu, 1971); bipolar more colorful than unipolar (Wadeson and Carpenter, 1976).
Content	Sexual, setting sun, orifices (Zimmerman and Garfinckle, 1942); often obscene (Dax, 1953); flowers, landscapes, sunrises, fires, waterfalls, animals, people, dance scenes (Enâchescu, 1971).	Poverty of ideas (Reitman, 1950); immobile figures with sunken heads, signs of death, starless nights rather than days, trees broken off, no flowers (Dax, 1953); representations of delusions (sin, poverty, hypochondriasis), torture, suicide (Plokker, 1965); mourning scenes, physical or moral disaster, abandonment, physical decompensation (Enâchescu, 1971).
Affect	Positive, assured (Zimmerman and Garfinckle, 1942); excitement (Reitman, 1950); careless (Dax, 1953); euphoric (Enâchescu, 1971).	Useless, depressive, cold, gloomy (Enâchescu, 1971).
Form and activity	Extreme agitation, productive, fluid composition, swirl-like forms (Zimmerman and Garfinckle, 1942); restless, disordered, incoherent lines (Reitman, 1950); rapidly produced, lacking in restraint (Dax, 1953); deterioration in composition (Plokker, 1965); rapid and expansive, far more productive than in depressed phase; lines are rash, thick, and crossed (Enâchescu, 1971).	Barenness and lack of detail (Dax, 1953); rarely engaged in artistic activity (Plokker, 1965); less creative activity (Enâchescu, 1971).

It must be perceived by all endowed with quick powers of association how constantly, when any particular thought or sentiment presents itself to their minds, its very opposite, at the same moment, springs up there also; if anything sublime occurs, its neighbour, the ridiculous, is by its side; across a bright view of the present or the future, a dark one throws its shadow; and, even in questions respecting morals and conduct, all the reasonings and consequences that may suggest themselves on the side of one of two opposite courses will, in such minds, be instantly confronted by an array just as cogent on the other. A mind of this structure—and such more or less, are all those in which the reasoning is made subservient to the imaginative faculty—though enabled, by such rapid powers of association, to multiply its resources without end, has need of the constant exercise of a controlling judgment to keep its perceptions pure and undisturbed between the contrasts it thus simultaneously calls up.

The manic-depressive, or cyclothymic, temperament carries with it the capacity to react strongly and quickly; it is, in a biological sense, an alert and excitable system. It responds to the world with a wide range of emotional, perceptual, intellectual, behavioral, and energy changes, and it creates around itself both the possibilities and chaos afforded by altered experiences and fluctuating tempos. The constant transitions can be painful and confusing. Such chaos in those able ultimately to transcend it or shape it to their will can, however, result in an artistically useful comfort with transitions, an ease with ambiguities and with life on the edge, and an intuitive awareness of the coexisting and oppositional forces at work in the world.

Of interest, two recent studies found increased cyclothymia in creative individuals (Akiskal et al., 2005; Nowakowska et al., 2005). The relationship between the cyclic and contrasting nature of manic-depressive illness and creative work is discussed in much further detail by Jamison (1993).

Experiences Derived from Having the Illness

I do strongly feel that among the greatest pieces of luck for high achievement is ordeal. Certain great artists can make out without it, Titian and others, but mostly you need ordeal. My idea is this: The artist is extremely lucky who is presented with the worst possible ordeal which will not actually kill him. At that point, he's in business. Beethoven's deafness, Goya's deafness, Milton's blindness, that kind of thing. And I think that what happens in my poetic work in the future work will probably largely depend not on my sitting calmly on my ass as I think, "Hmm, hmm, a long poem again? Hmm," but on being

knocked in the face, and thrown flat, and given cancer, and all kinds of other things short of senile dementia. At that point, I'm out, but short of that, I don't know. I hope to be nearly crucified.—John Berryman (1976, p. 322)

Berryman, a contemporary of Robert Lowell and Theodore Roethke, was, like them, a winner of the Pulitzer Prize for poetry and someone who suffered from bipolar illness. At the end of a full but highly painful and tumultuous life, he committed suicide (as had his father and aunt before him). He was far from alone in believing that suffering could be conducive to creative work. Learning through intense and deep emotional experiences and using that learning to add meaning and depth to creative work is probably the aspect of the relationship between mood disorders and accomplishment most widely accepted and written about. The influence of pain's dominion fills novels, biographies and autobiographies, sermons, and canvases; there is no shortage of portrayals.

Profound depression or the suffering of psychosis can, and often does, fundamentally change expectations and beliefs about the nature and length of life, God, and other people. Many writers have described the impact of their long periods of depression, how they have dealt with them, and how they have used them in their work. Anne Sexton, a contemporary of Lowell, Roethke, and Berryman, was also a Pulitzer Prize winner in poetry and someone who almost certainly had bipolar illness. After many hospitalizations for both mania and depression, she, like Berryman, committed suicide. She described the importance of using pain in her work:

I, myself, alternate between hiding behind my own hands, protecting myself any way possible, and this other, this seeing ouching other. I guess I mean that creative people must not avoid the pain that they get dealt. . . . Hurt must be examined like a plague. (Sexton and Ames, 1977, p. 105)

Robert Lowell, who wrote of depression, "I don't think it a visitation of the angels but a weakening in the blood," also wrote:

Depression's no gift from the Muse. At worst, I do nothing. But often I've written, and wrote one whole book—*For the Union Dead*—about witheredness. . . . Most of the best poems, the most personal, are gathered crumbs from the lost cake. I had better moods, but the book is lemony, soured and dry, the drought I had touched with my own hands. That, too, may be poetry—on sufferance. (quoted in Giroux, 1987, p. 287)

Both Lowell and Sexton wrote of their heightened psychological sensitivity and vulnerability in graphic and quite similar physical metaphors: "seeing too much and feeling

it/with one skin-layer missing" (Lowell) and "even illusion breaks its filament wings/on the raw skin of all I wouldn't know" (Sexton).

Hypomania and mania often generate ideas and associations, propel contact with life and other people, induce frenzied energies and enthusiasms, and cast an ecstatic, rather cosmic hue over life. Melancholy, on the other hand, tends to force a slower pace; cools the ardor; and puts into perspective the thoughts, observations, and feelings generated during more enthusiastic moments. Mild depression can act as ballast; it can also serve a critical editorial role for work produced in more fevered states. Depression prunes and sculpts; it also ruminates and ponders and, ultimately, subdues and focuses thought. It allows structuring, at a detailed level, of the more expansive patterns generated during hypomania.

Relative Importance of Different Aspects of the Illness to Various Types of Accomplishment

Changes brought about by bipolar illness—during hypomania, mania, depression, and normal states—produce different advantages and disadvantages in various fields of creative work and other types of accomplishment. Although there are no systematic data, a review of available studies strongly suggests that the actual prevalence of bipolar illness is distributed unequally across professions; for example, poets appear to have an unusually high rate, scientists a lower one. To a poet, the cognitive, energy, mood, and experiential advantages of the elated and depressive states may outweigh the disruptions, chaos, turmoil, and inconsistent productivity that would be insurmountable to most scientists. Pragmatic issues of education and job requirements also probably affect the rates of bipolar illness in various occupations. Composers and poets, while increasingly likely to obtain graduate levels of education or professional training, do not absolutely require it. On the other hand, medical and graduate schools—particularly those with highly structured programs, such as those for medicine and law—tend to select students who, by and large, have demonstrated an ability to conform to strict requirements for consistently high levels of performance over long periods of time. This may well exclude many individuals at risk or those with an actual history of bipolar illness, since they are more likely to show greater variability in their performance across seasons and years.

The risk period for a first manic or depressive episode overlaps considerably with the period of advanced education, eliminating some bipolar individuals from being selected. Further selection bias exists in the decisions made about those individuals who have actually had an

affective episode, especially a manic one, while in training. The professional consequences of a psychotic break are generally different for those in medicine, clinical psychology, nursing, or law school than they are for those writing poetry or composing music.

Even within the field of literary accomplishment, differences in the characteristics of bipolar illness are likely to produce relative gains and losses for various types of writers. Poets may benefit much more than novelists from mood and cognitive changes, for example, because the language and rhythms of poetry are more akin to primitive thought processes and psychosis and because the nature of sustained work is probably different in poetry and fiction.

Certain aspects of bipolar illness probably are important and helpful in other fields of accomplishment as well. It is likely that mood changes (elevated and expansive mood, inflated self-esteem, increased enthusiasm, increased emotional intensity, and infectious mood) are equally, if differently, important to those who create and to those in business or positions of leadership. This is probably true as well for increased energy levels and a decreased need for sleep. On a very general level, however, cognitive changes (sharpened and unusually creative thinking, flight of ideas, and hyperacusis) are likely more useful to those in the arts and sciences than to those in positions of political and military leadership. Conversely, interpersonal changes brought about by hypomania (enhanced liveliness, uninhibited people seeking, interpersonal charm, the ability to find vulnerable spots in others and to make use of them, increased perceptiveness at the subconscious or unconscious level, and increased social ease) are probably more likely to benefit those in leadership positions than those in the arts and sciences.

IMPORTANCE OF STUDYING POSITIVE ASPECTS OF MANIC-DEPRESSIVE ILLNESS

Although it certainly is possible to exaggerate or romanticize the positive aspects of mood disorders, it is important not to minimize their beneficial features or deal with them in only a perfunctory way. Understanding the assets that may accompany manic-depressive illness—the characteristics linking it to the arts, leadership, and society at large—is important to a thorough understanding of the illness. Three principal areas of consideration are relevant to the study of the positive features of manic-depressive: theoretical, clinical, and social–ethical.

Theoretical Considerations

Positive aspects of manic-depressive illness, including associations with accomplishment, are, of course, interesting in their own right. At first glance, the notion of advantage

gained from an otherwise catastrophic illness may appear counterintuitive, yet both history and clinical experience affirm the reality of this paradox. The association may be an infrequent one, but it is important. Most clinical research understandably has focused on the depressive spectrum and given relatively little emphasis to the manic continuum. There has been next to no study of the spectrum of elated states most relevant to the discussion here. Of the many still unexamined aspects of bipolar illness that could profitably be studied, its positive features are particularly germane. There has been little research into subtle oscillations in perception, mood, behavior, and cognition across the elated states. Quantitative and qualitative differences between the milder hypomanias and manias also require more study. Likewise, we need to learn to differentiate characteristics of high-functioning normal individuals—those with decreased need for sleep coupled with high energy, productivity, and mood—from the characteristics of individuals with hyperthymia, cyclothymia, or bipolar illness.

The existence of elated states also provides an opportunity for cognitive psychologists to study a long-standing theoretical question: Does cognition precede or follow mood change? The considerable body of literature on this question is based on studies of depression and, because of psychological assumptions about etiology, tends to assume that cognitive changes precede—indeed cause or facilitate—depressive affect. Similarly, many creative individuals and students of creativity assume that inspiration, creative ideas, and fluency of thinking precede euphoric affect. That is, many believe that the creative act generates euphoria, not that heightened mood facilitates the increased flow of thoughts and ideas. Notwithstanding these assumptions, evidence indicates that in a sizable proportion of highly creative writers and artists, elevated mood changes precede cognitive and behavioral changes, and that intense creative episodes are, in many instances, indistinguishable from hypomania (Richards and Kinney, 1990; Schulberg, 1990; Jamison, 1993, 2004).

Yet another important theoretical issue, one with enormous practical ramifications, centers on the highly seductive, if not actually addictive, qualities of the elated or euphoric states. Such altered states of consciousness and mood can be highly potent reinforcers during euthymic or depressed periods, creating in some patients a strong desire to induce or recreate such conditions. This phenomenon is roughly analogous to drug self-administration, in which a highly pleasurable and often immediate state can be obtained. Thus for some patients, the positive aspects of the illness may be similar to stimulant addiction.

Clinical experience suggests that patients may attempt to induce mania by discontinuing lithium not just at times when they are depressed but also when they face problematic

decisions and life events. Because the negative consequences are delayed, it is not always clear to the patient that the costs outweigh the benefits. The clinical implications of this phenomenon are discussed in the next section and in Chapters 21 and 22. Here it is important to mention that the addictive or addictive-like qualities of the elated states raise fascinating issues about the means used to self-induce these states (sleep deprivation, medication nonadherence, or psychological means), the relevance of this phenomenon to kindling models, and, of course, the use of cocaine and other stimulants to self-medicate or to induce euphoric and high-energy states. The high rate of affective illness in cocaine abuse (see Chapter 7) may reflect not only self-medication per se, but also an attempt to recapture a known, previously experienced and highly pleasurable mood state, a reality that makes bipolar individuals perhaps uniquely vulnerable to cocaine addiction on both psychological and biological grounds.

Clinical Considerations

The existence of potentiating positive features in bipolar illness, perceived to be or actually associated with increased creativity and productivity, affects the willingness of some afflicted with the illness to seek and comply with treatment. Many highly accomplished individuals in the arts, the sciences, and business are reluctant to seek treatment for their mood disorders because they are reluctant to give up the edge they feel they obtain from it. Others view their serious mood problems as part of the human condition, the price one pays for being “too sensitive,” having an artistic temperament, or leading an artistic lifestyle. Indeed, many such individuals see emotional turmoil as essential to their identity as performing or creative artists. Additionally, many writers and artists are concerned that psychiatric treatment will erode or compromise their ability to create. An appreciation of the potentially productive or “up” side of mood disorders may lead to greater credibility on the part of the treating clinician, as well as a stronger therapeutic bond. Strict adherence to an often arbitrary distinction between psychopathology on the one hand and a chaotic, tumultuous, and artistic lifestyle on the other can lead to unnecessary suffering and treatment resistance.

Writers and artists frequently express concern about the effects of psychiatric treatment on their ability to create and produce; these concerns are especially pronounced when it comes to taking medication. Some of this mistrust no doubt reflects unfounded preconceptions, fears of altering long-established work patterns and rituals, or simple resistance to treatment. In some instances, however, these concerns are grounded in reality. A review of the literature on mood-stabilizing medications reveals disturbingly little research on the effects of the drugs on productivity and creativity.

Even the early lithium researchers were well aware of problems created by lithium's effects on certain useful or enjoyable qualities of the illness (e.g., decreasing or eliminating the highs of hypomania, decreasing sexuality and energy levels), as well as by the drug's untoward side effects (possible cognitive slowing and memory impairment) (see Chapters 9 and 21). Schou (1968, p. 78) described the subjective effects of lithium in three "normal" subjects (medical researchers). This description has relevance to highly creative individuals who are dependent on the mind and the senses for their work:

The subjective experience was primarily one of indifference and slight general malaise. This led to a certain passivity. . . . The subjective feeling of having been altered by the treatment was disproportionately strong in relation to objective behavioral changes. The subjects could engage in discussions and social activities but found it difficult to comprehend and integrate more than a few elements of a situation. Intellectual initiative was diminished and there was a feeling of lowered ability to concentrate and memorize; but thought processes were unaffected, and the subjects could think logically and produce ideas.

It should be noted that Schou's study involved a relatively short-term trial of lithium, and there is some indication that patients partially accommodate to lithium's cognitive effects. Many patients, of course, experience no significant cognitive side effects, and for those who do, the risks of no treatment must always be weighed against those side effects.

What is actually known about the specific effects of lithium and other medications on productivity and creativity? Polatin and Fieve (1971, p. 864) described their clinical experience of using lithium in creative individuals:

In the creative individual who does his best work in the course of a hypomanic period, the complaint regarding the continued use of lithium carbonate is that it acts as a "brake." These patients report that lithium carbonate inhibits creativity so that the individual is unable to express himself, drive is diminished, and there is no incentive. These patients also indicate that when they are depressed, the symptoms are so demoralizing and so uncomfortable that they welcome the "mild high" when the depression disappears and prefer to settle for a cyclothymic life of highs and lows rather than an apathetic middle-of-the-road mood state achieved through the use of lithium carbonate.

Their argument is that if lithium carbonate prevents the high and may possibly prevent the "low," they prefer not to take lithium carbonate, since never to have a high as a result of the drug seems equivalent to being deprived

of an "addictive-like" pleasurable and productive state. Some of these patients are terrified of having a low again, but insist on taking their chances without lithium carbonate therapy, knowing that sooner or later they will be compensated by the high, even if they do go into a low state.

