patients' perspective, the four most important reasons for nonadherence were as follows:

- They disliked the idea of medication controlling their moods.
- They missed their highs.
- They felt depressed.
- They disliked the idea of having a chronic illness, symbolized by the necessity for lithium therapy.

Patient and clinician perceptions occasionally diverged, and when they did, the differences were significant. Patients were much more bothered than clinicians believed them to be by having medication control their moods. Those patients who reported discontinuing lithium were more likely than clinicians to report that feeling depressed was a significant factor. Although both clinicians and discontinuers ranked missing highs as particularly important in nonadherence, discontinuers were less likely to state that decreases in productivity and creativity were important in their decision to discontinue. This finding contrasts with prevailing notions about reasons for nonadherence and suggests that many patients do not necessarily equate highs with creativity or productivity. From the clinicians' point of view, the three most important reasons for lithium nonadherence were as follows:

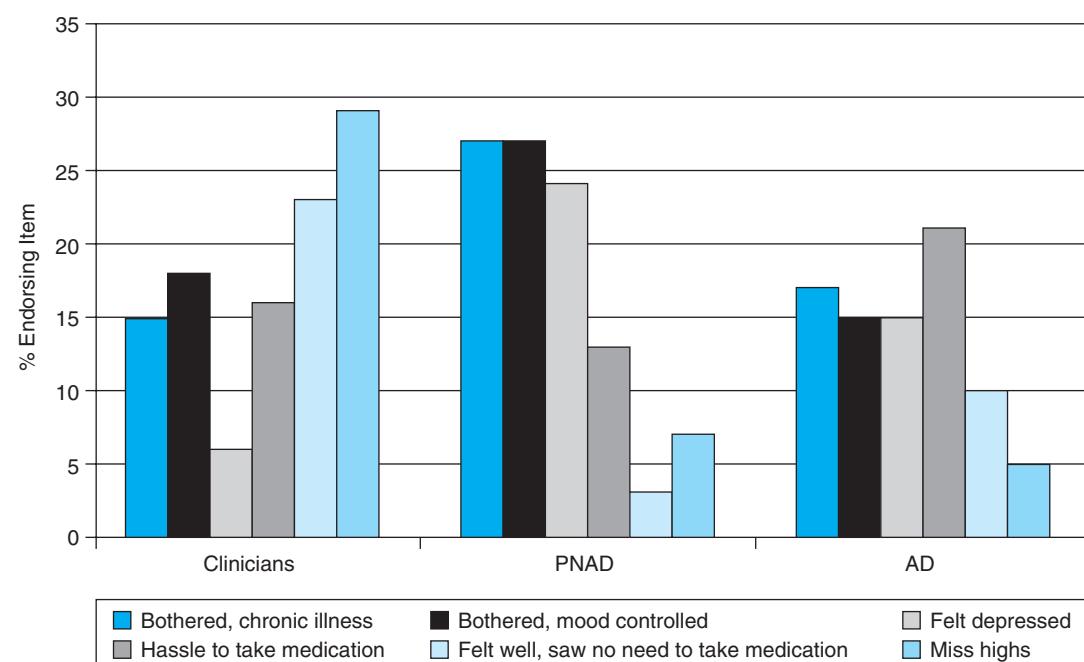

- The patient felt well and saw no need to continue the medication. (Nearly two-thirds of physicians thought that lithium nonadherence was "somewhat" or "very"

related to patients' acting out their denial of a serious lifelong illness.)

- The patient missed the highs of hypomania and/or mania.
- The patient was bothered by the idea of having a chronic illness.

More than 20 years after the UCLA study, Pope and Scott (2003) attempted to replicate it using a British sample of 72 patients and 41 psychiatrists (Fig. 21-1). They concluded that the reasons patients gave for medication nonadherence had "hardly altered since Jamison et al.'s (1979) original study" (p. 291). They also found, as the UCLA investigation had, that physicians' perceptions of reasons for nonadherence remained at variance with those of patients. Psychiatrists, for example, believed that patients stopped taking their medication because they missed their highs, which is certainly true for many patients, but most patients were more concerned about feeling depressed while medicated. Psychiatrists also failed to recognize the importance to patients of having to deal with a chronic illness, as well as having their moods controlled by medication. Psychological issues of control were paramount in a study of bipolar patients conducted by Stratigos and colleagues (2002), as well as in an extensive European study of patient attitudes (Morselli et al., 2003). By far the most important concern patients cited was "feeling dependent" on taking medication; next in importance was their perception that taking medication was tantamount to "slavery."

Figure 21-1. Primary reasons for stopping medication identified by clinicians ($n=41$) and by previously nonadherent (PNAD, $n=33$) and adherent (AD, $n=37$) patient groups. (Source: Pope and Scott, 2003. Reprinted with permission from Elsevier.)

Additional studies have attempted to understand patients' subjective reasons for nonadherence or to predict adherence over time. Some studies have tested versions of a "health belief" model in which patients' perceptions of the severity of their illness and beliefs about the benefits of medication, about themselves, and about control over their illness combine to predict adherence. For instance, Cochran and Gitlin (1988) assessed various attitudes and beliefs among a later sample from the UCLA Affective Disorders Clinic and tested a complex social psychological model of adherence. For the most part, their results confirmed the model, indicating that attitudes about lithium and its effects can predict adherence. An important finding was patients' belief that if their psychiatrist and their friends and family had positive views of the treatment and its effects—and if they themselves were motivated to meet the psychiatrist's and others' expectations—adherence was more likely. The investigators noted that relevant relationships, including the patient–physician relationship, may be important sources of adherence-related attitudes.

Keck and colleagues (1997) assessed patients' reasons for nonadherence to their medication regimen (various mood stabilizers and combinations of drugs) using a questionnaire derived from previous studies of reasons for nonadherence. In their sample of 140 hospitalized manic patients followed for a 1-year period, they found that only 31 percent were totally adherent. The most commonly cited reasons for total or partial nonadherence were denial of illness or poor insight (63 percent); side effects (27 percent); belief that they had recovered from the illness (11 percent); and others, including practical considerations such as the cost of medication.

Schumann and colleagues (1999) reported on a 6-year retrospective study of reasons for nonadherence among 76 patients in two clinics in Vienna and Berlin; 50 percent of the patients were bipolar, with the remainder being unipolar or schizoaffective. Although results were not reported by diagnostic group, the investigators indicated that diagnosis was not significantly associated with adherence or reasons cited for discontinuation of medication. They found that 54 percent of the patients had discontinued treatment at least once during the 6-year period. The most commonly cited reason was "resistance against long-term treatment." Comparisons of adherent and nonadherent patients revealed significant differences on three attitude items: resistance to prophylaxis, denial of the effectiveness of lithium, and denial of the severity of illness.

Greenhouse and colleagues (2000) specifically tested the role of cognitive acceptance or denial of illness in predicting self-reported adherence during a 1-week period. Acceptance and denial were defined by items on a coping questionnaire—for example, "I've been accepting the reality of the fact that it [diagnosis of bipolar-I disorder] has

happened" and "I've been saying to myself, 'this isn't real.'" The authors found that with lower acceptance and higher denial, medication adherence scores declined sharply. Noting that the correlations between acceptance and denial were only moderate, they argued that both processes may contribute separately to medication adherence. Adams and Scott (2000) found that patients' beliefs about the benefits of treatment and the severity of their illness contributed substantially to the prediction of adherence. They also observed that believing health is controlled by external rather than internal factors enhanced adherence.

In a prospective study of the relationship between illness concepts and medication adherence, Kleindienst and Greil (2004) randomly assigned 171 bipolar patients to either lithium or carbamazepine treatment. Illness concepts—trust in medication, trust in the treating physician, and absence of negative treatment expectations—were predictive of adherence to lithium but not to carbamazepine.

Side Effects: A Complex Issue

Several studies, especially those based on primarily lithium-treated patients, have found that side effects are often cited in subjective reports of reasons for nonadherence (e.g., Weiss et al., 1998; Scott and Pope, 2002a). In the prospective study of Kleindienst and Greil (2004), however, neither the number nor the severity of side effects was related to adherence in patients taking lithium or carbamazepine.

Side effects are a complex issue for several reasons. The side effects of a medication may be real, but their importance to patients may be highly subjective in ways unrelated to their frequency or to the perceptions of others, and they may or may not be related to adherence. For example, Gitlin and colleagues (1989) found that the most common side effects of lithium—thirst and polyuria—were far less bothersome to patients than weight gain and cognitive effects. The total number of side effects was related to nonadherence only slightly and nonsignificantly; specific side effects (especially tremor and mental slowness) were associated most strongly (although only moderately) with actual nonadherence. Further, patients indicated that weight gain was the major side effect *potentially* bothersome enough to cause them to stop lithium. Thus the role of side effects in actual medication nonadherence is somewhat ambiguous.

Jamison and colleagues (1979) found further that clinicians may misperceive the role of side effects; the clinicians in their study viewed side effects as more important in nonadherence than did patients who had discontinued lithium treatment. Clinicians may also attribute some "side effects" to mood episodes rather than to medication. Such tendencies may reflect a reluctance to acknowledge certain negative effects, such as cognitive changes, or they may accurately characterize illness factors that patients attribute

to their medication. Not only may mood symptoms be misperceived as medication side effects, but mood symptoms—especially depression—may affect the degree to which patients experience and are bothered by somatic side effects (e.g., Abou-Saleh and Coppen, 1983). Indeed, it is likely that personality and interpersonal–environmental characteristics influence patients' perceptions and tolerance of medication side effects.

Side effects, therefore, represent both real deterrents to medication adherence and psychological issues that may play a complex role in adherence. There are some indications that different mood stabilizers may have fewer or differing side effects, resulting in varying levels of adherence to the prophylactic regimen, but significant differences have not been convincingly documented. One study of adherence to antipsychotic medication among a sample of outpatient veterans (most diagnosed with schizophrenia) is suggestive. The investigators found significantly better rates of adherence to atypical than to typical antipsychotic medications, as measured by prescription refills (Dolder et al., 2002). Yet while better adherence was found for the medications with fewer side effects at 6-month follow-up, no differences were seen at 12 months. A recent large study of claims data for antipsychotic treatment in more than 15,000 commercially insured bipolar patients found greater adherence for individuals taking atypical rather than typical antipsychotics (Gianfrancesco et al., 2006). British researchers, however, found significantly lower adherence to atypical antipsychotics than to lithium (Horne et al., 2006).

Greater availability of medical resources to treat adverse side effects may enhance acceptance of long-term medication. Certainly, education about side effects is essential. A recent British study found that more than 60 percent of the 223 patients surveyed were dissatisfied with the information they received about side effects from their physicians (Boskhill et al., 2006). It must be emphasized, however, that subjective and psychological factors also play an important role in patients' reactions to side effects. In their prospective study of adherence in bipolar patients, for example, Kleindienst and Greil (2004) demonstrated that concepts patients hold about their illness strongly influence the subjective impairment caused by medication. Chapters 18 through 20 address side effects and their management in greater detail.

Empirical Correlates of Nonadherence

In addition to the reasons for nonadherence that can be articulated by patients, further information is available from studies of empirical correlates of nonadherence. Table 21-3, presented earlier, summarizes studies of adherence among bipolar patients. Most of these studies focused on lithium and examined a variety of demographic and clinical factors,

using diverse measures of adherence and populations from a range of clinical settings. These studies were characterized by numerous methodological and conceptual shortcomings, including the use of predominantly small sample sizes, which precludes subgroup comparisons and limits generalizability; a relative absence of theoretical or predictive models to guide the analyses; and failure to evaluate complex interactions among variables and changes in medication use over time. Nevertheless, these studies serve as useful first steps toward understanding adherence issues.