No controlled studies of lithium's effects on productivity have been conducted, but Marshall and colleagues (1970) and Schou (1979) studied a total of 30 artists, writers, and businessmen taking lithium. Their findings are summarized in Table 12-9. More than three-quarters (77 percent) of the patients reported no change or an increase in their productivity while on lithium. Approximately one-quarter reported a decrease. In 17 percent, lithium was seen as leading to problems sufficient to warrant refusal to take it. It is not known how accurately these figures reflect artists and writers at the upper end of creative accomplishment. Most of these subjects, although earning their living by their creative work, were not at that level. Schou (1979) pointed out that lithium may affect inspiration, the ability to execute, or both, and saw the following as contributing factors in a creative individual's response to lithium: the severity of illness, the type of illness, the artist's habits of using manic periods of inspiration, and individual sensitivity to the pharmacological action of the drug.

Three other studies of particular relevance for artistic creativity yielded conflicting results. Judd and colleagues (1977) found no effects of short-term lithium treatment on creativity in normal subjects. A study using bipolar patients as their own controls, however, found substantial detrimental effects of the drug on associational productivity and originality of responses (Shaw et al., 1986; see Fig. 12-9). These differing results may be due in part to the fact that lithium's effect on cognition is probably quite different in bipolar patients and normal controls (Pons et al., 1985). Lithium exerts effects not only on cognition, but also on drive and personality (see Chapter 10); although cognitive side effects are undeniably important to creative work, so, too, are these noncognitive effects. Kocsis and colleagues (1993) found that lithium discontinuation resulted in improvement on memory and creativity measures (although not idiosyncratic word associations), as well as motor performance. In an open, nonrandom case series of seven bipolar patients who reported cognitive dulling during lithium therapy, Stoll and colleagues (1996) concluded that the partial or full substitution of divalproex sodium for lithium as the primary mood stabilizer "reduced the cognitive, motivational, or creative deficits attributed to lithium" (p. 359). To our knowledge,

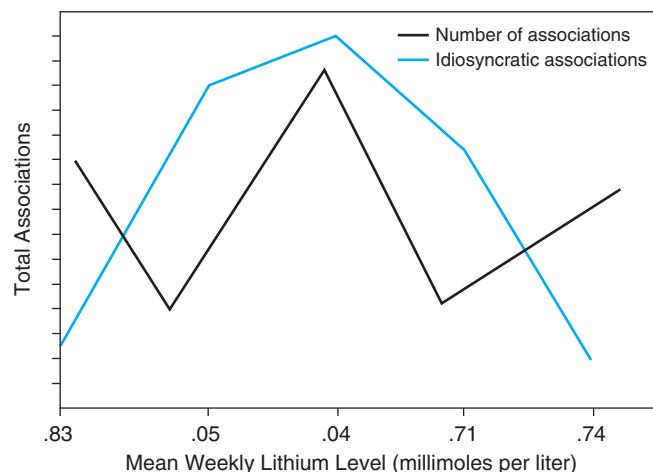

TABLE 12–9. Productivity While Taking Lithium

	Marshall et al. (1970)	Schou (1979)	Combined Number	Combined %
Subjects	6 artists and businessmen	24 artists and writers	30	
Productivity on lithium				
Increased	5	12	17	57
No change	0	6	6	20
Decreased	1	6	7	23
Refused to continue lithium treatment	1	4	5	17

however, there has been no replication of this preliminary finding. Individual differences in clinical state, serum lithium levels, sensitivity to cognitive side effects, and the severity, frequency, and type of affective illness clearly affect the degree to which an individual will experience impairment in intellectual functioning, creativity, and productivity. Artists, writers, and many others who rely on their initiative, intellect, emotional intensity, and energy for their life's work underscore the need for a reexamination of this problem.

Artists and writers represent a group at high risk for affective illness and should be assessed and counseled accordingly. Ideal treatment requires a sensitive understanding

Figure 12–9. Associational patterns and lithium level. (Source: Adapted from Shaw et al., 1986. Reprinted with permission from the *American Journal of Psychiatry*, American Psychiatric Association.)

of the possible benefits of mood disorders to creativity and also the severe liabilities of untreated depression and mania, including the risk of suicide, hospitalization, and substance abuse. Moreover, the clinician must be aware of available medications and side effects that could potentially be damaging to the creative process. Physicians should minimize medication levels whenever possible.

Social and Ethical Considerations

As noted in Chapter 13, genetic research has progressed to the point that ethical issues are now arising about prenatal screening and selective abortion, as well as the identification and treatment of individuals at high risk for developing bipolar illness. It becomes particularly important under these circumstances to have at least some broad notion of the possible benefits, as well as catastrophic outcomes, of bipolar illness not only for potential parents and the unborn child, but also for society at large. The implications of losing societal variance in such basic characteristics as drive, cognitive style, energy, risk taking, and temperament have not yet been examined in any systematic way, although evolutionary perspectives on depression and bipolar illness have been discussed at some length.⁹ Ironically, these issues were considered, to some extent, in the 1930s; in one study, carried out in Germany, the advisability of sterilizing manic-depressive individuals was examined. Luxenburger (1933) found manic-depressive illness to be greatly overrepresented in the higher occupational classes and recommended against sterilizing these patients, "especially if the patient does not have siblings who could transmit the positive aspects of the genetic heritage." Myerson and Boyle (1941, p. 20), in their study of

manic-depressive psychosis in socially prominent American families, concurred:

Perhaps the words of Bumke need to be taken into account before we embark too whole-heartedly on any sterilization program: "If we could extinguish the sufferers from manic-depressive psychosis from the world, we would at the same time deprive ourselves of an immeasurable amount of the accomplished and good, of color and warmth, of spirit and freshness. Finally only dried up bureaucrats and schizophrenics would be left. Here I must say that I would rather accept into the bargain the diseased manic-depressive than to give up the healthy individuals of the same heredity cycle."

Treatable common illnesses such as bipolar illness—ones that may confer societal and individual advantage and that vary greatly in the nature of their expression and their severity—are particularly problematic. Francis Collins (1990), director of the U.S. National Human Genome Research Institute and a scientist who was instrumental in identifying the genes for cystic fibrosis and neurofibromatosis, was asked in an interview about prenatal testing for diseases that vary in severity or that first occur only later in life:

This is where it gets muddy, and everyone is going to draw the line differently. Consider the situation with manic-depressive illness, a reasonably common disorder. It is clearly genetically influenced, though not in a simple way. Now, manic-depressive illness can be a terrible cross to bear. The swings into depression are awful, and the highs can be very destructive. Yet a substantial number of highly creative people have suffered from this disease. Suppose we find the gene responsible for manic depression. If every couple has a prenatal test to determine if a fetus is at risk for manic depression, and if every time the answer is yes that fetus is done away with, then we will have done something troubling, something with large consequences. Is this what we want to do?

CONCLUSIONS

There is strong scientific and biographical evidence linking mood disorders to artistic creativity. Biographies of eminent poets, composers, and artists attest to the prevalence of extremes of mood in creative individuals. Systematic studies are increasingly documenting the link as well. It should be emphasized, however, that most creative writers, artists, and musicians have no significant psychopathology. Conversely, most individuals with manic-depressive illness are not unusually creative.

We have considered the issue of the reliability—indeed, the advisability—of making a posthumous diagnosis of

manic-depressive illness. This concern is important and valid. Labeling as manic-depressive anyone who is unusually creative, accomplished, energetic, intense, moody, or eccentric both diminishes the notion of individuality within the arts and trivializes a very serious, often lethal illness. We have been careful to base our conclusions and suggestions on what is known clinically and scientifically about depression and bipolar disorder.

That the illness and its related temperaments are associated with creativity appears clear; the clinical, ethical, and social implications of this association are less so. We have tried to convey that bipolar disorder and depression are destructive, painful, sometimes fatal, and yet intriguing and important illnesses. In the great majority of instances, the effective treatments now available will not hinder creative ability. Indeed, treatment almost always results in longer periods of sustained productivity. One of our concerns, however, remains the study, public discussion, and development of treatments that will minimize the side effects of currently available medications.

The neurochemical and anatomical processes responsible for the cognitive changes occurring during manic and highly creative states are poorly understood. It remains for molecular biology, neuropsychology, and quickly evolving neuroimaging techniques to provide us with a more sophisticated understanding of the underlying changes in thought and behavior that are enhanced, left unaffected, or impaired by shifting patterns of mood (see, e.g., Hoffman et al., 2001; Folley et al., 2003; Ghacibeh et al., 2006).

Perhaps some suffering must always accompany great artistic achievement. Certainly, depth and intensity of human feeling must be a part of creation in the arts. But modern medicine now allows relief of the extremes of despair, turmoil, and psychosis. It allows choices not previously available. Most of the writers, artists, and composers discussed in this chapter had no such choices.

NOTES

1. George Gordon, Lord Byron. "Manfred," act II, scene 4, lines 160–161. *Lord Byron: The Complete Poetical Works*, vol. 4, p. 86. Edited by Jerome J. McGann. Oxford: Clarendon Press, 1986.
2. Much of the discussion of manic-depressive illness and creativity in this chapter is based on Jamison's elaboration, in *Touched with Fire*, of the arguments originally presented in the first edition of *Manic-Depressive Illness*.
3. Fully 70 to 90 percent of all suicides are associated with bipolar or depressive illness; therefore, if an individual has died by suicide, it is usually the case that a mood disorder was at least contributory.
4. An episodic, cyclic course of symptoms with normal functioning in between; usual onset of symptoms in the late

teens or early twenties, with temperamental signs often exhibited much earlier; seasonal aspects to the mood and energy changes; and if untreated, a worsening of the illness over time. (See Chapter 4.)

PART IV

PATHOPHYSIOLOGY

This page intentionally left blank

That other inward, inbred cause of melancholy is our temperature, in whole or part, which we receive from our parents . . . such as the temperature of the father is, such is the son's, and look what disease the father had when he begot him, his son will have after him, "and is as well inherited of his infirmities as of his lands."

—*Robert Burton (1621, p. 211)*

A generation ago, few mental health professionals believed that inherited vulnerabilities could be central to the development of psychiatric illness. Fearing that discovery of a genetic diathesis might cast a stigma on patients and lead to therapeutic nihilism, many clinical observers found social and developmental reasons to explain the inescapable fact that mental illness runs in families. Gradually, the genetic evidence became too compelling to ignore. Recent advances in the molecular genetics of several neuropsychiatric diseases, particularly the discovery of linkage and association of deoxyribonucleic acid (DNA) markers with the bipolar subtype of manic-depressive illness, appear to reaffirm the older evidence. If, as expected, particular gene variants are definitively implicated in manic-depressive susceptibility, better understanding of pathophysiological mechanisms should follow.

Along with its theoretical importance, knowledge of genetics has practical relevance, and the new discoveries could result in new diagnostic tests and improved treatment methods. Clinicians now use family histories to help diagnose an illness correctly and to manage psychotropic medications properly. They also need a familiarity with the most up-to-date evidence to answer the questions of an increasingly sophisticated population of patients, relatives, spouses, and prospective spouses requesting genetic counseling.

At present, the most clinically useful evidence for genetic transmission continues to be the traditional genetic-epidemiological findings from twin, family, and adoption studies. In addition to demonstrating genetic transmission, the genetic-epidemiological data suggest the degree to which illness in the population is familial, and they help specify diagnoses that aggregate together. The role of age, gender, and other demographic and sociocultural vari-

ables can also be clarified from this evidence. Genetic-epidemiological studies of diagnosis do not, however, allow one to identify the mode of genetic transmission in recurrent affective disorder. And neither they nor pedigree studies illuminate other important genetic issues: Is there biological heterogeneity? What is the pathophysiological inherited process in an illness? Where on the gene map is the disease locus (or loci)? What are the gene defects? To answer these questions, pathophysiological and genetic linkage studies are needed.

The focus here is on bipolar forms of manic-depressive illness, but we consider the central question of the genetic relationship between bipolar and recurrent unipolar subgroups, particularly the more highly recurrent forms. A common genetic diathesis for both bipolar and recurrent unipolar disorders would suggest that the correct conceptual model for these illnesses is the spectrum or continuum model in which recurrence (cyclicity) is fundamental to what is being transmitted. Different risk genes, however, would argue for a categorical model of discrete and independent affective disorders defined by clinical diagnosis (see Chapters 1 and 3). More careful quantification of the degree of recurrence in bipolar and (especially) unipolar samples might allow one to address new questions such as whether the genetic diathesis for bipolar disorder has more to do with recurrence (cyclicity) or polarity (as is often simply assumed) (see Chapter 1).

This chapter begins with a brief review of major developments in the history of the study of genetics. We then turn to a summary of the findings of family, twin, and adoption studies that make up the literature on the genetic epidemiology of manic-depressive illness, studies that attempt to determine whether the illness is heritable, as well as the mode of its inheritance. Next we summarize recent

advances made in understanding the human genome and the nature of genes to set the stage for an examination of the various molecular methods used in attempting to locate the genes for manic-depressive illness and the results stemming from their use. Four such methods are then reviewed: (1) the linkage method, used to identify a chromosomal region that harbors a susceptibility gene; (2) alternative phenotypic definition, which attempts to identify homogeneous clinical subtypes of manic-depressive illness; (3) the association method, an alternative to the linkage method for identification of disease genes; and (4) consideration of alternative genetic mechanisms, an approach that uses clues, both biological and clinical, to home in on genes with unique features potentially relevant to manic-depressive illness. We follow this review with a discussion of gene expression and pathogenesis—a topic that takes the argument for the involvement of a gene in manic-depressive illness beyond statistical association to the field of neurobiology. Next we address pharmacogenetics, or the clinical observation of inherited differences in drug effects, and genetic counseling, which is aimed at helping concerned parents address vulnerabilities they may pass on to their children. Finally, we look to the future, examining research directions and prospects for patients as the study of the role of genetics in manic-depressive illness builds on the work reviewed in this chapter.

HISTORY OF THE STUDY OF GENETICS

Early Observations

Though the twisted, or helical, structure of DNA was not discovered until 1953, the observation that traits run “in the blood,” or in families, was first made in antiquity. Lucretius, a Roman who lived from 94 BC to 55 BC, wrote, for example, that “children are born like the mother, thanks to the mother’s seed, just as the father’s seed makes them like the father. But those whom you see with the form of both, mingled side by side the features of both parents, spring alike from the father’s body and the mother’s blood” (quoted in Mellon, 1996, p. 13).

The recognition of a hereditary component to mental illness dates back at least as far as the Renaissance. In 1520 the Swiss physician Paracelsus wrote *Diseases Which Lead to a Loss of Reason*, in which he described a subgroup of the “truly insane,” which he called the *insani*: “*Insani* are those who have been suffering from it since birth and have brought it from the womb as a family heritage . . . [T]he circumstance is such that if there is insanity in the brain, the child’s mother also has some deficiency in her brain, for the brain of the parents is continued in the brain of the son.” Paracelsus went on to make note of the apparent

complexities of the hereditary influence on insanity: “This [hereditary transmission] does not always happen because the sperma become mixed, and either the man or the woman may or may not be insane, and the child may follow the insanity or take after the one who has the greater influence. It may even happen that if both [parents] are insane they still would give birth to a healthy child” (quoted in Mellon, 1996, p. 21).

In his book *The Anatomy of Melancholy*, published in 1621, Robert Burton wrote of the familial nature of depression in particular: “Their voice, pace, gesture, looks, is likewise derived with all the rest of their conditions and infirmities; such a mother, such a daughter . . . I need not therefore make any doubt of Melancholy, but that it is a hereditary disease” (quoted in Mellon, 1996, p. 25). The familial nature of mania was evident to some early observers as well. Philippe Pinel, a French psychiatrist who is considered one of the founders of modern psychiatry, wrote in his 1809 textbook on mental illness: “It would be difficult not to concede a hereditary transmission of mania, when one recalls that everywhere some members of certain families are struck in several successive generations” (quoted in Shorter, 1996, p. 29).

The Birth of Genetics

The birth of modern genetics dates to 1865. In that year the Austrian monk Gregor Mendel presented the results of his studies of traits in pea plants under the title *Experiments in Plant Hybridization*. His experiments led to the following conclusions: (1) distinct traits, such as length of the stem and color of the seed, assort themselves independently; (2) each trait exists in alternative forms, and each individual has two forms (or factors), such as that for tall and for short, or for purple and for white, and these factors separate (or segregate) independently rather than blending together; and (3) one factor is dominant over the other (which is recessive), so that if the dominant factor is present, it will be expressed. Though ignored for many years, this work was rediscovered and confirmed in 1900.