Patient-Related Factors

As noted earlier, few demographic variables (age, gender, income, education) appear to predict adherence to lithium or other medications reliably, an observation consistent with results of medication adherence studies in general (see Table 21-1). Among the exceptions to this rule are findings that being married is associated with better adherence and that living alone is associated with poorer adherence³; less consistently, adherence increases with age.⁴

Clinical features are also inconsistently associated with adherence, with the exception of a constellation of variables related to elevated mood. As discussed earlier, Jamison and colleagues (1979) found that missing of highs was one of the few factors significantly differentiating adherent from nonadherent patients (see Table 21-4). Likewise, Connolly and colleagues (1982) observed that nonadherence was associated with elevated mood. Lenzi and colleagues (1989) found that grandiosity was significantly associated with nonadherence, while Rosen and Mukherjee (unpublished data) noted that nonadherence was associated with a history of grandiose delusions. Similarly, a study of patients with bipolar-I disorder showed lithium adherence to be less likely among those who experienced recurrent manic episodes (without evidence for clinical depression) than among those who experienced both disabling depressive and manic episodes (Lenzi et al., 1989).

Miklowitz (1992) found that among manic patients, those with more severe psychotic symptoms (and schizoaffective-manic patients generally) were more nonadherent. Other illness factors, such as polarity of episodes, severity, family history, diagnostic subtype, and frequency of affective episodes, are ambiguously or inconsistently related to adherence. Nonetheless, it might be predicted that number of years ill, in complex interaction with age and clinical history, would affect adherence. Clinical experience suggests that younger patients tend to be less accepting of their diagnosis and prognosis, and their attitudes change with experience and the consequences of the illness over time.

The role of mania, and perhaps psychosis in particular, may be especially relevant to the patient's level of insight,

awareness, and acceptance of illness. Ghaemi (1997) reviewed studies examining insight (awareness that one has a mental disorder or that one is exhibiting symptoms of psychopathology) among patients with severe psychopathology and its correlation with clinical features. In general, he found that lack of insight is just as prevalent in patients with mania as in those with schizophrenia. Yen and colleagues (2004) found that poorer insight in bipolar illness is more likely in males and in patients with a shorter duration of illness and a history of psychosis. It is also related to the nature of the clinical episodes experienced by patients (see Chapter 22). Patients who experience pure mania show less insight than those who have predominantly mixed states (Cassidy et al., 2001; Dell'Osso et al., 2002); depressed patients show greater insight than manic patients⁵; and bipolar-II patients appear to show less insight than bipolar-I patients (Pallanti et al., 1999). Ghaemi (1997) found no studies examining the role of insight in medication adherence among bipolar patients; however, results of studies previously mentioned concerning patients' beliefs that they are not ill, or no longer ill, clearly reflect a similar concept. Research in the field of schizophrenia has demonstrated a strong association between lack of insight and nonadherence (e.g., Fenton et al., 1997; Young et al., 1999), and further studies of the meaning, correlates, and consequences of lack of insight among bipolar patients are needed. Treatment for bipolar illness often results in improved insight,⁶ but the effect of this on adherence has not been adequately studied.

Two further patient characteristics warrant consideration in the context of adherence. The first is substance abuse, which is increasingly recognized as a common and complicating feature of the course of bipolar disorder (see Chapter 7). It may play a particularly pernicious role in poor adherence to medication, as several studies have now reported.⁷

A second salient patient characteristic is one that has rarely been examined: personality disorders that may interact with clinical and attitudinal variables to affect adherence. One large study of 200 bipolar-I and -II patients found that personality disorders assessed by the Structured Clinical Interview for the *Diagnostic and Statistical Manual* (DSM) (SCID) II were strongly associated with medication nonadherence (Colom et al., 2000), as did an earlier, considerably smaller study (Danion et al., 1987) and a Danish one (Aagaard and Vestergaard, 1990). On the other hand, another study, which did not report details on the method used for assessing personality disorders, did not find such an association (Schumann et al., 1999), nor did a recent prospective study of 171 bipolar patients conducted in Germany (Kleindienst and Greil, 2004). It might be speculated that the relatively poor clinical course associated with many forms of personality disorder (see Chapter

10) involves medication nonadherence as a key mechanism of the effects of personality pathology. Personality pathology is highly likely to contribute not only to behavioral problems, such as poor perseverance and inadequate environmental supports, but also to increased substance abuse and maladaptive understanding of the illness, its consequences, and the role of medication. However, patients with personality pathology may also respond more poorly to medication and thus perceive less benefit from adhering to their treatment regimen.

In their comprehensive review of 25 studies of medication adherence in bipolar patients, Perlick and colleagues (2004b) concluded that the most consistent risk factors for nonadherence are comorbid substance abuse, comorbid personality disorder, being single or living alone, having limited insight or knowledge about bipolar illness, and difficulties with side effects (especially cognitive changes, weight gain, lethargy, and problems with tremor and coordination). For an important subgroup, manic symptoms and missing highs are also important. Less clearly related are gender, number of affective episodes, and age.

Environmental Factors

Supportive resources and practical matters have been identified as key contributors to medication adherence in patients with schizophrenia, but have been studied far less often in the context of bipolar disorder. Many studies have found that living alone or being single is predictive of nonadherence in bipolar patients⁸; in a related finding, Lenzi and colleagues (1989) noted that adherence was associated with degree of social support (see also Tables 21-1 and 21-3). The existence of positive relationships doubtless affects adherence in both direct and indirect ways, and such issues deserve considerably more investigation. Also, of course, marriage and adherence may both be associated with positive personal attributes and a relatively better clinical course. Obviously, too, if supportive relationships help facilitate medication adherence, psychotherapy may be an important source of support and may influence adherence directly as well as indirectly (see Chapter 22).

Environmental factors also include the occurrence of chronic and episodic stressors and the extent to which such experiences may undermine efforts to adhere to medication. To date, only one study has directly investigated the potential effect of life events on symptomatology through the mechanism of changes in adherence. Johnson and colleagues (1998) examined this model among a sample of 67 bipolar-I patients over a 1-year period but found no such effect; instead, they found that both adherence and life events affected symptomatology independently and directly.

Other issues concerning practical matters—in particular, medication costs and treatment affordability and

availability—are obviously important but have not been adequately studied.