The first demonstration of a Mendelian trait in man was the report in 1902 by Archibald Garrod at St. Bartholomew’s Hospital in London that alkaptonuria, a disease characterized by dark urine, followed a recessive pattern of inheritance. Garrod later described this as an “inborn error of metabolism.” The field of medical genetics—founded in England by, for example, Ronald Fisher, J.B.S. Haldane, Lionel Penrose, and John Roberts and developed in the United States by others, such as James Neel (University of Michigan) and Victor McKusick (Johns Hopkins)—was built on Garrod’s conception of genetic disease.

From the 1860s through the turn of the century, DNA and chromosomes were discovered, and it was proposed

that chromosomes could bear the Mendelian factors. What Mendel called factors would come to be known as *genes*, and the alternative forms of each factor were dubbed *alleles*. (An allele is defined as an alternative form of a genetic locus; a single allele for each locus is inherited from each parent.) In the same period, the Englishman Francis Galton pioneered the application of statistical methods to the study of biological and mental phenomena, creating a new field called *biometrics*. He first suggested that studies of twins could be employed to disentangle the genetic and environmental contributions to physical and mental traits such as height and intelligence; this work would give rise to the field of statistical genetics.

The German School of Psychiatric Genetics

Emil Kraepelin was a German psychiatrist who gave definition to the current conception of manic-depressive illness in the 1899 edition of his classic textbook on mental disorder, which he wrote during his years as professor at the University of Heidelberg (see Chapter 1). In his chapter on the causes of manic-depressive illness (which included bipolar and recurrent unipolar depression), he stated: “The causes of the malady we must seek, as it appears, essentially in morbid predisposition. . . . Hereditary taint, I could demonstrate in about 80 per cent of the cases [I] observed in Heidelberg” (Kraepelin, 1899, p. 165). He went on to declare that “compared to innate predisposition external influences only play a very subordinate part in the causation of manic-depressive insanity” (p. 127).

Kraepelin founded what has been called the German school of psychiatric genetics (Kallman, 1953, p. 34). Ernst Rudin, a student of Kraepelin’s who later became his deputy, developed this school. Rudin, who conducted and directed family and twin studies of mental illness from about 1913 until the late 1930s, presided over family studies of manic-depressive illness (Banse, 1929; Slater, 1936a,b, 1938), as well as the first twin study to shed light on the illness (Luxenburger, 1928).

Eugenics

Eugenics had its origins in the work of Francis Galton, who believed that genetic selection could be employed to improve the genetic fitness of “the race.” The eugenics movement took hold in many countries around the world, including the United States, where the Cold Spring Harbor Eugenics Records Office was set up in 1905 to gather data on family histories of the “feeble-minded” (among other subjects). The aim of this effort was to reduce the societal load of these illnesses by preventing procreation of the “eugenically undesirable” and limiting their immigration into the country (Kevles, 1995, pp. 56, 92). In Germany, the Society for Race Hygiene was established in 1905, and Ernst Rudin

served the society in numerous roles, including president. Rudin also was an editor of *Archives of Racial and Social Biology* (Weber, 1996). In 1934, after the Nazis’ rise to power, Rudin played a role in shaping the “Law for the Prevention of Progeny with Hereditary Defects,” which allowed for the forced sterilization of people with a number of hereditary diseases, including manic-depressive illness. Over the next 5 years, hundreds of thousands of sterilizations were performed in Germany, and by 1940 mass executions of mental patients had begun, based on selections made by physicians, including psychiatrists (Mellon, 1996, p. 111).

Post–World War II Era

Because the atrocities committed by the Nazis had in part grown out of eugenics principles, there was a massive recoil away from eugenics and, by extension, from genetics, among the psychiatric community in the post–World War II era. This development coincided with the rise of psychoanalysis, which was perceived as offering the possibility of treatment and even cure. By contrast, genetics, and biological psychiatry more broadly, were perceived by some as treating patients like guinea pigs—research subjects from whom something could be learned but for whom little could be done.

Despite this general turning away from psychiatric genetics, a few investigators persisted in their efforts at defining the genetic contribution to manic-depressive illness. Among them were Elliot Slater in England and Franz Kallman, who had left Germany for the United States in 1936, both of whom published family and twin studies of manic-depressive illness in the 1950s. In the late 1960s, interest began to revive in the genetics of manic-depressive illness, as it did in biological psychiatry and in medical genetics generally. This interest has grown enormously in the past decade as the computer-based and molecular tools available to study heredity and the genome have multiplied exponentially.

GENETIC EPIDEMIOLOGY OF MANIC-DEPRESSIVE ILLNESS

The first stage in the study of the genetics of an illness involves defining who is and is not to be considered ill (see Fig. 13–1). In the language of genetics, the question is: “What is the phenotype, or trait, under study?” Clear criteria must be applied in defining the phenotype to maximize the homogeneity of the sample. While the field has in recent years focused mainly on the bipolar-I (BP-I) phenotype, much work has also focused on the broader concept of manic-depressive illness, which encompasses the BP-I, bipolar-II (BP-II), and recurrent major depression phenotypes, along with some studies including schizoaffective

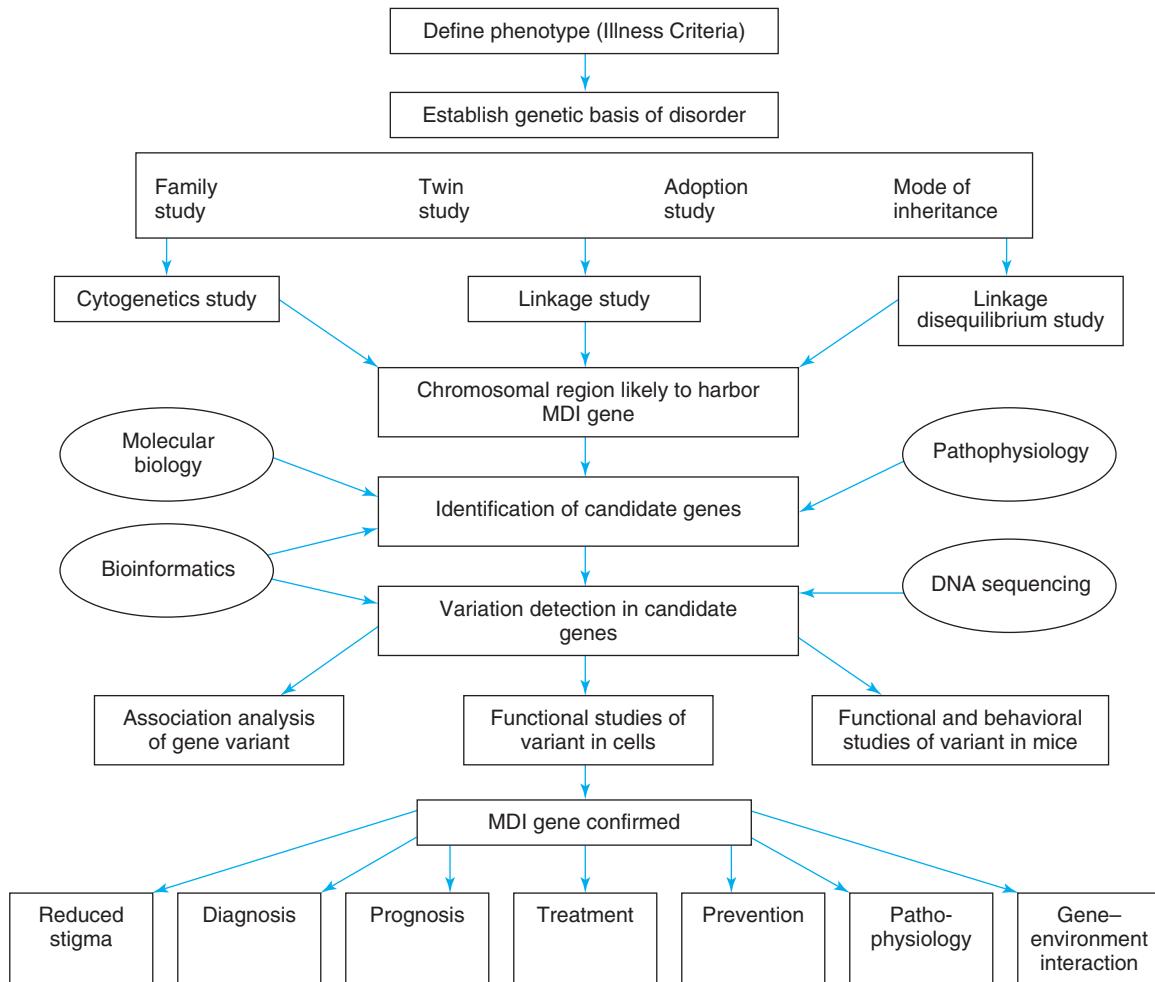

Figure 13–1. The sequence of genetics research on manic-depressive illness (MDI). This figure demonstrates both the historical sequence through which research on the genetics of manic-depressive illness has progressed and the logical sequence of reasoning about gene discovery in the illness. See text for details. (Source: Haines and Pericak-Vance, 1998. Reprinted with permission of John Wiley & Sons, Inc.)

disorder, manic or bipolar type. Systematic case definitions were lacking until the 1970s, when the Research Diagnostic Criteria (RDC) first came into widespread use (Spitzer and Endicott, 1975). Since the 1980s, the *Diagnostic and Statistical Manual* (DSM) has provided the standard diagnostic criteria for genetic studies. We note that while researchers in genetic epidemiology (the term applied to these kinds of studies) have emphasized recurrent unipolar depression when they have studied the relationship of unipolar to bipolar illness, the DSM-III and -IV definitions of major depressive disorder do not require recurrence. Indeed, by separating bipolar disorder out as a separate illness “from the top,” with recurrent unipolar depression (defined perhaps too broadly as simply more than one episode) becoming a tertiary category under depressive disorders, DSM-III and -IV have made it more difficult to conceptualize the relationship between bipolar

disorder and the more recurrent forms of unipolar depression.

The second stage of inquiry involves determining whether the illness is heritable. Only when heritability has been firmly established does it make sense to begin looking for the particular genes responsible for this inheritance. Determination of heritability starts with studies of familial aggregation and proceeds with twin and adoption studies (see Fig. 13–1). Study of the genetic epidemiology of manic-depressive illness also includes research on the mode of inheritance of the illness, through which investigators try to determine how many genes are involved and how they are transmitted within families.

Family Studies

If a disease has a genetic basis, it is expected to run in families. Studies of familial aggregation typically begin with

individuals who have manic-depressive illness—the first such person identified in a family is referred to as a *proband*—and assess whether family members of this proband have unexpectedly high rates of illness. Ideally, to ensure good sensitivity, the needed information is obtained through direct interviews of relatives rather than through family history and/or medical records alone (Andreasen et al., 1986). Clear diagnostic criteria enhance reliability and allow for comparability in replication. Use of a set of families ascertained through a control proband helps reduce diagnostic bias and provides rates against which the ill families can be appropriately compared.

Early studies assessed the morbid risk for manic-depressive illness. Prior to the 1960s, about 14 studies demonstrated the substantial risk of manic-depressive illness in first-degree relatives of probands with the disorder (see Table 13–1). Only since the late 1960s have studies assessed the independent morbid risk for bipolar disorder and for major

depression (see Table 13–2).¹ There have been many studies using bipolar probands; the 12 in which the majority of subjects were directly interviewed are summarized in Table 13–2.² These studies have found rates of 10.7 percent for bipolar illness in relatives of ill probands and 1.0 percent for the illness in relatives of control probands. It is interesting that in the families of bipolar individuals, rates not only of bipolar illness but also of major depression are elevated. Relatives of bipolar probands have a 15.9 percent risk of major depression, while the risk in relatives of controls is 7.3 percent.

The first study to report systematically on manic-depressive illness subtypes essentially as they are currently delineated was that of Gershon and colleagues in 1982. They documented the lifetime prevalence of illness in 1,254 adult first-degree relatives of probands with schizoaffective (11 families), BP-I (96 families), BP-II (34 families), and major depressive (30 families) disorders and in relatives of normal control probands (43 families). This study, performed

Note: The mix of highly recurrent and minimally recurrent patients in the MDD group can obscure the relationship between bipolar disorder and some forms of unipolar depression.

BP=bipolar disorder; MDD=major depressive disorder; SA=schizoaffective disorder; —=not studied or reported.

at the National Institute of Mental Health (NIMH), involved direct interviews of most first-degree relatives using the Schedule for Affective Disorders and Schizophrenia—Lifetime Version, a semistructured interview (Endicott and Spitzer, 1978). Two independent clinicians used a modified version of the RDC to make diagnoses based on these interviews, along with family informant data and medical records. A consensus diagnosis was then established. In calculating the lifetime risk of mood disorders in relatives, the raw data were modified to account for the variable age at onset of the disorders. This was done using the Stromgren method, which weighs the number of people at risk by the proportion of the risk period through which they have passed.

The findings of Gershon and colleagues (1982, 1985, 1986, 1988, 1989) and Gershon and Goldin (1989) provide among the best accounts available of the familial aggregation of affective disorders. The lifetime risk of BP-I among relatives in the BP-I proband families was elevated at 4.5 percent (versus 0 percent in controls). The risk for BP-II among relatives was also elevated in BP-I proband families at 4.1 percent (versus 0.5 percent in controls). Similarly, the risk for major depressive disorder in these families was increased at 14.0 percent (versus 5.8 percent in controls). There was an overall lifetime risk of 23.7 percent for an affective disorder in the first-degree relatives of the BP-I probands compared with a risk of 6.8 percent in the control families. Of interest, the risk for BP-I was also increased in relatives of the schizoaffective probands (10.7 percent); the risk for BP-II was elevated as well in relatives of the BP-II probands (4.5 percent) and schizoaffective disorder probands (6.1 percent); and the risk for major depression was substantial—two to three times that of controls—in relatives of all affected probands. When all families were taken together, children of one affectively ill parent had a 27 percent lifetime risk of affective disorder, compared

with a risk of 74 percent among children of two ill parents (Gershon et al., 1982).

A useful way of estimating the strength of the genetic contribution to illness is to apply the concept of *relative risk* to siblings, which entails comparing the rate of illness in siblings of ill probands with that in the general population. The family studies shown in Table 13–2 demonstrate a relative risk of 10.7 for bipolar disorder in first-degree relatives of bipolar probands.³ This risk is roughly the same as that for schizophrenia, but far below that for single-gene diseases such as phenylketonuria, for which the relative risk to siblings is 2,500.0. The magnitude of the relative risk to siblings suggests that while there is an important genetic contribution to bipolar disorder, other, presumably environmental, factors play a role as well. The comparable relative risk for major depression is 2.8, suggesting a more modest genetic component, though the risk for early-onset recurrent depression (part of Kraepelin's manic-depressive illness) is probably at least 4.0–5.0 (Levinson, 2006).

Family studies can do more than simply reveal the presence or absence of aggregation; they can also be useful in segregation analysis for assessing whether the pattern of transmission of an illness favors one mode of inheritance (e.g., single major locus or gene) over another (e.g., polygenic or multifactorial). Several segregation analyses of bipolar disorder have provided support for a major locus effect (Rice et al., 1987; Pauls et al., 1995; Spence et al., 1995), but other analyses have not found such evidence (Bucher et al., 1981; Goldin et al., 1983).

Models of the mode of inheritance have also been constructed using the relative risk metric. The increased risk for illness in relatives may be conferred by either one or multiple genes. If multiple genes are responsible, each has its own locus-specific relative risk, which contributes some fraction of the total increased risk. Risch (1990) defined both a heterogeneity model, in which a variety of single

genes act independently in different families to cause disease, and a multiplicative multilocus model, in which multiple genes interact to cause disease. Using this metric, Craddock and colleagues (1995b) showed that the heterogeneity model is not consistent with the relative risk data available for bipolar disorder. Instead, the multiplicative model with at least three, and more likely four or more, risk genes provides the best fit with the data. Craddock and colleagues concluded that, although there may be occasional families with a single-gene form of bipolar illness, such families must be rare and cannot explain the majority of familial occurrence of the disorder. These results are consistent with the idea of manic-depressive illness, even in its more homogeneous bipolar form, as a genetically complex disorder (see the discussion below of the linkage method).