Clinician-Related Factors

The therapeutic alliance has rarely been studied in the context of bipolar patients' adherence to medication, although its importance has been well documented in studies of schizophrenia (see, e.g., the review by Fenton et al., 1997). As noted previously, Cochran and Gitlin (1988) tested a complex model of attitudes associated with adherence and found that patients' perceptions of physicians' attitudes about lithium were important to the patients' own attitudes, although that study did not examine the quality of the therapeutic relationship. Yet it appears probable that the clinician's role is critical, extending well beyond the mechanics of appropriate prescribing (Frank and Frank, 1991; Slavney, 2005).

Medication-Related Factors

Patients' perceptions of both the efficacy and the side effects of the medications they take, or do not take, are clearly important. The relationship between perceived efficacy of medication and adherence is complex and little studied. Two studies (Jamison et al., 1979; Connelly et al., 1982) found no association between adherence and patients' evaluation of medication efficacy, but two others found to the contrary (Bech, 1982; Bonin, 1999). Adherence, as we have seen, is complexly affected by individual differences in perception and toleration of side effects. Several studies have found that nonadherence is associated with the severity or number of subjective concerns about side effects.⁹ Other investigators, however, have not found this association.¹⁰

Certain intrinsic features associated with the pharmacological treatment of bipolar patients may result in exceedingly difficult clinical situations that clinicians must work to overcome. These intrinsic qualities of lithium and the other medications used to treat bipolar illness are listed below with respect to lithium; their generalizability to other medications is apparent, although incomplete.

- Lithium (unlike analgesics, neuroleptics, or benzodiazepines) has a long-delayed therapeutic action: 5 to 7 days for an antimanic effect, usually much longer for an antidepressant effect.
- Patients are expected to stay on the drug for an indeterminate time, much of it in a more or less normal clinical state, with no immediate felt need for the drug.
- If a patient stops the medication, the negative consequences of nonadherence (recurrence of mania and/or depression) are often delayed. Rarely is there an immediate negative effect.

- The cessation of lithium, on the other hand, is often accompanied by relatively immediate positive experiences, either because of the disappearance of side effects or because of breakthrough hypomania (often a contributing factor to lithium nonadherence in the first place).
- The initiation of lithium treatment often is associated with unpleasant events in the patient's memory (e.g., psychosis, hospitalization, violence, agitation).
- If lithium is first prescribed for a manic episode, the natural history of the illness predicts that the patient is at significant risk for a postmanic depression, which further associates the onset of lithium treatment with unpleasant psychological and physical experiences.

Compounding these difficulties, lithium has no known intrinsic reinforcing qualities, either immediate or delayed.

Psychotherapy and Medication Adherence

We cannot emphasize enough the importance of psychotherapy for patients who have bipolar illness, especially those to whom medication adherence does not come easily. We review specific psychotherapeutic interventions, as well as their impact on recurrence of illness and adherence, in Chapter 22. Sajatovic and colleagues (2004) recently summarized clinical trials that specifically examined interventions designed to enhance medication adherence; we reproduce their summary here (Table 21-5) and discuss the details of the psychotherapeutic techniques and specific psychotherapy studies in Chapter 22. Several clinical trials have been completed since the review of Sajatovic and colleagues. Two found no significant difference in medication adherence between the treatment and comparison groups (Ball et al., 2006; Scott et al., 2006); two found increased adherence in the treatment groups (Miklowitz et al., 2003; Lam et al., 2005). These studies are discussed in Chapter 22.

CONCLUSIONS

Many clinicians, having once diagnosed bipolar illness and prescribed an effective medication, tend to assume that the difficult part is over. On the contrary, in the words of one patient, "the war has just begun." Nonadherence to the use of lithium and other medications is costly not only to bipolar patients, but also to those who know them, and to society as a whole.

Research on the factors involved in nonadherence among bipolar patients is relatively sparse, but much information exists in research conducted on related illnesses, such as schizophrenia. One set of factors includes patient variables such as attitudes about the illness and the role of medication, as well as reactions to side effects. The role of the patient's insight into the disorder may be crucial, with

TABLE 21–5. Summary of Studies of Interventions to Enhance Treatment Adherence among Patients with Bipolar Disorder

Study	Design	Intervention	Participants	Outcome	Comments
Shakir et al., 1979	Mirror design	Weekly interpersonal group psychotherapy	N=15; bipolar-I=12, bipolar-II=3	Lithium levels; pretreatment=.53 mEq/l; post-treatment=.94 mEq/l	Average duration of group treatment was 51 wk; mean number of participants per session was 8.2
Cochran, 1984	Randomized controlled trial	Weekly modified cognitive-behavioral intervention for 6 wk	N=28; 14 to intervention, 14 to usual care	Significantly enhanced adherence immediately after intervention and at 6 mo	Patients who received the intervention stopped lithium less often and were hospitalized less often
Van Gent and Zwart, 1991	Randomized controlled trial	Five theme-oriented groups for partners of patients with bipolar disorder	N=26 partners of patients; 14 to intervention, 12 to control group	Nonadherence did not differ between groups	Group support was of benefit to partners; partners in both groups reported increased well-being
Harvey and Peet, 1991	Randomized controlled trial	Videotaped lecture on lithium, handout, and home visit	N=59; 29 to educational group, 30 controls	Intervention group had fewer missed lithium doses ($p<.07$)	Improved adherence was associated with improved attitudes toward lithium ^a
Clarkin et al., 1998	Randomized controlled trial	Manual-driven marital therapy (25 sessions)	N=42; 19 to intervention, 23 to usual care	Mean level of medication adherence was higher in the intervention group ($p=.008$)	Patients receiving marital therapy had better overall functioning but were not less symptomatic
Perry et al., 1999	Randomized controlled trial	Individual teaching of early symptom recognition (7 to 12 sessions)	N=69; 34 to intervention, 35 to control group	No difference in adherence between groups	Experimental treatment was effective in reducing relapse to mania but not to depression