Twin Studies

Familial aggregation of disease suggests, but does not prove, a genetic contribution to disease. Environmental factors, such as exposure to toxins or emotionally traumatic family experiences, could in theory also lead to familial aggregation. Twin studies have been the approach used most widely to attempt to disentangle these contributions. The logic of twin studies is this. Identical or *monozygotic* (MZ) twins are 100 percent genetically the same, whereas fraternal or *dizygotic* (DZ) twins share just 50 percent of their genes; yet the two twin types are assumed to be no different in the degree to which they share environments.⁴ Therefore, any increased similarity in manifestation of manic-depressive illness detected in MZ twins compared with that in DZ twins should be due to the greater genetic similarity of the former. The main measure in these studies is the *concordance rate* for illness; that is, starting with an ill twin as the proband, what is the rate of illness in the co-twin?

Early studies tested for manic-depressive illness (see Table 13–3). Six such studies found concordance rates of 77 percent for MZ twins and 23 percent for DZ twins, with a heritability of .71 (where 1.00 would be complete heritability and 0 would be none). More recent studies have used the bipolar and major depressive disorder phenotypes.⁵ Three studies assessed bipolar disorder; they found a 63 percent concordance rate for MZ twins and a 13 percent rate for DZ twins, with a heritability of .78. Seven studies assessed major depressive disorder; they found concordance rates of 34 percent in MZ twins and 26 percent in DZ twins, with a heritability of .34, although this estimate would be higher if the studies had focused on those patients with more highly recurrent forms of the disorder (see below).

Among the most meticulously conducted twin studies of manic-depressive illness is that of Bertelsen and colleagues (1977), which drew on the Danish Central Psychiatric

Register and the Danish Twin Register to identify 126 probands with the disorder from among 110 twin pairs. The work was done in the 1960s and 1970s using a database of Danes born during 1870–1920. A single psychiatrist conducted an unstructured interview of 133 of the 138 living twins and made diagnoses in conjunction with a second psychiatrist using the interview results and information available through the registers. Zygosity was determined in about half of the twins using serological examination of 16 to 25 different red blood cell types, tissue types, serum protein variants, and enzymes. In the other half of the twins, zygosity was assessed anthropometrically from information gathered through questions about pronounced similarity of general appearance and mistaken identity by others. For three twin pairs, zygosity could not be determined, and these pairs were dropped from the analysis.

Bertelsen and colleagues presented their findings in two ways. In the first, all identified ill twins are counted as probands. This method, called the *proband-wise concordance*, is considered the most epidemiologically correct, though it has the intuitive flaw of counting some pairs twice, as both affected members of a twin pair may occasionally be assessed independently as probands. The other method, called the *pair-wise concordance*, counts all twin pairs only once and is more conservative as it yields lower estimates of heritability. The following results are the proband-wise concordance rates. They are presented by proband diagnosis, with *concordance* defined as the likelihood of the co-twin having either major depression or bipolar disorder. Results are expressed as percentages; perfect concordance would be 100 percent, while no concordance would be 0 percent. The rates of concordance for BP-I are MZ = 80, DZ = 13; for BP-II, MZ = 78, DZ = 31; and for major depression, MZ = 54, DZ = 24. Heritability is calculated most simply as (concordance rate in MZ twins—concordance rate in DZ twins) divided by (100—concordance rate in DZ twins). Using this metric, the heritability for each disorder is as follows: BP-I = .77, BP-II = .68, and major depression = .39. Notably, of 32 concordant MZ pairs, 7 included one subject with bipolar disorder and one with major depression (Bertelsen et al., 1977).

Many observers have cited the lack of complete concordance between MZ twins as evidence that environmental factors must play a role in the etiology of bipolar disorder. More recently, others have suggested that this lack of complete concordance could be due to epigenetic factors—that is, factors that affect the control of gene expression—and that these factors may or may not be influenced by the environment (Petronis, 2001). In support of this hypothesis, there is evidence that MZ twins, despite having identical DNA sequence for all their genes, may differ in the way their genes are expressed (Weksberg et al., 2002).

TABLE 13–3. Twin Studies of Manic-Depressive Illness and Bipolar Disorder

Proband/Study	Sample Size (Pairs)	Findings		Concordance (%)	Heritability ^a

Proband/Study	Sample Size (Pairs)	Findings			Heritability ^a
		MZ	DZ	Concordance (%)	
Kendler et al., 2000	3,790	44	39		.34
<i>Weighted mean</i>	10,219	34	26		.34

Note: DZ = dizygotic; MZ = monozygotic. For studies since 1960, only those in which a majority of subjects were directly interviewed are included. DZ, dizygotic; MZ, monozygotic.

^aWhere authors calculate heritability, these figures are provided. If heritability is not provided in a report, Holzinger's heritability (MZ concordance – DZ concordance/100 – DZ concordance) has been calculated.

Patterns of concordance can be converted to a heritability value—often thought of as the percentage of the liability to illness that is genetic—in several ways. Current twin studies employ a liability threshold model (Falconer, 1965), which simultaneously tests the heritability of and environmental contribution to illness. When individuals cross the liability threshold, they develop illness. The model requires the specification of a population prevalence of illness to indicate how many people in the population lie on the ill side of the threshold. Moreover, heritability estimates will vary with the prevalence figures used, an issue of particular importance for major depression, for which population estimates have varied dramatically. For example, one depression study reported that heritability was 48 percent when one estimate was used and 75 percent when another was used (McGuffin et al., 1996).⁶

Adoption Studies

A second paradigm for separating genetic from environmental effects is the adoption study. The conceptual basis for this approach is that in adoptees, the genetic inheritance occurs through one set of parents, while the cultural and environmental experience occurs through a different set. The two sets of factors and their potential association with illness can therefore be disentangled.

There are several possible ways to conduct an adoption study. One that has been used for manic-depressive illness is the adoptees' relatives method. In this method, ill and control adoptees are identified as probands, and rates of illness are then compared in the biological and adoptive relatives of each group. If genetics plays a role, the biological relatives of ill adoptees will have elevated rates of illness compared with those in the other three relative groups.

Only four adoption studies have addressed manic-depressive illness (see Table 13–4). The most methodologi-

cally rigorous such study is that of Mendlewicz and Rainer (1977), who reported on a cohort of patients identified in Belgium. This study employed four proband groups with a total of 102 probands: bipolar adoptees, bipolar non-adoptees, control adoptees, and individuals who had contracted polio in their youth. The latter group was included to control for the effect on parents of bringing up a disabled child. Clinicians who were blind to the status of the proband interviewed biological and adoptive parents of adoptees and parents of nonadoptees. A total of 299 parents were included in the study. Parents were instructed at the beginning of the interview not to speak about their children unless specifically asked. A semistructured interview was used, as well as standardized diagnostic criteria. The principal finding was that the biological parents of bipolar adoptees had a 31 percent rate of affective disorder—significantly higher than the 12 percent rate in the adoptive parents of these adoptees, the 2 percent rate in the biological parents of the control adoptees, and the 10 percent rate in the parents of the polio probands. Conversely, the 31 percent rate of affective disorder in the parents of the bipolar adoptees was quite similar to the 26 percent rate in parents of bipolar nonadoptees.

Inclusion of the control groups in the Mendlewicz and Rainer study was important, as it helped address some of the criticisms of this method. Adoptive parents are often screened for stability and therefore might be expected to have a lower-than-average rate of affective disorder. The rates in these adoptive parents were not lower than those in the polio proband parents. Conversely, biological parents of adoptees may be more likely to be unstable, but the biological rates of affective disorder in parents of normal adoptees were not higher than those in the polio proband parents. The results strongly support a genetic basis for the bipolar form of manic-depressive illness.

TABLE 13–4. Adoption Studies

Proband/Study	Sample	Rate of Manic-Depressive Illness		
		Biological III Proband Group	Biological Control Group	Adoptive Relatives
Manic-Depressive Illness				
Cadoret et al., 1985	443 adoptees	22.2	10.1	—
Wender et al., 1986	1,080 relatives	5.2	2.3	2.8
Bipolar-I				
Mendlewicz and Rainer, 1977	299 parents	31.6	2.3	12.2
Unipolar Depression				
von Knorring et al., 1983	—parents	5.1	5.4	2.7

Note: — = not studied or reported.

Adoption studies are not easy to conduct because they require access to large databases, and there are barriers of confidentiality involved whose breach can be a highly sensitive matter. Two such studies that have been done have used national registries, those of Sweden and Denmark. In these studies, direct interviews were not performed. In these two studies, moreover, probands had diagnoses including “affect reaction” and “neurotic depressive reaction,” which are not readily reconcilable with current diagnostic nomenclature. The results of one of these studies supported genetic transmission of depression (Wender et al., 1986), while those of the other did not (von Knorring et al., 1983). Another adoption study used relatives as probands and measured rates of depression in the adoptees of those relatives who were affectively ill compared with those who were not. The results supported genetic transmission (Cadoret et al., 1985). Thus, of the four adoption studies of manic-depressive illness, three provide support for a genetic vulnerability, and one does not.

ADVANCES IN UNDERSTANDING THE HUMAN GENOME

In the next section, on the linkage method, the discussion shifts from the question of whether there is a genetic component to susceptibility to manic-depressive illness to the question of where the disease genes are located in the human genome. Before examining the progress made in answering that question, however, we must review the remarkable advances that have occurred in our understanding of

the nature of those transmissible “factors,” first identified by Mendel, that we now call “genes.” We begin by tackling some basic genetic and biological concepts. Two analogies may be helpful.

First, think of the human genome as being like the *Oxford English Dictionary*. The *genome* refers to the full complement of human DNA. Just as the *Oxford English Dictionary* is a compendium of all the words that can create meaning in the English language, the genome is a collection of all the genes that can create things in the human body. The *Oxford English Dictionary* has 23 volumes, and the human genome has 23 chromosomes. Each volume contains many word entries, and each *chromosome*—a long stretch of DNA—contains many genes. Each of the 405,000 words is spelled using the 26-letter English alphabet, and each of the 20,000 genes is spelled using the four-nucleotide genetic alphabet. The four nucleotides (or *bases*) are A for adenine, T for thymine, G for guanine, and C for cytosine; each is a molecule that conveys information much as a letter does. The human genome contains 3 billion of these nucleotide letters. Just as there can be normal variant spellings of a word—e.g., “organization” versus “organisation” (the British spelling)—there can be variant nucleotide sequences for a gene that make no difference for the gene. And just as there can be typographical errors that change word meanings—“well” versus “hell” or “hype” versus “hope”—there can be mistakes in the gene sequence that change gene function. Functionally significant variations are the ones that concern us when we consider vulnerability to manic-depressive illness.

What does gene function have to do with such vulnerability? Consider a second analogy. Genes are like blueprints that direct the workings of cells, including brain cells. Genes made of DNA code for messengers made of a molecule called *ribonucleic acid* (RNA). The messenger RNA directs the production of specific proteins. Proteins are the molecules that do the work in brain cells. They act as building blocks, signal receptors, and chemical switches. So if the blueprint for a gene is misdrawn, aberrant proteins will result, and brain cells may misfire or malfunction. Francis Crick, codiscoverer of the structure of DNA, called this conception—DNA makes RNA, and RNA makes proteins—the central dogma of molecular biology.

The investigation of differences in *DNA sequence* among individuals became possible in the late 1970s to early 1980s with the discovery of *restriction fragment length polymorphisms* (RFLPs). These are single nucleotide variations among individuals, or polymorphisms, in the DNA sequence that occur at greater than 1 percent frequency and result in differential susceptibility to being cleaved by bacterial enzymes called *restriction enzymes*. These enzymes can thus be used as tools for establishing the sequence at points in the DNA where variability exists.

In the late 1980s to early 1990s, *microsatellite DNA markers* were discovered and exploited to assess DNA variation among individuals. These markers generally are not located within the coding regions of genes, called *exons*. These regions code for the production of messenger RNA, with every three nucleotides forming a *codon*, which ultimately directs production of a particular *amino acid*, a building block for a specified protein. Exons are like islands in a vast sea; only about 3 percent of DNA takes this form. The noncoding regions of DNA can lie within genes; between the exons, in which case they are called *introns* (an intron thus interrupts the protein-coding sequence of a gene, being transcribed into RNA but cut out of the message before being translated into protein); or between genes, in which case they are called *intergenic* regions. The microsatellite markers are generally located in these non-coding regions. They comprise stretches of DNA with two-, three-, or four-nucleotide repeat sequences, such as CA-CACACA or GATAGATAGATA, where the repeat occurs a variable number of times. For example, the CA repeat at a given location in the DNA might occur 7 consecutive times, 18 consecutive times, or somewhere in between. This variability allows two copies of a chromosome to be distinguished from each other. This DNA variability in microsatellite markers is extremely useful in linkage studies.

Beginning in the late 1990s, extensive sequencing of the human genome began to reveal very large numbers of single nucleotide differences, or polymorphisms—called *single nucleotide polymorphisms* (SNPs)—across the genome

(see Fig. 13–2). These polymorphisms have been found to exist at about 1 of every 200 nucleotides. This finding suggests that people are about 99.5 percent the same in terms of DNA sequence, and that it is in the 0.5 percent difference that the factors influencing vulnerability to bipolar disorder lie. About 10 million SNPs have been identified in the public SNP database (dbSNP); it is expected that 15 million SNPs should exist, of which about 6 million should be common. Studies of bipolar disorder that take advantage of this understanding of SNPs began to appear in 2002 (Sklar et al., 2002).

The explosion of sequence information has largely been a product of the Human Genome Project, a U.S. government–funded initiative begun in 1987. The project's mandate was initially to provide a dense map of the human genome, and eventually to provide the full sequence. As of this writing, the sequence is considered more than 99 percent complete. To return to the *Oxford English Dictionary* analogy, the word entries have been largely spelled out. Much work remains to be done, however, particularly in clarifying the functions of genes, a task analogous to defining the meanings for each word entry in the dictionary.

Advances in computer science have been of great help in this enterprise, generating the new field of bioinformatics. These advances have enabled the creation of large and complex Web-based databases cataloguing the genes on each chromosome, the sequence of the genes, their variations, their functions, and more.⁷ On each of these sites, information can be obtained in a matter of minutes or hours that would have taken scientists months or years to obtain just a decade ago.