498

Weiss et al., 2000	Controlled trial, sequential block enrollment	Weekly integrated group therapy (12–20 sessions)	<i>N</i> =45; 21 to intervention, 24 to control conditions; all participants had dual diagnoses ^b	No difference in adherence between groups	Improvements in substance dependence and mania but not depression for intervention group
Miklowitz et al., 2000	Randomized controlled trial	Manual-driven family-focused psychoeducational treatment; 21 sessions over 9 mo	<i>N</i> =101; 28 to family treatment, 51 to control group; 22 terminated early	No main effect of psychosocial treatment on predicting medication adherence	Over 12 mo, family therapy provided greater prophylaxis against relapse to mood disorder, particularly depression
Lam et al., 2000	Randomized controlled trial	Cognitive-behavioral therapy, 12–20 sessions within 6 mo (mean=16.3 sessions)	<i>N</i> =25; 13 to intervention, 12 to control group	Therapy group showed significantly better adherence over 12 mo ($p <.05$) ^c	Patients in the therapy group had significantly fewer bipolar episodes and fewer hospitalizations
Colom et al., 2003	Randomized controlled trial	Psychoeducational group program, 21 sessions, 90 min each	<i>N</i> =120 euthymic bipolar-I and -II patients; 60 to intervention, 60 to control group	At 2 yr follow-up, intervention patients had higher lithium levels ($p=.03$)	Group psychoeducation significantly reduced the number of patients who had relapses, the number of recurrences per patient, and hospitalizations
Lam et al., 2003	Randomized controlled trial	Individual manual-driven cognitive therapy	<i>N</i> =103; 51 to intervention, 52 to control group	Significantly greater adherence in treatment group ($p=.02$ for self-report; $p=.06$ for serum levels)	Cognitive therapy reduced relapse, improved social functioning

factors that reduce such insight (e.g., mania, being young or at an early stage of the illness, comorbid substance abuse) contributing to nonadherence. Other important factors in adherence involve the clinician–patient relationship and the patient’s environment, including the extent of supportive relationships with others. Further research on adherence among bipolar patients is needed to further our understanding of issues that may be unique to this population.

Clinicians wishing to increase medication adherence can take several steps: minimize medication levels to the extent possible; minimize and treat aggressively any side effects; track the patient’s adherence; examine their own, as well as the patient’s, concerns about long-term medication maintenance; educate patients and their families about bipolar illness and the role of medication in attenuating its course; and, when indicated, actively encourage adjunctive psychotherapy.

NOTES

1. This description and others by “a patient with manic-depressive illness” were written by one of the authors, Kay R.

Jamison. Some were modified slightly and incorporated into her memoir, *An Unquiet Mind* (New York: Alfred A. Knopf, 1995).

At this point in my life, I cannot imagine leading a normal life without both taking lithium and being in psychotherapy. Lithium prevents my seductive but disastrous highs, diminishes my depressions, clears out the wool and webbing from my disordered thinking, slows me down, gentles me out, keeps me from ruining my career and relationships, keeps me out of a hospital, alive, and makes psychotherapy possible. But, ineffably, psychotherapy heals. It makes some sense of the confusion, reins in the terrifying thoughts and feelings, returns some control and hope and possibility of learning from it all. Pills cannot, do not, ease one back into reality; they only bring one back headlong, careening, and faster than can be endured at times. Psychotherapy is a sanctuary; it is a battleground; it is a place I have been psychotic, neurotic, elated, confused and despairing beyond belief. But, always, it is where I have believed—or have learned to believe—that I might someday be able to contend with all of this.

No pill can help me deal with the problem of not wanting to take pills; likewise, no amount of analysis alone can prevent my manias and depressions. I need both. It is an odd thing owing life to pills, one's own quirks and tenacities, and this unique, strange and ultimately profound relationship called psychotherapy.

—Patient with manic-depressive illness¹

Manic-depressive illness is, by any measure, gravely serious—complex in its origins, diverse in its expression, unpredictable in its course, severe in its recurrences, and too often fatal in its outcome. Yet in the bipolar subgroup milder forms of the disorder may, in some individuals, enhance productivity, creativity, and sociability (see Chapters 10 and 12). Severe mania and depression are debilitating, but mild hypomania is a state that is often sought. Moods are such an essential part of the substance of life, of individuality and identity, that distinguishing normal moods from mild and moderate expressions of the illness is an exacting task for patients. Given such complexity, it is clearly unrealistic to expect treatment to proceed smoothly simply because effective medications are available.

Psychological support for the treatment of bipolar patients ranges from a few minutes with the prescribing physician to combined use of psychoeducation and individual, family, and group psychotherapy. Most commonly, a general psychiatrist or psychopharmacologist provides support for patients who are taking mood stabilizers, usually within a limited time frame of 20 to 30 minutes every few weeks. Although psychotherapeutic work per se may not take place in such a context, the physician can create an emotionally supportive atmosphere, be aware of and focus on the general psychological issues involved in taking a mood stabilizer and having a mood disorder, and encourage

patients to express their concerns. Creating and maintaining such an atmosphere is essential to good clinical care.

The practice guidelines of the American Psychiatric Association (2002) for managing bipolar disorder recommend that clinicians (1) perform a diagnostic evaluation, (2) evaluate the patient's safety and determine a treatment, (3) establish and maintain the therapeutic alliance, (4) monitor treatment response, (5) provide education to the patient and family, (6) enhance treatment adherence, (7) promote awareness of stressors and regular patterns of activities and sleep, (8) work with the patient to anticipate and address early signs of relapse, and (9) evaluate functional impairments. A therapeutic relationship of this kind not only increases the likelihood of medication adherence, but also makes it more likely that the patient will be referred for formal psychotherapy should the need arise. Formal, structured psychotherapy best follows control of acute episodes. Unfortunately, many physicians do not provide this type of therapeutic relationship, nor do they make the necessary referrals to qualified psychotherapists.

Indeed, the very efficacy of mood stabilizers and other medications may lead clinicians to minimize the value of psychotherapy or their own role in the treatment of bipolar illness. In 1990, a consensus conference of the National Institute of Mental Health (NIMH) identified as the most underdeveloped area in the treatment of bipolar illness the

use of adjunctive psychosocial therapies to alleviate the behavioral and social adjustment problems associated with the disorder (Prien and Potter, 1990). Likewise, Vasile and colleagues (1987) found that psychiatrists and mental health professionals often de-emphasize psychotherapy in the treatment of affectively ill patients. Patients themselves, by contrast, often find psychotherapy a potent adjunct to mood stabilizers. In the one study in which patients and therapists were actually asked about the value of psychotherapy in the treatment of bipolar illness, twice as many patients as physicians thought psychotherapy was helpful to them in remaining adherent to medication (Jamison et al., 1979). These findings are consistent with those of a survey of a national depression and bipolar support group completed two decades later (Goodale and Lewis, 1999).

While medication is the central treatment for bipolar disorder—in both the acute and maintenance phases—psychotherapy is a particularly important adjunct to medication in maintenance treatment. This is true for several reasons.

First, problems that typically accompany bipolar illness invite psychotherapeutic intervention. The personal, interpersonal, and social consequences of the disorder, which are usually severe, can include suicide, violence, alcoholism, drug abuse, unemployment, divorce, parental neglect, and hospitalization. Although biological variables predominate in the etiology, the primary manifestations of bipolar illness are behavioral and psychological, with profound changes in perception, attitudes, personality, mood, and cognition. Psychotherapeutic interventions can be of unique value to patients undergoing such devastating changes in the way they perceive themselves and are perceived by others, providing the needed monitoring of mood and life changes. Indeed, some of the newer psychotherapies focus on monitoring these changes as a way of preventing recurrences. The psychosocial consequences of bipolar disorder—such as loss of employment or a significant decline in employment status, alcohol or other substance abuse, alienation from loved ones, and frequent marital and other interpersonal disputes—are also precipitants of recurrences of the disorder. Such life events, often the subject matter of psychotherapy sessions (Coryell et al., 1993; Goldberg et al., 1995), may trigger manic or depressive episodes through, for example, disruption of circadian rhythms, loss of sleep, or distorted cognitions (Wehr et al., 1987a; Frank et al., 1994; Miklowitz et al., 1996). In helping to alleviate the stress-related precipitants of manic and depressive episodes, psychotherapy may temper the progression of the natural course of the illness (Post et al., 1986).

Second, suicide tends to occur early in the illness (see Chapters 8 and 25), when patients have the least support

and information and are most likely not to adhere to medication. Indeed, nonadherence to lithium or other mood stabilizers becomes a major theme in the therapy of many patients (Jamison et al., 1979; Jamison, 1995; Keck et al., 1997) (see Chapter 21). Confusion often arises because the illness itself, as well as its pharmacological treatments, can affect cognition, perception, mood, and behavior. Psychotherapeutic sessions frequently involve concerns about being on medication. For example, the effectiveness of medication in ameliorating the illness is not always welcome because it deprives some patients of energy and much-sought-after highs and can burden them with bothersome side effects. Moreover, some patients (at least 10 to 15 percent) have a poor response to mood stabilizers (Goldberg and Harrow, 1999), which may be due in part to nonadherence. Close monitoring of adherence is therefore important, especially because discontinuation of medication may lead to recurrences of mania and/or depression and increased risk of suicide.

Third, there are times when clinicians treat bipolar patients who are not taking medication, such as those who refuse it, those who have medical contraindications or need surgery, and women who stop taking medication during their pregnancies. In such cases, psychotherapy may have to serve as the sole treatment, providing critical support and monitoring. Psychotherapy, in conjunction with medication or electroconvulsive therapy (ECT), may also be the treatment of choice for acutely suicidal patients or for breakthrough depressions in patients prone to antidepressant-induced cycling.

The emphasis in this chapter is on psychotherapeutic interventions for patients maintained on mood stabilizers. The first section focuses on psychotherapeutic issues of importance in the clinical management of bipolar illness. These issues are relevant to all aspects of clinical management, whether the patient is being seen for medications only (the most common clinical situation) or for medications in conjunction with formal psychotherapy—individual, group, or family—or with involvement in a self-help group. The discussion encompasses new developments in psychotherapeutic practices, as well as educational and informational resources, including books, self-help groups, and websites. Some psychotherapies have been modified for bipolar patients and described in manuals for testing in clinical trials; a number of such trials are either completed or ongoing. The literature on these psychotherapies and their efficacy is reviewed in the second section of the chapter, with a focus on treatment modalities combining psychotherapy and mood stabilizers. Psychotherapeutic techniques per se, however, are not discussed in detail, in part because we assume a basic knowledge of the principles and practice of psychotherapy and in part because no one type

of psychotherapy has been demonstrated to be *uniquely* effective in this patient population. The lack of psychotherapeutic specificity in the discussion here reflects the reality of clinical practice, namely, the predominance of pharmacological treatments for bipolar disorder and the relatively recent emphasis on psychological interventions. However, we wish to reemphasize our belief that formal psychotherapy is beneficial to many, if not most, bipolar patients and is unquestionably essential for many others, especially those who are suicidal or unwilling to take medication in the manner prescribed. The limitations of even the most beneficial medications are increasingly apparent to clinicians treating affective illness. It may be hoped that ongoing and future research efforts will determine the specific nature of the most effective psychological interventions.

CLINICAL MANAGEMENT

We begin this section by summarizing the historical context for the psychotherapeutic treatment of bipolar disorder. We then review key issues that arise during such treatment. The section ends with discussion of important aspects of psychotherapeutic treatment of bipolar illness, including mood charting, patient education, family education and family therapy, and the self-help programs of national and local support associations.