THE LINKAGE METHOD

The Method

The goal of a linkage study is to identify a chromosomal region that harbors a susceptibility gene (see Fig. 13–1). There are three stages to this type of study: (1) clinical assessment of subjects to determine whether they have manic-depressive illness (either the bipolar or recurrent unipolar subtype) (phenotype); (2) testing of DNA from the subjects (from their white blood cells) to determine their genetic profile at a series of markers; and (3) use of statistical techniques to test whether bipolar or recurrent unipolar disorder and DNA markers travel independently or together (*cosegregation*). If they cosegregate, we say that the DNA marker is located close to the disease gene on the same chromosome. Because the locations of the DNA markers on chromosomes are established, the observation of cosegregation or linkage tells us roughly where a disease gene should lie. The usefulness of linkage hinges on the recombination

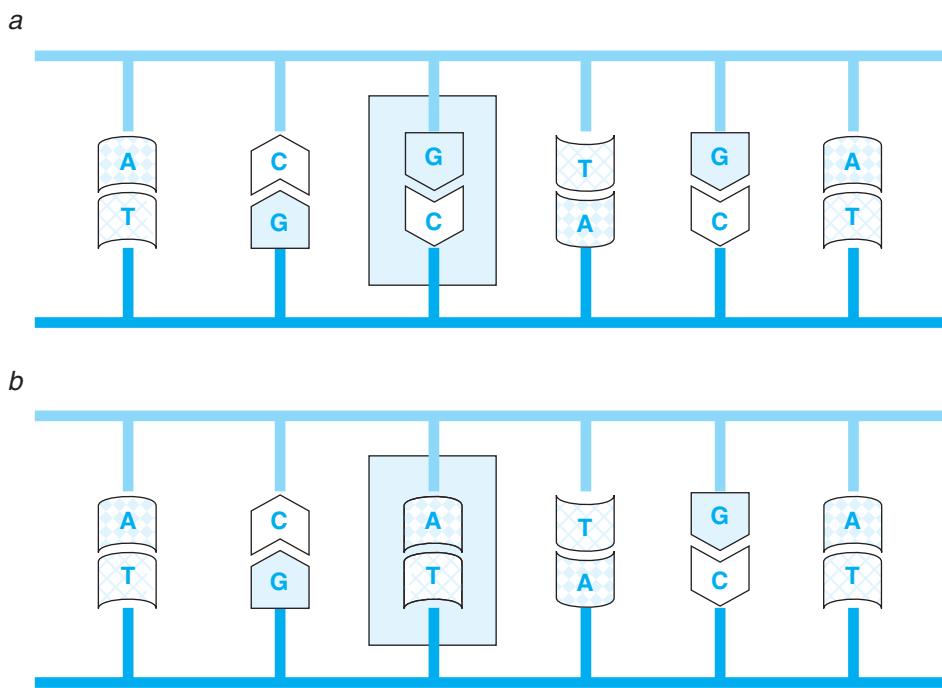

Figure 13–2. Single nucleotide polymorphisms (SNPs): the most common form of genetic variation. SNPs occur about once every 200 nucleotides. They typically have two allelic variants consisting of one of two nucleotides. *a* and *b* here represent an individual's two copies of a segment of chromosome 11 that is part of the coding sequence for the BDNF gene. Note that each chromosome has two strands, called either *forward* and *reverse* or *sense* and *antisense*. The sequence of one strand determines the sequence of the other because A and T are always paired, as are G and C. Sequence *a* contains a G allele on the forward strand, shown as the top strand, which is the one that codes for the gene. Sequence *b* contains an A allele on the top strand in the same position, so that this individual is a heterozygote for this SNP. The third, fourth, and fifth bases in the sequence form a codon, which codes for an amino acid. GTG codes for valine, while ATG codes for methionine. Some evidence suggests the G allele confers risk for bipolar disorder, while the A allele is protective.

between pairs of similar, or *homologous*, chromosomes during meiosis, which increases as a function of the distance between marker and gene (see Fig. 13–3). The rate of recombination is measured in centimorgans (cM), with each cM corresponding to a 1 percent likelihood of recombination and to roughly 1 million base pairs of DNA (1 Mb).

Thomas Hunt Morgan first employed the linkage method in the development of gene maps of the fruit fly in the early twentieth century. The method was used to link presumed genes for one fly trait to presumed genes for another. The first linkage study of manic-depressive illness was reported in 1968, before DNA markers were available. ABO blood types were used as markers, so that the presumed genes for the blood types were tested for linkage to the illness (Tanna and Winokur, 1968).

The linkage method has since been widely applied in mapping of human disease genes, especially since the 1980s, after Botstein and colleagues (1980) suggested that RFLPs (the DNA markers discussed in the preceding section) distributed across the genome could be used to detect

linkage to disease genes. The first published genetic studies of the bipolar form of manic-depressive illness to use DNA markers, all in the same issue of *Nature* in 1987, were conducted by three groups that focused on chromosome 11 (Detera-Wadleigh et al., 1987; Egeland et al., 1987; Hodgkinson et al., 1987b). The first study of bipolar illness to employ microsatellite markers was conducted by the Gershon group at NIMH in 1990 (Berrettini et al., 1990). These researchers used markers on the X-chromosome in an attempt to verify prior reports of linkage in the region.⁸

The more variable or *polymorphic* a marker is—the larger the number of alleles—the more genetically informative it becomes for linkage studies. The variations among individuals can easily be detected using laboratory methods that reveal which of two variants, or *alleles*, an individual has at a given point, or *locus*, along the chromosome. The characterization of the two alleles is referred to as the *genotype* for that DNA marker. A standard genomewide scan today would use 400 microsatellite DNA markers at an average spacing of 10 cM to genotype individuals at locations

across all 23 chromosomes. Newer genomewide scans employing 5,800 SNP DNA markers at an average spacing of .64 cM are just becoming available.

A positive result in a linkage study implicates a chromosomal region that is typically quite broad—as much as 30 cM from a linkage peak—which means as much as 60 cM in total (Roberts et al., 1999). A linkage region is indicated by the identity of the chromosomal arm (short [p] or long [q]) and the segment of that arm (numerical designation) on which the linkage peak falls (see Fig. 13–4).

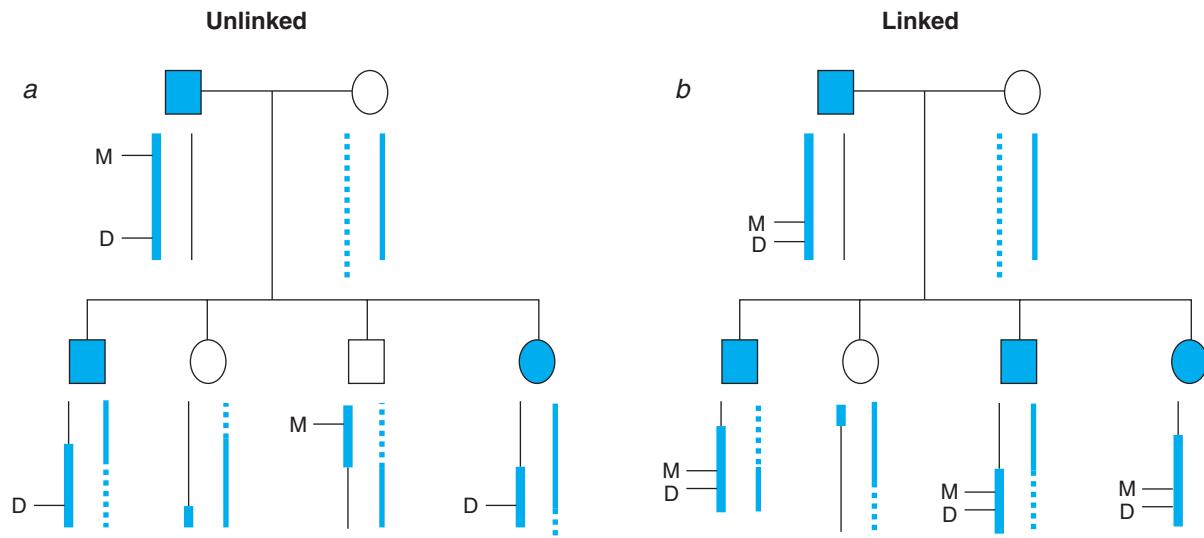

LOD Score Approach

One statistical method used to test for linkage of markers to illness phenotype is the logarithm of the odds of linkage (LOD) score approach, which is mode of inheritance-based; that is, it requires specifying whether transmission is dominant, recessive, or X-linked. This approach has been highly successful in isolating genes for Mendelian diseases. The *odds* here refer to the ratio between the likelihood that the inheritance pattern observed in a pedigree or set of pedigrees would result from a particular amount of linkage between the genetic marker and the phenotype being investigated and the likelihood that the observed data would

result if there were no linkage. When a single locus and a single illness phenotype are tested, an LOD score of 3.0 is sufficient to claim linkage because this score indicates a 5 percent likelihood that a linkage finding is due to chance. However, genome scans employ tests of multiple markers and test further for linkage using multiple definitions of the disease phenotype. To guard against the possibility of *type I error*, or false positive linkage claims, Lander and Kruglyak (1995) calculated new statistical thresholds. These often-cited criteria raised the bar for declaring an initial linkage finding significant, requiring an LOD threshold of 3.3 (the threshold for “suggestive” linkage is 1.9). A more recent approach uses simulation to determine the statistical significance of a finding. Computer programs can employ the set of families and DNA markers used in a given study to calculate the likelihood of a given LOD score’s arising by chance in thousands of simulated genome scans. An empirical *p* value for a linkage finding is derived by comparing actual results with these simulated results.

The virtue of such a mode of inheritance-based method is that with a correct model, the test is very powerful and gives both an LOD score and an estimate of the genetic distance between the marker and the disease gene or locus.

Figure 13–3. Recombination: the basis for linkage studies. Genetic linkage between a disease and markers is determined for each chromosome by identifying how frequently a DNA marker and a presumed bipolar gene are passed together from parent to child. Circles are females, and squares are males. The solid shapes represent those affected with bipolar illness, and the open shapes are unaffected individuals. In *a*, there is a DNA marker, M, that is on the same chromosome as the disease gene, D, but is physically far from it. For the top-left individual, the father, the thick line represents copy 1 of chromosome 13, and the thin line represents copy 2 of chromosome 13. During meiosis, as sperm cells are being formed, these two copies of chromosome 13 pair, and parts of each are exchanged with the other. This process, which occurs for every chromosome in egg as well as in sperm, is called *recombination*. Because of recombination, the disease gene and the marker are not necessarily inherited together; the two are thus not linked. In *b*, the marker under consideration is physically close to the disease-causing gene, so that recombination does not separate them. All three children who inherit the bipolar gene also inherit the nearby marker. If the pattern in *b* were seen in many families, it would suggest linkage. Note that in linkage, D is not actually observed; D is presumed to be present when the subject is affected with bipolar illness.

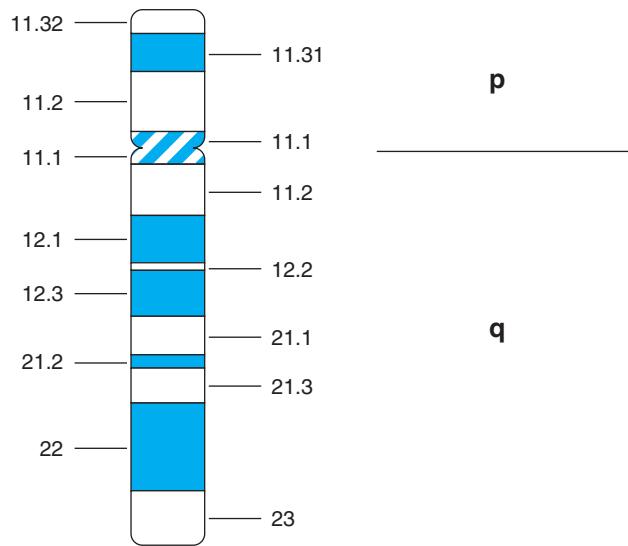

Figure 13–4. Schematic of a human chromosome (chromosome 18) depicting nomenclature based on cytogenetic banding patterns. Each human chromosome has a short arm (*p* for *petit*) and long arm (*q* for *queue*), separated by a *centromere*. The ends of the chromosome are called *telomeres*. Each chromosome arm is divided into regions, or *cytogenetic bands*, that can be seen using a microscope and special stains. The cytogenetic bands are labeled *p*1, *p*2, *p*3, *q*1, *q*2, *q*3, etc., counting from the centromere out toward the telomeres. At higher resolutions, sub-bands can be seen within the bands. The sub-bands are also numbered from the centromere out toward the telomere. (Source: National Center for Biotechnology Information Web site: <http://www.ncbi.nlm.nih.gov/Class/MLACourse/Original8Hour/Genetics/chrombanding.html>)

However, the LOD score approach requires a number of assumptions about the mode of transmission, as well as other factors.⁹

Affected Sibling Pair Method

So-called model-free or *nonparametric* approaches, such as the affected sibling pair method, require few assumptions and are thus more robust than a mode of inheritance-based method. The affected sibling pair method measures sharing of alleles at various DNA markers. Siblings are expected to share 50 percent of their alleles at any locus; significantly increased allele sharing among siblings with illness at a given marker constitutes evidence for linkage. Those without illness (unaffected) are not included in the analysis to avoid the uncertainty created by the possibility that they will become ill later. Such model-free methods can also be applied to affected relatives. The Lander and Kruglyak (1995) threshold for significance using model-free methods is a *p* value of 2.2×10^{-5} , corresponding to a nonparametric LOD score of 3.6 (the threshold for “suggestive” linkage is 7.4×10^{-4} or a nonparametric LOD score of 2.2). The first bipolar study published using

the affected sibling pair method was reported in 1994 (de Bruyn et al., 1994).

A drawback of the affected sibling pair method is that it is not as powerful for localizing disease genes as mode of inheritance-based methods. To minimize the likelihood of failing to detect linkage in a region where a susceptibility gene of modest effect (relative risk of 2.0) exists, a large sample of sibling pairs is required. In fact, if a nonparametric LOD score of greater than 3.0 is the criterion for detection, a sample size of about 400 affected sibling pairs is required to achieve adequate power (Hauser et al., 1996). The first study to achieve a sample size of this magnitude was published in 2003; the NIMH Bipolar Disorder Collaborative completed its Wave 3 study with 446 affected sibling pairs (see the discussion below).

Findings

There have been 21 genome-wide linkage scans for bipolar illness published to date, and these studies have identified a number of regions potentially harboring genes for susceptibility to the disorder (see Fig. 13–5). Note that these findings were sometimes obtained using the bipolar subtype of manic-depressive illness, but in other instances the broad definition incorporating recurrent major depression was used. At least five bipolar linkage findings (and perhaps more, depending on the interpretation of statistical thresholds) have reached genome-wide statistical significance in multifamily samples: 6q22 (Middleton et al., 2004), 8q24 (Cichon et al., 2001), 15q14 (Turecki et al., 2001), 21q22 (Liu et al., 2001b), and 22q12 (Kelsoe et al., 2001). Promising though they are, these findings have not been replicated consistently across studies. Other regions that have been repeatedly implicated in bipolar disorder include 1q41, 4p16, 4q32–35, 12q23–24, 13q31–33, 16p12–13, 18p11, 18q12–23, and Xq24–28.

Meta-analyses

Three meta-analyses of linkage studies have been performed, with results differing because of differences in the studies included and the techniques employed. A 2002 meta-analysis of 11 genome scans for bipolar illness used the multiscan probability technique, which combines *p* values across scans in regions with clusters of positive scores. This analysis revealed that two regions reached genome-wide significance across the studies: 13q32 ($p < 6 \times 10^{-6}$) and 22q12–13 ($p < 1 \times 10^{-5}$) (Badner and Gershon, 2002). Despite this suggestion of a convergence of findings in these two regions, however, a second meta-analysis was less encouraging. This latter analysis used data from 18 genome scans, supplemented by unpublished data when the published data were incomplete (see Table 13–5). The authors used a rank-based method to ensure that the meta-analysis would not be biased by statistical methodology. They found