Historical Context

Clinical pragmatism, buttressed by biological assumptions about etiology, long ago determined the dominance of medical therapies in the treatment of bipolar illness. Thus physicians, ancient and modern, have for the most part sought cures for mania and melancholia not through talking and listening, but through direct actions of control: mineral baths, bloodletting, herbs, chains, vapors, bromides, opiates, warm waters, cold waters, and physical and chemical restraints.²

Psychotherapy, as generally conceptualized, is a set of formal psychological procedures or exercises that are followed by a therapist and patient and that are designed to relieve symptoms, improve function, or produce insight. These procedures, discussed at length later in the chapter, are derived from a particular theory of psychological development or change.³

Even the pioneers of psychotherapy, the psychoanalysts, tended to perceive patients suffering from bipolar illness as not very good candidates for psychotherapeutic treatment. Fromm-Reichmann (1949) characterized them as lacking in "complexity and subtlety"; Abraham (1911) as "impatient, envious, exploitative, and with dominating possessiveness"; and Rado (1928) as continually involved in a "raging orgy of self-torture." Bipolar patients generally were

compared with schizophrenic patients and found to lack introspection and to be too dependent and "clinging" (Fromm-Reichmann, 1949), disconcertingly capable of finding vulnerable spots in the therapist (Fromm-Reichmann, 1949; Janowsky et al., 1970), and prone to eliciting strong feelings of countertransference in the analyst (English, 1949; Rosenfeld, 1963). Despite these perceived difficulties, many leading analysts from the prepharmacotherapy era sustained a dedicated commitment to the psychoanalytic treatment of bipolar illness. Thus in 1911, Abraham noted:

Psycho-analysis, which has hitherto enabled us to overcome this obstacle [depression interfering with the development of transference], seems to me for this reason to be the only rational therapy for manic-depressive psychoses. (Abraham, 1927, pp. 153–154)

Nevertheless, before lithium was available, enthusiasm for treating bipolar illness was limited—and understandably so. One can imagine the frustration of attempting to treat a hypomanic or manic patient in psychotherapy. Getting such a patient into the office and keeping him there would have been difficult enough; engaging in a meaningful therapeutic endeavor could only have been daunting. Likewise, any clinician can appreciate the different kind of frustration involved in treating a profoundly depressed patient. The high spontaneous remission rate characteristic of bipolar illness no doubt encouraged therapists in some cases to attribute clinical changes to their therapeutic interventions; conversely, when no change or a relapse occurred, therapists tended to assume responsibility as well or to blame the patient.

The psychoanalysts and early psychotherapists provided a source of clinically descriptive information, virtually all of it from unmedicated patients. This material is all the more significant because present medical ethics strongly discourage the psychotherapeutic treatment of unmedicated patients with bipolar illness. The psychoanalytic school is also important because it has had a profound effect on clinical thinking about bipolar illness. Not only most psychotherapists, but also many who contributed to the early biological and pharmacological literature, have been deeply influenced by psychoanalytic conceptions of the illness.

Psychotherapeutic Issues

The competent and compassionate psychotherapy of bipolar illness is predicated on a solid knowledge of the disorder. Kraepelin's injunction to his turn-of-the-century medical students remains compelling: "It is one of the physician's most important duties to make himself, as far as possible, acquainted with the nature and phenomena of

insanity" (Kraepelin, 1904, p. 3). A solid knowledge of bipolar disorder encompasses phenomenology, the natural history of the illness (including its recurrent nature, problematic course, high mortality rate, and seasonal patterns), biological aspects (including medication responses in mania and depression), biological theories of etiology, and mechanisms of action of the drugs used for treatment. Therapists with a good scientific grasp of the psychological phenomenology of the illness, as well as the biological, will be more therapeutically competent. They will also be more likely to avoid the biological determinism that is common in therapists who are well grounded in biological theories but poorly trained in psychological studies such as personality theory and development, neuropsychology, and social psychology.

The psychotherapy of bipolar illness requires considerable flexibility in style and technique. Flexibility is necessary because of the patient's changing moods, thinking, and behavior, as well as fluctuating levels of therapeutic dependency intrinsic to the illness. Fluctuations in functioning that occur within as well as between episodes of the illness pose a serious challenge to therapists, who must adjust their treatment options, strategies, and attitudes to meet the demands of the individual patient and the specific phase of the illness. In the therapeutic relationship, a long-lead approach is often useful to maximize the patient's awareness of and sense of control over his or her behavior. It is important not to attempt to control the patient unduly and not to allow medications to become the focus of a power struggle; various psychoeducational treatments have been developed and tested for this purpose (see the later discussion). A thin line exists between too much and too little therapeutic control: too much may lead to increased dependency, maladaptive rebellion, decreased self-esteem, or nonadherence; too little may lead to feelings of insecurity, an unnecessarily tenuous hold on reality, and feelings of abandonment. The patient may see signs of caring in the therapist's firm, consistent orders for routine medication levels or tests of thyroid, liver, and kidney functioning but engage in unnecessary power struggles and refuse to comply with medication regimens when the therapist places undue emphasis on precise medication patterns (e.g., not allowing for some degree of self-titration).

Because bipolar disorder has a long-term course with highly variable manifestations, therapeutic alliance and support play a central role in treatment. The alliance is the product of good rapport, combined with knowledge about the course of the individual patient's illness. Collaborative aspects of management through self-ratings, chartings, and patient and family education (using films, lectures, books, or handouts), discussed later in the chapter, are integral to

good clinical care. The therapist must also be able to use hospitalization, when appropriate, as an occasionally necessary adjunct to outpatient care and must not regard it as an indication of failure in the therapeutic endeavor.

In the remainder of this section, we review issues that commonly arise in the psychotherapeutic treatment of bipolar illness: anger, denial, and ambivalence surrounding both the illness and its treatment; disappointment and frustration attendant to less-than-complete treatment success; losses associated with medication; fears of recurrence; the problem of learning to discriminate normal from abnormal moods; the need to deal with developmental tasks of late adolescence and early adulthood; concerns about family and other relationships; concerns about genetics; and clinician attitudes and expectations. First, however, we discuss patients' perspectives on some of the major psychological issues of importance in psychotherapy.