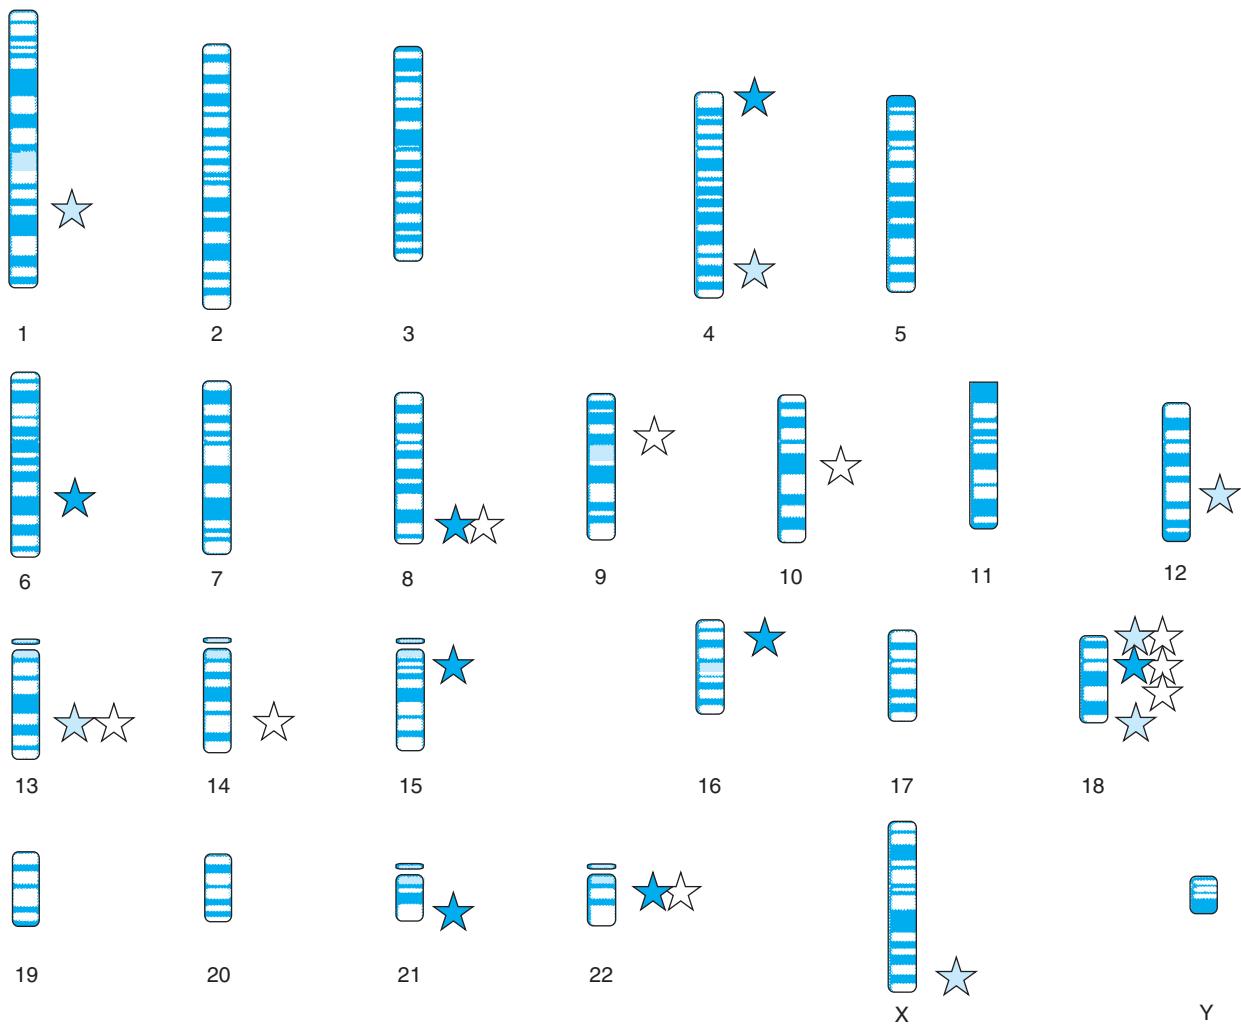

Figure 13–5. Chromosomal regions implicated in bipolar disorder, based on individual studies and two meta-analyses. Dark blue stars represent regions where a genome-wide significant linkage has been found. Light blue stars are regions with more than one suggestive linkage finding. White stars are regions with the strongest evidence for linkage in either of two meta-analyses of genome-wide bipolar disorder linkage scans.

that no region reached genome-wide significance across the combined studies. The strongest regions were 9p21–22, 10q11–22, 14q24–32, 18p–18q21, and to a lesser extent 8q24 (Segurado et al., 2003). The most recent meta-analysis differed from the two earlier ones in using original genotype data rather than published results. The authors combined data on 1,067 families from 11 studies and found genome-wide significant results for chromosomal regions 6q and 8q (McQueen et al., 2005).

These data add to the evidence from mode of transmission studies that no single gene accounts for the susceptibility to bipolar disorder in a majority of affected families. Thus, multiple susceptibility genes may contribute to the risk. Indeed, it is likely that multiple genes contribute cumulatively to susceptibility in each family, a notion referred to as *epistasis* (see the discussion below).

Promising Linkage Regions

Chromosome 4

Two regions of chromosome 4 have been implicated in bipolar illness. On 4p16, Blackwood and colleagues (1996) initially reported significant linkage in a single large Scottish family, with an LOD score of 4.8. Supporting data have come from several other studies (see Evans et al., 2001, for references). Of interest, one study in four large Amish families reported evidence for a protective locus in this same chromosomal region. Using “never mentally ill” family members as the “affected” phenotype, an LOD score of 4.05 was obtained (Ginns et al., 1998).

On the opposite end of the chromosome, 4q35, there is also some evidence for a susceptibility gene for bipolar disorder. Suggestive evidence of linkage—an LOD score of

3.19—was first obtained for this region in a single very large Australian pedigree (Adams et al., 1998). Subsequently, McInnis and colleagues (2003) found suggestive evidence of linkage in this region in 65 Johns Hopkins pedigrees, and Willour and colleagues (2003) found a nonparametric LOD score of 2.49 in the same region in 56 NIMH Wave 2 families.

Chromosome 6q16–22

This region was first implicated in bipolar disorder in 2003, when the results of the largest bipolar genome scan to date were analyzed (Dick et al., 2003). The sample, the third to come out of the NIMH Bipolar Disorder Collaborative

(Wave 3), contained 245 families and 741 affected subjects. This region was the strongest in the genome for this scan, with a peak LOD score of 3.05 (Schulze et al., 2004). Similarly, a study of 25 Portuguese bipolar families found the strongest signal in the genome at 6q22, with a maximum nonparametric linkage (NPL) score of 4.2 (Middleton et al., 2004). As noted, this region reached genomewide significance in the McQueen and colleagues (2005) meta-analysis.

Chromosome 8q24

Cichon and colleagues (2001) implicated this region at the significant level in a study of 75 German, Israeli, and Italian families (the Bonn sample). They found a parametric

LOD score of 3.62 using a dominant model of inheritance and a narrow phenotype definition that included only BP-I as affected. The region had been implicated earlier by Friddle and colleagues (2000), who used the first 50 families of the Johns Hopkins sample. In an expanded Hopkins sample of 65 families, McInnis and colleagues (2003) found an NPL score of 3.13. When further markers were genotyped in this region in the 65 families, a parametric LOD score of 3.32, which is genomewide significant, was obtained (Avramopoulos et al., 2004). As noted, this region reached genomewide significance in the McQueen and colleagues (2005) meta-analysis.

Chromosome 12q24

This region became interesting after investigators reported the cosegregation of bipolar illness with Darier disease, a rare dominantly inherited skin disorder located on chromosome 12q24 in one family (Craddock et al., 1994). In a genome scan of a Quebec region genetic isolate, Morissette and colleagues (1999b) reported suggestive linkage in the region, while Ewald and colleagues (1998) found an LOD of 3.37 in two Danish families using a DNA marker located nearby. Of interest, the d-amino acid oxidase (*DAO*) gene, recently implicated in schizophrenia (Chumakov et al., 2002), is in this region, about 1.4 Mb from the Darier disease gene.

Chromosome 13q31–33

The 22-family genome scan of Detera-Wadleigh and colleagues (1999) identified 13q32 with a nonparametric LOD of 3.5, just short of genomewide significance. Subsequent genotyping narrowed the interval, but did not improve the LOD score (Liu et al., 2001a). The 13q31–33 region has also been implicated at the suggestive level by Kelsoe and colleagues (2001), and by Potash and colleagues (2003b) in a subset of Johns Hopkins bipolar families characterized by multiple members with psychotic features (see the discussion below of alternative phenotypic definition). Several groups have detected association with a pair of overlapping genes in this region, *G72* and *G30* (see the later section on the association method). As noted, this region reached genomewide significance in the Badner and Gershon (2002) meta-analysis.

Chromosome 16p12–13

Six independent studies have implicated this region. Ewald and colleagues (1995a) reported an LOD of 2.5 on 16p13, and McInnes and colleagues (1996) reported an LOD of 1.46 on 16p13. The NIMH Collaborative found modest evidence of linkage to 16p12–13 in its Wave 1 sample (Edenberg et al., 1997) and stronger evidence for the same region in its Wave 2 sample (Dick et al., 2002).

Maziade and colleagues (2004) and Ekholm and colleagues (2003) each found evidence of linkage to 16p12 in their genome scans. The findings from these six studies are spread over 50 cM.

Chromosome 18

Chromosome 18 may harbor several regions of interest. Evidence of possible linkage was first reported in the pericentromeric region, an area straddling the short and long arms of the chromosome (Berrettini et al., 1994). This linkage was later narrowed to 18p11.2, with an LOD score of 2.32 being obtained (Detera-Wadleigh et al., 1999). Evidence for pericentromeric linkage was also reported in the Johns Hopkins sample, in which suggestive linkage was detected in the 18q21 region as well (Stine et al., 1995). These results are notable for a parent-of-origin effect, the evidence for linkage being derived primarily from families with paternal inheritance of bipolar illness and from paternally transmitted DNA marker alleles. The Johns Hopkins group followed up on its original report with evidence from an entirely new set of 30 families that again supported linkage on 18q (McMahon et al., 1997). A combined analysis of the 58 Johns Hopkins families showed the strongest evidence for linkage on 18q21–22, as did an analysis of a slightly expanded sample of 65 families (McInnis et al., 2003).

Other groups have also found evidence for linkage on chromosome 18, though in varying regions, including 18p11.3 (McInnes et al., 1996), 18q12 (Ewald et al., 1997; Maziade et al., 2001), 18q22 (de Bruyn et al., 1996), and 18q23 (Coon et al., 1996; Freimer et al., 1996; Nothen et al., 1999). The meta-analysis by Segurado and colleagues (2003) divided chromosome 18 into four parts for purposes of the study. Three of the four parts were significantly linked to bipolar disorder, at least nominally, when the results from 18 genome scans were pooled.

Chromosome 21q22

Investigators initially reported linkage on chromosome 21q22 based on a single large multigenerational pedigree with an LOD score of 3.41 (Straub et al., 1994). The same group subsequently documented an analysis of this chromosomal region involving 56 families, which yielded an LOD score of 3.48 (Liu et al., 2001b). In two different datasets, Detera-Wadleigh and colleagues (1996, 1997) found evidence for linkage on 21q. Smith and colleagues (1997) obtained an LOD score of 1.29 in this region. However, when they used a model that simultaneously incorporated the effects of two loci—the 21q locus and the tyrosine hydroxylase locus on 11p15—the LOD score increased to 3.87, suggesting that genes in these two regions may interact to cause disease.

Chromosome 22q11–13

In a genome scan of 20 families, Kelsoe and colleagues (2001) found a parametric LOD score of 3.84 at 22q12, which was genomewide significant. In this same study, the authors reported results from the NIMH Wave 2 sample, which yielded LOD scores of 1.58 at 22q12 and 2.72 at a marker on the border between 22q11 and 22q12. Other suggestive findings in this region include that of Detera-Wadleigh and colleagues (1999), who reported a nonparametric LOD score of 2.1, and that of Potash and colleagues (2003b), who studied a subset of Johns Hopkins bipolar families characterized by multiple members with psychotic features and found an NPL score of 3.06 in the 22q12 region (see the discussion below of alternative phenotypic definition). As noted, this region reached genomewide significance in the Badner and Gershon (2002) meta-analysis.

X-Chromosome

Rosanoff and colleagues (1935) first proposed the idea that a gene on the X-chromosome might be implicated in manic-depressive illness. A number of subsequent studies of the bipolar subgroup found evidence for linkage in the Xq28 region using markers for color blindness and G6PD deficiency, but this evidence has not proven replicable, even within the same families.¹⁰ However, there have also been reports of linkage in the q24–27 region, starting with the Factor IX locus (Mendlewicz et al., 1987). Another study found an LOD score of 3.9 at the same locus in one pedigree (Lucotte et al., 1992). And a Finnish group reported an LOD score of 3.54 at a DNA marker in the Xq24–27 region, also based on one pedigree (Pekkarinen et al., 1995). Thus, the existence of a bipolar susceptibility gene on Xq24–27 remains a possibility.

Complex Disorders

The linkage method has yielded spectacular successes in medicine, with detection of linkage being followed by the discovery of a disease gene for Huntington's disease, cystic fibrosis, and Duchenne muscular dystrophy, among others. These illnesses, which are all uncommon, are called *simple mendelian disorders* because they follow the relatively simple rules laid out by Mendel. Like many illnesses currently under study, however, including asthma, hypertension, and diabetes mellitus, manic-depressive illness is common and does not follow these mendelian rules. For these illnesses, referred to as *complex genetic disorders*, there is not a one-to-one correspondence between gene and disease; rather, these disorders may result from the actions of any one of several genes. A variant of one gene may cause the illness in one family, while a variant of a different gene may cause it in another family (*genetic heterogeneity*). Many

people may carry the susceptibility gene, but not manifest the illness (*incomplete penetrance*, penetrance being defined as the proportion of individuals of a particular genotype that express its phenotypic effect in a given environment). Many others may have the illness, but not carry the susceptibility gene (*phenocopy*).¹¹ Additionally, as mentioned earlier, two or more genes may interact to cause disease (*epistasis*).¹² These types of inheritance complexities have contributed to the difficulty of establishing linkage for bipolar disorder.

For common diseases such as bipolar illness, geneticists have hypothesized that common gene variants likely play a role, rather than rare variants (Reich and Lander, 2001). The common disease–common variant hypothesis has implications for how gene hunting will proceed in the future, including the kinds of samples collected and the kinds of DNA markers studied.

ALTERNATIVE PHENOTYPIC DEFINITION¹³

Given that manic-depressive illness is likely to be *oligogenic*—a term denoting a phenotypic trait produced by two or more genes working together, each with modest but detectable effect—the question arises of whether it is possible to identify clinical and biological features of the illness that might define more genetically homogeneous subtypes. Clinical subtyping has borne fruit in the study of other illnesses. In breast cancer research, for example, restricting the gene search to families with early onset of the disease led researchers to a gene—*BRCA1*—that turned out to be common in families with comorbid ovarian cancer (Miki et al., 1994), as well as a second gene—*BRCA2*—that is less likely than *BRCA1* to be associated with ovarian cancer and more likely than *BRCA1* to cause male carriers to develop disease (Wooster et al., 1994). In Alzheimer's disease research as well, identification of families with early onset of the illness led to detection of the genes presenilin-1, presenilin-2, and amyloid precursor protein, all of which can cause the illness when abnormal (mutated) (St. George-Hyslop, 2000). This section first reviews clinical subtypes of major depressive disorder and then of bipolar disorder for which there is evidence of familial aggregation and in some cases, for which there is molecular evidence. A discussion of potential biologically defined phenotypes, or *endophenotypes*, follows.

Clinical Subtypes of Major Depressive Disorder

Genetic studies have tended not to focus exclusively on major depressive disorder because of its lower heritability relative to bipolar disorder. Instead, as noted earlier, many linkage studies have employed a broad phenotype model that includes recurrent major depressive disorder along with bipolar disorder. Findings derived from such a broad

model should implicate genes predisposing to both bipolar disorder and recurrent unipolar depression, which might properly be considered manic-depressive illness genes. The first three genomewide linkage scans of major depressive disorder were published in 2003–2004. To address the lower-heritability problem, these studies all employed clinical subtyping strategies, with the idea that a restricted phenotype might have greater heritability than major depressive disorder generally.

Recurrent, Early Onset

Two features of many patients with major depression—recurrent episodes and early age at onset—have a robust association with increased familial risk, with the former association perhaps having been found more consistently (Sullivan et al., 2000). In a study of 763 first-degree relatives of 75 probands with major depression, for example, Bland and colleagues (1986) found that relatives of probands with recurrent depression and early age at onset had a 17.4 percent risk of depression, while relatives of probands with single-episode depression and late age at onset had a 3.4 percent risk.

Two groups have ascertained families through a strategy of selecting for recurrent early-onset cases of major depression. The Zubenko group performed linkage analysis in 81 families ascertained through probands with recurrent, early-onset major depression. They detected linkage in several regions, the strongest being 11p15 (Zubenko et al., 2003). The Genetics of Recurrent Early-onset Depression (GenRED) project, a multicenter collaborative project on the genetics of depressive illness, has recruited 680 families that include 971 affected sibling pairs—a sample large enough to have the power to detect linkage even for a susceptibility gene of modest effect. The families were recruited through probands with recurrent major depressive disorder who experienced their first episode prior to age 31. Linkage analysis of about half of the sample revealed a significant signal on chromosome 15q25–26 (Holmans et al., 2004).

Investigators in the primarily European Depression Network (DeNT) study are recruiting probands whose major depressive disorder is recurrent, though they are not screening for early onset. In the initial phase of the study, they recruited 414 families with 470 affected sibling pairs (Farmer et al., 2004); the aim is to recruit a total of 1,200 families.

Gender-Specific

Because rates of major depressive disorder in women are about twice those in men, investigators have wondered whether susceptibility genes may differ to some extent by gender. One study estimated that the genetic effects for males and females were just over half correlated (Kendler

and Prescott, 1999), while another estimated they were entirely correlated (Kendler and Walsh, 1995). Data from three family studies are consistent with partial overlap (Merikangas et al., 1985; Faraone et al., 1987; Reich et al., 1987). Sullivan and colleagues (2000) concluded that “although the data are limited, the most parsimonious explanation appears to be that men and women share most but not all genetic influences for major depression.”

One study found significant parametric evidence of linkage to markers in 2q33–34 in 170 affected female sibling pairs, but not in male pairs (Zubenko et al., 2002). The region between the markers that yielded the peak LOD score includes the *CREB1* gene, which encodes a cyclic adenosine monophosphate (cAMP)-responsive element-binding protein (CREB), an attractive candidate gene because CREB has been implicated in depression and antidepressant response. This protein appears to be important for many aspects of neuronal functioning. Levels of CREB have been found to be abnormally low in persons with major depression and in the brain tissue of suicide victims, and have been observed to be altered by exposure of rat neurons to antidepressants and lithium (see Chapter 14).

A second study found evidence of linkage uniquely in families with at least four affected males (Abkevich et al., 2003). This linkage, in chromosomal region 12q22–23.2, was detected in a sample of Mormon families in Utah in which ascertainment was restricted to families with a minimum of four affected relatives. In addition to subjects with recurrent major depressive disorder, individuals with only a single episode of major depression were considered affected, as were those with bipolar disorder (who made up about 15 percent of the individuals with mood disorder in these families).

Clinical Subtypes of Bipolar Disorder

Psychotic Features

The term *psychosis* has been used in a variety of ways. Here we use it to refer to the presence of hallucinations and/or delusions, as does the specifier for psychotic features in the mood disorders section of DSM-IV. By this definition, psychosis occurs in about two-thirds of manic episodes (see Chapter 18) (Coryell et al., 2001). In two samples of families with bipolar illness, Potash and colleagues (2001, 2003a) found evidence for familial aggregation of psychotic symptoms in manic-depressive illness generally and BP-I specifically. Taken together, results of these studies showed that the odds of having psychotic features were about three times greater for a BP-I relative of a psychotic BP-I proband than for a BP-I relative of a nonpsychotic BP-I proband. Another study found a significant correlation ($p < .001$) between bipolar sibling pairs for scores on

a psychosis rating scale (Omahony et al., 2002), while still another showed that delusional thinking aggregated in families of psychotic bipolar subjects (Schurhoff et al., 2003). Potash and colleagues (2001) hypothesized that psychotic symptoms in bipolar disorder may be a clinical manifestation of a shared genetic vulnerability to bipolarity and schizophrenia.

In the chapter on genetics in the first edition of this book, we hypothesized the existence of some shared genetic liability between bipolar disorder and schizophrenia, based on results of family studies of the two disorders (Gershon et al., 1982, 1988). Those studies showed an excess of major depression and schizoaffective disorder in the relatives of

both bipolar and schizophrenic probands. The excess of major depression in both groups has been a consistent finding (Maier et al., 1993), although the excess of schizoaffective disorder has been less so. Most studies have not found an excess of schizophrenic relatives in bipolar proband families or an excess of relatives with bipolar disorder in schizophrenic proband families. Studies using three large datasets have addressed the issue of overlap between psychotic mood disorder (both bipolar and unipolar) and schizophrenia (see Table 13–6). Two of the datasets showed higher-than-expected rates of psychotic mood disorder in relatives of schizophrenic probands and vice versa¹⁴; the third dataset also suggested shared liability

TABLE 13–6. Family Studies Comparing Schizophrenia and Psychotic Affective Disorder

^bThis study examined only children of probands, whereas the other two studies examined all first-degree relatives.

^cSchizoaffective, mainly schizophrenic type.

^dThis is significantly higher than the controls (odds ratio [OR] = 9.6, chi-square = 41.8, $p < .001$).

^eThis is significantly higher than the controls (OR = 7.7, chi-square = 22.8, $p < .001$).

^fSchizoaffective, mainly affective.

^gThis is significantly higher than the controls (OR = 3.3, chi-square = 16.1, $p < .001$).

^hThis is significantly higher than the controls (OR = 3.8, chi-square = 13.1, $p = .001$).

ⁱThe Roscommon study used unscreened controls, while the other two studies used screened controls.

between the two disorders (Erlenmeyer-Kimling et al., 1997). In addition, some twin studies have found evidence of shared heritability between psychotic mood disorder and schizophrenia (Farmer et al., 1987; Cardno et al., 2002).

Linkage studies of bipolar disorder and schizophrenia have implicated overlapping chromosomal regions that could harbor susceptibility genes shared by the two disorders (Berrettini, 2000). On chromosome 10p12–14, three studies found evidence of linkage for schizophrenia (Faraone et al., 1998; Straub et al., 1998; Schwab et al., 2000). In the NIMH Bipolar Disorder Collaborative study (Wave 1), the strongest signal in the genome was found at 10p12 (Foroud et al., 2000). On chromosome 18p11.2, three studies found evidence of linkage for bipolar disorder (Berrettini et al., 1994; Stine et al., 1995; Nothen et al., 1999), and one study uncovered suggestive evidence of linkage and evidence of linkage disequilibrium for schizophrenia (Schwab et al., 1998). The latter study found a stronger signal when the phenotype was broadened to include mood disorder. On chromosome 13q32, two significant findings (Blouin et al., 1998; Brzustowicz et al., 1999) and a more modest one (Lin et al., 1997) were reported for schizophrenia. Two suggestive findings were reported for bipolar disorder (Detera-Wadleigh et al., 1999; Kelsoe et al., 2001). On chromosome 22q11–13, modest evidence of linkage for schizophrenia was found (Gill et al., 1996; Schizophrenia Collaborative Linkage Group for Chromosome 22, 1998). One group reported significant linkage for bipolar disorder in the same region (Kelsoe et al., 2001). Of interest, the meta-analysis of 11 genome scans for bipolar disorder that identified 13q31–33 and 22q11–13 as the two strongest linkage regions in the genome for the disorder also identified these two regions as the strongest across 18 genome scans for schizophrenia (Badner and Gershon, 2002).

Potash and colleagues (2003b) tested the hypothesis that those bipolar pedigrees most enriched for psychotic symptoms would show increased evidence of linkage to the regions of prior overlap in linkage between bipolar disorder and schizophrenia. Linkage in the four regions was assessed for the full family set and for subsets of families defined by the presence of psychotic symptoms in affectively ill family members. The 10 (of 65) families in which three or more members had psychotic mood disorder showed suggestive evidence of linkage to 13q31 (NPL score = 3.56) and 22q12 (NPL score = 3.32). These results differed significantly from those for the full 65 families, which showed little or no evidence of linkage in the two regions. The 10 families did not show evidence of linkage to 10p12–14 or 18p11.2. These findings suggest that bipolar illness with psychotic features may be a genetically meaningful subtype and that this subtype may share some susceptibility genes with schizophrenia.

Data from a genome scan for bipolar disorder were reanalyzed by Park and colleagues (2004) according to the presence or absence of psychotic features. Some evidence of linkage to psychotic bipolar disorder was obtained on chromosome 13q32, though the strongest results were on chromosomes 9q31 and 8p21. No signal emerged for chromosome 22q11–13.

The hypothesis of etiologic overlap suggests the existence of either psychosis genes (within an oligogenic model) or joint mood and psychosis genes. This latter possibility implies that examination of mood-related subtypes of schizophrenia would further illuminate the issue of etiologic overlap. Indeed, results of four studies suggest that elevated familial rates of mood disorder may occur in a subset of schizophrenic subjects.¹⁵ Pulver and colleagues (2000) tested the hypothesis that some families with schizophrenia may carry genes predisposing to both psychotic and mood symptoms. In an effort to reduce genetic heterogeneity in schizophrenia, they analyzed a subset of 6 families (from a set of 54) in which at least one relative had a psychotic mood disorder. The strongest linkage signal in the genome for this family subset was on chromosome 22q12, where results were suggestive; linkage evidence was also suggestive for 13q33.

Bipolar-II

Results of several studies conducted in the 1980s indicated that the diagnosis of BP-II in genetic studies was unreliable (Andreasen et al., 1981). A more recent study, however, found that the reliability of the Research Diagnostic Criteria BP-II diagnosis was extremely good in the genetic study done at Johns Hopkins, with a kappa value of .72 for hypomania (Simpson et al., 2002). One possible explanation for this difference is that at Johns Hopkins, academic psychiatrists specializing in affective disorders conducted the interviews. The three studies that examined the familial aggregation of BP-II and used a methodology that included direct examination of the majority of subjects are summarized in Table 13–2. These studies showed that this form of the disorder appears to breed true, as rates of BP-II are elevated in relatives of BP-II probands. In the one twin study that specifically analyzed probands with BP-II, a high heritability was observed (Bertelsen et al., 1977).

Interest in BP-II at Johns Hopkins derived from the observation that it was the most common phenotype in the first set of 28 BP-I proband families ascertained (Simpson et al., 1993). Subsequent analyses of the Johns Hopkins linkage data on chromosome 18q21–22 in these families showed that linkage depended mainly on BP-II–BP-II sibling pairs. Sharing of DNA markers was demonstrated among 18 of 22 pairs in which both siblings had BP-II in the original dataset. When a second dataset of 30 more families was prospectively examined, 9 of 11 BP-II pairs

showed significant DNA marker sharing at 18q21–22. When the 15 of 58 families that contained BP-II–BP-II pairs were analyzed for linkage, they generated an LOD score of 4.67¹⁶ (McMahon et al., 2001), which was significantly higher than that for the overall sample. Subsequent genotyping of more markers increased the LOD score to 5.42 (Schulze et al., 2003).

Bipolar Disorder with Comorbid Panic and Anxiety Disorders

Using two independent datasets, MacKinnon and colleagues (1997, 2002) found that affectively ill relatives of BP-I probands with comorbid panic disorder are more likely to have comorbid panic disorder themselves than are similar relatives of BP-I probands without this comorbidity. This finding suggests that comorbid panic disorder may define a genetically meaningful subtype of bipolar disorder. This hypothesis was tested using linkage data from chromosome 18, a region where the Johns Hopkins group had previously found bipolar linkage. MacKinnon and colleagues found that bipolar families having at least one member with panic disorder showed stronger linkage in this region than did other bipolar families. Another study stratified bipolar families by the presence of comorbid anxiety disorders generally and found that among relatives of children with bipolar and anxiety disorders, the two disorders appeared to cosegregate. However, this result was based on a small dataset, as there were only seven relatives with bipolar disorder (Wozniak et al., 2002).

Early Onset

As with depression, several studies have found a higher rate of bipolar disorder among relatives of early-onset bipolar probands than among relatives of later-onset probands (Strober et al., 1988; Coryell et al., 2001; Grigoriou-Serbanescu et al., 2001). Other studies have revealed significant correlation between bipolar sibling pairs for age at onset (Baron et al., 1981; Leboyer et al., 1998; Omahony et al., 2002). Faraone and colleagues (2004) studied the correlation between relatives with bipolar illness for age at onset of mania. They found a significant correlation, with an estimated heritability for age at onset of .41. They went on to use age at onset of mania as a quantitative trait for linkage analysis—a powerful approach because it provides a finer-grained assessment of the phenotype than is derived from a simple dichotomous depiction of the data. The results showed suggestive evidence for linkage in three regions that had not emerged in the conventional phenotype linkage analysis of their dataset: 12p, 14q, and 15q. A similar approach was taken by the Johns Hopkins group, which showed that age at onset was familial (Lin et al., 2005, 2006) and that early onset was correlated with linkage

on 21q22.13 in two distinct datasets. This region of chromosome 21 is one previously implicated in bipolar disorder (see above).

Bipolar Disorder with Comorbid Attention-Deficit Hyperactivity Disorder (ADHD)

Results of three studies from Massachusetts General Hospital suggest that comorbid ADHD in childhood-onset bipolar disorder may mark a genetically meaningful subtype of the illness (Wozniak et al., 1995; Faraone et al., 1997, 2001a). In these studies, 143 first-degree relatives of probands with bipolar disorder and comorbid ADHD were examined. Among the 33 relatives with ADHD, 14 had bipolar disorder (42 percent), whereas among the 110 relatives without ADHD, only 6 had bipolar disorder (5 percent). These results suggest that the two disorders occur together, or *co-segregate*, within families. Further support for the familial connection between the two disorders comes from a meta-analysis, performed by the same group, of five studies comparing rates of ADHD in children of bipolar parents (15 percent) with rates in children of controls (5 percent) (Faraone et al., 1997). A subsequent study found that 28 percent of children of bipolar probands had ADHD (Chang et al., 2000). In the converse meta-analysis, examining rates of bipolar disorder in the relatives of children with ADHD and of controls, rates were 2.6 percent in the former group and 1.3 percent in the latter. Although the difference was not as dramatic as that found in the meta-analyses examining rates of ADHD, it did reach statistical significance (Faraone et al., 1997). A major methodological issue in this work concerns the overlapping diagnostic criteria for childhood onset bipolar disorder and ADHD (see also Chapter 7). Symptoms such as distractibility, increased activity, and increased talkativeness are shared by the two criteria sets, which makes conclusions about the true biological relationship between the disorders more difficult to draw (Kent and Craddock, 2003).

Cognitive Features

Cognitive decline was one of the defining features of Kraepelinian dementia praecox (schizophrenia); by definition, Kraepelinian manic-depressive illness was a disorder in which such decline was not seen. Although the issue has not been resolved, some evidence from studies of euthymic bipolar patients supports the hypothesis that residual neuropsychological impairments persist in a subgroup of patients (Ferrier and Thompson, 2002). Studies of this kind are potentially confounded, however, by the possibility of residual symptoms in patients and by the potential cognitive effects of medications (see Chapter 9). The presence of cognitive abnormalities in unaffected family members can provide a more definitive answer to the question of whether cognitive deficits are a heritable bipolar trait in some cases.

The potential genetic overlap between bipolar disorder and schizophrenia was discussed earlier; we noted that psychotic symptoms (hallucinations and/or delusions) have been proposed as a possible clinical manifestation of this overlap. Cognitive impairment may plausibly represent another phenotypic aspect of the same overlap. Such deficits may define a subgroup of patients. In one study (Decina et al., 1983), children of bipolar probands had significantly higher verbal than performance IQ. In another study, children of psychotic manic-depressive parents were significantly impaired on a digit span test compared with controls (Erlenmeyer-Kimling and Cornblatt, 1992). In the only neuropsychological study of identical twins discordant for bipolar illness, seven unaffected twins demonstrated mild impairments in several tests of learning and memory, as did their affected twins (Gourovitch et al., 1999). More research is needed to clarify these results.

Rapid Cycling

Three studies of familial aggregation of rapid-cycling bipolar disorder yielded negative results (Nurnberger et al., 1988; Coryell et al., 1992; Lish et al., 1993). One recent study assessed a related clinical variable—the rapid switching of mood—and found modest evidence for the familial clustering of this trait in a large sample (MacKinnon et al., 2003a). In a related study, rapid switching was found to be more common in bipolar families in which multiple members also had panic attacks (MacKinnon et al., 2003b). More research is needed to determine whether this variable will prove valuable in resolving the genetic heterogeneity of bipolar disorder.

Endophenotypes

Lithium Responsiveness

Three types of studies have investigated lithium responsiveness as a potentially genetically informative trait: studies of family history of manic-depressive illness, studies of the familial aggregation of lithium response, and molecular studies. The family history studies have yielded mixed results: some found a positive family history of bipolar disorder or more broadly defined manic-depressive illness to be associated with a good response to lithium, while others did not (see Coryell et al., 2000, for references). Studies of the familial aggregation of lithium response have been few and small. These studies, discussed below in the section on pharmacogenetics, generally support the hypothesis that lithium response in one family member is predictive of lithium response in others. Given the biological plausibility of lithium response as an endophenotype in bipolar disorder, Turecki and colleagues (2001) ascertained 31 Canadian bipolar families through excellent lithium responders.

A complete genome scan of these families revealed parametric linkage support for chromosome 15q14 at a genomewide significant level. Further testing with positive lithium response as the phenotype implicated a locus on chromosome 7q11.2.

White Matter Hyperintensities

A number of brain imaging abnormalities have been reported to be associated with bipolar disorder and major depression (see Chapter 15). An increase in white matter hyperintensities may be the most consistent of the abnormalities seen in bipolar patients. While the heritability of these changes in bipolar subjects has not been assessed, a study of elderly male twins in the cardiovascular literature found a heritability of 73 percent for white matter hyperintensities in 514 twin pairs (Carmelli et al., 1998). One large extended family has been documented in which all 9 members with bipolar illness and 6 of 10 members without affective disorder had white matter hyperintensities (Ahearn et al., 2002). The investigators performed a linkage study employing white matter hyperintensities as an endophenotype and using DNA markers near the *NOTCH3* candidate gene. No evidence for linkage was found. There have also been suggestions of abnormalities in volume or metabolism in the prefrontal cortex, hippocampus, and amygdala in patients with manic-depressive illness. The extent to which these abnormalities represent inherited traits is currently unclear, however. Only one small study has assessed brain region volumes in twins discordant for the bipolar subgroup (Noga et al., 2001).

Evoked Potentials

The auditory P300 event-related potential is a “brain wave” that appears on an electroencephalogram (EEG) when subjects monitor series of stimuli for rarely presented targets. The P300 is thought to reflect the operations of short-term working memory. Results of one study suggest that aspects of P300 abnormality have a genetic basis. There is a large Scottish family in which 7 members have schizophrenia, 1 has bipolar disorder, and 10 have major depression. All 18 of these family members, as well as 11 others, carry a balanced chromosomal translocation resulting in chromosomal breakpoints on 1q and 11q. (See the later section on testing gene- and allele-specific function for a discussion of cytogenetics and these breakpoints.) When 12 family members carrying the translocation were tested on the P300 along with noncarriers and normal controls, the carriers were abnormal by two measures—prolonged latency and elevated amplitude—in comparison with the other two groups (Blackwood et al., 2001). Further studies are needed to determine whether other families show cosegregation of P300 abnormalities.

FROM THE BOOK OF NUMBERS TO THE BOOK OF GENESIS: THE ASSOCIATION METHOD

The Method

Association is an approach to disease gene identification that provides an alternative to the linkage method. While linkage is a property of genes or loci and occurs within families, association is a property of alleles and occurs across a population. An association study can be used for two different purposes. The first is to test directly whether a gene variant may be implicated in manic-depressive illness (most, though not all, such studies focus on the bipolar subgroup). An association between a phenotype and an allele at a locus may mean that the allele in question leads to susceptibility to the phenotype. The second use of association studies is for the narrowing of linkage regions through linkage disequilibrium mapping. This indirect approach can provide information about the location of a disease gene with resolution that is roughly 1,000-fold greater than that of a linkage study. An association between a phenotype and an allele at a locus may mean that the allele is in linkage disequilibrium (discussed below) with a susceptibility allele either within the same gene or at a nearby gene.

One can test candidate genes for their association with bipolar disorder by determining whether a particular allele occurs more commonly in those with bipolar illness (cases) than in controls. The choice of controls in a case-control association study can be problematic, however, as differences in allele frequency between the disease and control groups due to differing genomic backgrounds and unrelated to the phenotype (population stratification) may confound the study results. This problem is often addressed by selecting controls thought to be ethnically identical to the

cases. A more rigorous approach to handling this problem is now available, in which genotypes at random DNA markers are used as a way of testing the similarity in genomic background between cases and controls. Failure to find significant differences in genomic background suggests that the controls are adequate. Relatively few studies to date have used this method, however.

The preferred method for avoiding the stratification problem is to use family-based association. The most widely used test of this kind—the transmission disequilibrium test—counts the number of times an allele is transmitted by parents to affected probands and compares this result with the number of times that allele is not transmitted by parents to affected probands (Spielman et al., 1993) (see Fig. 13–6). This family constellation—a proband and his or her parents—is referred to as a *trio*, and these data are being collected by many groups for association studies. It is important to note that family-based association may be less prone to false-positive findings than the approach of selecting ethnically identical controls, but because of potentially reduced power, it may be more prone to false negative results (Risch, 2000).

There are two types of candidate genes—functional candidates and positional candidates. In the 1990s, tests of association were typically applied to *functional candidate genes*—those coding for a protein thought to have some biological role in manic-depressive illness. Because of neurobiological data implicating the neurotransmitters, particularly serotonin, norepinephrine, and dopamine, in bipolar disorder and depression, most studies focused on functional candidate genes from these systems. Results have been mixed, with a number of genes yielding both negative and weakly positive results (see Table 13–7). A subset of functional candidate genes that has been studied in relation to

Figure 13–6. Family-based association: the transmission disequilibrium test. The test is performed using trios composed of an affected individual and his or her parents. It does not matter for this test whether the parents are affected. The test determines whether a particular allele is transmitted to affected individuals more often than it is not transmitted. In this example, there are four heterozygous parents—the father in *a*, the mother in *b*, and both parents in *c* (squares are males, circles are females, and filled-in symbols are affected). Each of these four parents could have transmitted either the G or T allele to his or her affected child. In all four cases, the G was transmitted. Note that the mother in *a* and the father in *b* could transmit only a T because they are homozygous for this allele. Thus, they are not informative for this test. A consistent pattern of overtransmitting the G allele across a large number of trios would implicate this allele in association with disease.

TABLE 13–7. Genes That Have Been Tested for Association in Bipolar Disorder (*continued*)

Gene	Function	Chromosome Location	Positive ^a	Negative ^a	Studies
WFS1	Wolframin	4p16.1	+	---	Middle et al., 2000; Kato et al., 2003; Serretti et al., 2003; Koido et al., 2005
DAO	D-amino acid oxidase	12q24.11		-	Schumacher et al., 2004
DUSP6	MAP kinase phosphatase	12q21.33		-	Toyota et al., 2000
PLA2A	Phospholipase	12q24.23	+	-	Dawson et al., 1995; Jacobsen et al., 1996
PLA2G1B	Phospholipase	12q24.23		-	Meira-Lima et al., 2003a
G72/G30	Possible NMDA receptor regulation	13q33	++++		Hattori et al., 2003; Chen et al., 2004; Schumacher et al., 2004; Schulze et al., 2005
ADCY9	Adenylate cyclase	16p13.3		-	Toyota et al., 2002
SSTR5	Somatostatin receptor	16p13.3	+	-	Nyegaard et al., 2002
GRIN2A	NMDA receptor subunit	16p13.3	+		Itokawa et al., 2003
GOLF	G-protein	18p11.21		-	Turecki et al., 1996
IMPA2	Myo-inositol monophophatase	18p11.21	+		Sjoholt et al., 2004
NDUFV2	Mitochondrial protein	18p11.22	+		Washizuka et al., 2003
PACAP	Pituitary adenyl cyclase activating peptide	18p11.32		-	Ishiguro et al., 2001
ABCG1	Transporter	21q22.3		-	Kirov et al., 2001
XBP1	Transcription factor	22q12.1	+	--	Kakiuchi et al., 2003; Cichon et al., 2004; Hou et al., 2004
PLA2G6	Phospholipase	22q13.1		-	Meira-Lima et al., 2003b

Notes: The phenotype here is defined narrowly as bipolar only for some studies, while it is defined as bipolar plus major depression for others. The relatively few studies examining only major depression are not included.

^aA positive result indicates a finding that was statistically significant; a negative result represents a finding that was not statistically significant. This determination is based on overall results, and does not take account of secondary analyses.

bipolar disorder is the group of genes that contain trinucleotide repeat sequences. This structural feature has been implicated in numerous neuropsychiatric diseases and has been hypothesized to play a role in bipolar disorder (see the later section on consideration of alternative genetic mechanisms).

The *positional candidate genes* are those that reside in linkage regions and are thus in a chromosomal position of interest. Studies of positional candidate genes conducted in the 1990s were confined primarily to work on genes that were both positional and biological candidates. Work is currently under way on larger-scale association testing of many positional candidate genes in linkage regions. Genes with at least three positive association findings are discussed below.

Promising Candidate Genes

Serotonin Transporter

The serotonin transporter gene, *5-HTT*, is the most heavily studied gene in research on manic-depressive illness because of the importance of serotonin in depression, the central role of *5-HTT* in serotonergic function at the synapse, and the demonstration of a functionally meaningful DNA variation in the promoter region of the gene. The promoter region plays a crucial role in the expression of the gene, and *5-HTT* has a stretch of promoter DNA that exists in a short and a long form. The short form has been found to result in decreased levels of gene expression compared with the long form. Four studies of bipolar disorder have found a positive association between the short variant and illness,¹⁷ while 13 studies have found no significant difference (see Table 13–7). Of these studies, 5 were family based, and only 1 of these 5 showed positive association.¹⁸ A meta-analysis of 15 case-control samples found evidence for a significant, though quite small, effect of this polymorphism in bipolar disorder, reporting an odds ratio of 1.13 for having the short versus the long allele among the cases as compared with the controls (Lasky-Su et al., 2005).

A second polymorphism in the gene, a repeat in intron 2, has also been heavily studied, and there is evidence as well from a transgenic mouse model that this polymorphism may influence gene expression (MacKenzie and Quinn, 1999) (see the later section on testing gene- and allele-specific function). There have been 6 positive and 10 negative studies of this polymorphism. Five of these were family-based studies, and of these five, one was positive and three were negative.¹⁹

Several studies have used the alternative phenotypic definition approach (discussed previously) in testing association with these markers. Two studies found modest evidence of association between the short promoter variant and violent suicide attempters with manic-depressive illness

(Bellivier et al., 2000; Courtet et al., 2001), and a third found an association between the short variant and completed suicide (Bondy et al., 2000). One negative study for the phenotype of violent suicidal behavior in a primarily manic-depressive sample has been reported (Rujescu et al., 2001) (see Chapter 8).

MAOA

This gene encodes monoamine oxidase A (MAOA), an enzyme that degrades monoamine neurotransmitters, such as dopamine, norepinephrine, and serotonin. There are several reasons why MAOA may have a role in manic-depressive illness. First, monoamine oxidase inhibitor (MAOI) medications, such as tranylcypromine, treat depression. Second, in a large Dutch kindred with a form of X-linked mild mental retardation, all affected males showed aggressive, impulsive, and sometimes violent behavior, including arson, attempted rape, exhibitionism, and attempted suicide (Brunner et al., 1993). Each of the affected males in the family was shown to carry a mutation in the *MAOA* gene. The behavioral phenotype in this family was believed to bear some resemblance to a manic syndrome.

Thirteen studies have examined the possible association of four *MAOA* polymorphisms with either bipolar disorder or bipolar disorder combined with major depression. Four of these studies yielded statistically significant positive findings, while nine failed to show an association (see Table 13–7). However, two meta-analyses that examined pooled data from seven and five studies, respectively, found significant associations for the two polymorphisms they examined (Furlong et al., 1999a; Preisig et al., 2000). One of these polymorphisms, a microsatellite marker in intron 2, had an allele that was 1.55 times more likely to be found in Caucasian bipolar subjects than in controls and an allele that was 2.65 times more likely to be found in Japanese bipolar subjects than in controls. For a single base variant in the coding sequence, one allele was 1.30 times more likely in Caucasian cases than in controls (Furlong et al., 1999a). An important caveat is that these meta-analyses, like all of the positive studies, used the case-control method. The only two studies to use family-based methods both failed to show evidence for an association (Nothen et al., 1995; Parsian and Todd, 1997), so the possibility that the positive findings for this gene are due to undetected population stratification cannot be ruled out.

TH

This gene encodes tyrosine hydroxylase, the rate-limiting enzyme in the synthesis of dopamine and norepinephrine. A total of 21 studies have sought an association between bipolar disorder and *TH* polymorphisms, including four RFLPs and one microsatellite repeat within intron 1; of these, 5 yielded

positive results and 16 negative (see Table 13–7). A meta-analysis of 11 studies using the microsatellite marker showed no evidence for association with bipolar disorder in the pooled data (Furlong et al., 1999b). Current evidence does not support involvement of the *TH* gene in bipolar disorder.

COMT

This gene codes for an enzyme involved in the degradation of dopamine and norepinephrine. It has been much studied in relation to schizophrenia in part because it lies in a chromosomal region within 22q11 that has been implicated in psychotic illness through velocardiofacial syndrome (VCFS). This syndrome, which is often accompanied by psychotic symptoms, results from microdeletion or loss of a segment from the 22q11.2 region. Another interesting feature of *COMT* is the existence of an SNP shown to be functionally significant, with the variant coding for methionine having a three- to four-fold lower level of enzymatic activity than the one coding for valine. There have been five positive and seven negative studies of this variant (see Table 13–7). A meta-analysis of seven case-control reports, representing 910 bipolar cases and 1,069 controls, found a statistically significant, though very modest, effect whereby the low-activity methionine variant was 1.18 times more likely in subjects with bipolar disorder than in controls (Craddock et al., 2001). None of the three family-based studies showed significant evidence for an association (Mynett-Johnson et al., 1998; Kirov et al., 1999a; Geller and Cook, 2000).

DRD2

The dopamine D₂ receptor (*DRD2*) has been the subject of intense interest because of its critical role in the mechanism of action of antipsychotic medications. There have been 4 positive and 11 negative association studies of this gene in relation to bipolar disorder (see Table 13–7). Notably, the most recent study had three to four times more patients than any of the prior studies. This study found that one allele of a microsatellite marker within intron 2 was 1.7 times more common in bipolar cases than in controls ($p=.00035$) (Massat et al., 2002b). While this finding might be construed as indicating that when the sample is sufficiently large, a real though modest association can be found with *DRD2*, again one would like to see confirmatory evidence from family-based association studies. Two such studies have been done to date; both were negative. Thus, firm conclusions about an etiologic role for *DRD2* in bipolar disorder cannot be drawn at present.

DRD4

The dopamine D₄ receptor (*DRD4*) has been of interest in psychiatric genetics since its discovery as a dopamine receptor with a high affinity for clozapine and the discovery

shortly thereafter of multiple variants in the population (Van Tol et al., 1991, 1992). The most studied variant is a repeat polymorphism in exon 3, encoding the third intracellular loop of the gene. One of the variants, the 7-repeat variant, was shown to be less potent at inhibiting dopamine-stimulated cAMP formation in cells as compared with the other two common variants (Asghari et al., 1995). This variant has been shown to be significantly associated with ADHD in separate meta-analyses of 8 case-control studies and 14 family-based studies (Faraone et al., 2001b). There have been 3 positive and 7 negative studies of association of bipolar disorder with *DRD4* (see Table 13–7). Three of these studies were family based; 2 were negative (Bocchetta et al., 1999; Serretti et al., 2002a), and 1 was positive (Muglia et al., 2002). Of interest, the latter positive study was associated with a parent-of-origin effect (see the section below on alternative genetic mechanisms).

BDNF

At the start of the new century, armed with greater awareness of the neurobiology of manic-depressive illness, a wider array of identified SNPs, and a greater technical capacity to perform SNP genotyping, Sklar and colleagues (2002) undertook a family-based association study of 76 functional candidate genes located in diverse regions of the genome. The study yielded two nominally positive associations with the bipolar subgroup, and only one of these—brain-derived neurotrophic factor (*BDNF*)—was supported, albeit weakly at a nonstatistically significant level, in two replication samples. The authors found that two samples shared an undertransmitted haplotype (an ancestral chromosomal fragment) marked by two SNPs. A second study (Neves-Pereira et al., 2002) also found an association between *BDNF* and bipolar disorder using the same SNP identified in the Sklar et al. screen, which in its G form leads to synthesis of the amino acid valine, but in its A form results in methionine. As in the study by Sklar and colleagues, the A allele was found to be undertransmitted in this family-based study. Replication attempts in one European (Oswald et al., 2004) and three Asian (Nakata et al., 2003) case-control datasets were negative, however (Nakata et al., 2003). Further support for the Sklar group's finding comes from a report that the G allele of *BDNF* was shown to be preferentially transmitted to people with prepubertal and early-adolescent bipolar disorder (Geller et al., 2004). Similarly, the G allele was associated with neuroticism, a personality trait correlated with depression (Sen et al., 2003), although a Chinese case-control study of major depression was negative (Tsai et al., 2003). The potential genetic role of *BDNF* in mood disorder is intriguing because of the part it plays in the brain's response

to stress, in the treatment of animal models of depression, and in the putative mechanism of action of antidepressant medications (Licinio and Wong, 2002; see also Chapter 9).