Perspectives of Patients

The following description of the bipolar form of manic-depressive illness was written by a patient who, by age 30, had been through two violently psychotic, ecstatic manic episodes, countless expansive and euphoric hypomanias, occasional mixed states, several lengthy and incapacitating suicidal depressions, and a nearly lethal suicide attempt:

There is a particular kind of pain, elation, loneliness, and terror involved in this kind of madness. When you're high it's tremendous. The ideas and feelings are fast and frequent like shooting stars and you follow them until you find better and brighter ones. Shyness goes, the right words and gestures are suddenly there, the power to seduce and captivate others a felt certainty. There are interests found in uninteresting people. . . . Feelings of ease, intensity, power, well-being, financial omnipotence, and euphoria now pervade one's marrow. But, somewhere, this changes. The fast ideas are far too fast and there are far too many; overwhelming confusion replaces clarity. Memory goes. Humor and absorption on friends' faces are replaced by fear and concern. Everything previously moving with the grain is now against—you are irritable, angry, frightened, uncontrollable, and enmeshed totally in the blackest caves of the mind. You never knew those caves were there. It will never end. Madness carves its own reality.

It goes on and on and finally there are only others' recollections of your behavior—your bizarre, frenetic, aimless behaviors—for mania has at least some grace in partially obliterating memories. What then, after the medications, psychiatrist, despair, depression, and overdose? All those incredible feelings to sort through. Who is being too polite to say what? Who knows what? What did I do? Why? And

most hauntingly, when will it happen again? Then, too, are the annoyances—medicine to take, resent, forget, take, resent, and forget, but always to take. Credit cards revoked, bounced checks to cover, explanations due at work, apologies to make, intermittent memories (what *did I do?*), friendships gone or drained, a ruined marriage. And always, when will it happen again? Which of my feelings are real? Which of the me's is me? The wild, impulsive, chaotic, energetic, and crazy one? Or the shy, withdrawn, desperate, suicidal, doomed, and tired one? Probably a bit of both, hopefully much that is neither. Virginia Woolf, in her dives and climbs, said it all: "How far do our feelings take their colour from the dive underground? I mean, what is the reality of any feeling?" (Patient with manic-depressive illness¹)

Alluded to here are many of the fears and worries common to most individuals with bipolar illness: the frightening, tumultuous, and extremely damaging aspects (to self and others) of mania and depression; the powerful effects of the illness on subsequent functioning and ongoing and potential relationships, as well as general expectations of the future; the inherent unpredictability of the course of the disease; and the pervasive fear, often terror, of recurrence. Practical consequences of mania and depression usually include, among others, the alienation of friends, lovers, and family members; the inability to move forward or naturally in a career; and major financial problems stemming from overspending, ill-considered investments, substantial and often uninsurable medical expenses, and legal difficulties. Alcohol and substance abuse are common (see Chapter 8). Additionally, many individuals who have bipolar illness find it difficult to adjust to the idea of having a serious, chronic, and life-threatening illness, one that generally requires lifelong maintenance medication, with side effects, for its control. Consequential features pervade this illness, including a fundamental, if usually transitory, inability to perceive reality with accuracy and to judge a course of action with prudence. Once an acute episode is over, the person is left with palpably shaken self-confidence. For a considerable period after a manic or depressive episode, many patients continue to question their judgment, their ability to assess situations, and their capacity to understand their relationships with other people.

Etiological assumptions about the disorder deeply affect the highly individualized experience of bipolar illness. Despite the compelling arguments for its biological origins—and despite the potential of such arguments to alleviate the associated guilt and stigma—patients often find these explanations intuitively unpersuasive, especially in the early stages of illness. Thus although some patients come to believe that profound depression is biologically rooted, others interpret it as a character problem or a spiritual crisis, and

still others as psychological in origin. Hypomania is often perceived as highly intoxicating, powerful, productive, and desirable; patients have difficulty thinking of it as a sickness or as part of the same illness as depression and mania.

In the following sections, we review common themes that appear repeatedly in patients' descriptions of their illness: they are fearful of recurrence; they are concerned about transmitting it to their offspring; they feel shame and humiliation; they suffer the havoc wrought by each episode on their relationships with others; they confront disturbing psychological, financial, and social issues during recovery; and they reflect on the long-term meaning of the illness in their lives.

Fears that the illness will return are common, and a profound mistrust of the future often forms the crux of patients' concerns about work and personal relationships. A physician hospitalized several times for mania described his fears of recurrence (especially of mania), as well as the damaging effects of his illness on his career, thus (Anonymous, *Lancet*, 1984, p. 1268):

Two years is a long time out of professional medical circulation—things forgotten, things not learned or heard of, but the most daunting problem is the prospect of further episodes of mania. The depression if it occurs is a more private feature of the syndrome. Mania is very public and is accompanied by a multitude of embarrassing excesses and, not infrequently, scandals.

Questions remain: will there be further episodes; how frequently; and will they be as debilitating? No-one can offer guarantees or even reliable answers yet. Meanwhile what about my capacity to work, earn a living, to occupy myself, and fulfill my responsibilities? The qualities for a doctor are vastly different from those of a poet. A hospital consultant is nothing if not reliable. My unreliability is already manifest.

Another typical concern derives from the heritable component of bipolar illness and recurrent depression. Many patients, having grown up in an environment of mental illness and/or extreme mood swings, express fear that they will end up like the affected parent, especially if that parent has been severely disabled, repeatedly hospitalized, violent, or alcoholic. The fear is even greater if the parent died by suicide. The daughter of a woman with bipolar disorder described her fear of inheriting the illness and her difficulty in establishing an independent identity (Anthony, 1975, p. 292):

Ever since I was small, I have been told that I was just like my mother. I was named after her, and very soon I took to thinking that I was going to be committed when I was 21, like she was. . . . I was sure that they were going to come and haul me away. . . . I felt that the only way I could

separate my thoughts and feelings from her would be for her to die, and I often hated her and wished for her death, especially when she was manic.

Often, too, patients (and their spouses) agonize over the possibility of passing on the illness to children. Playwright and producer Joshua Logan wrote about this fear in describing a conversation with his first wife (Logan, 1976, p. 153):

I asked her if she wanted to have children with me.
She said no.
I asked why, but she refused to answer. . . . She would never have children by me, and that
I should know why. I looked at her blankly, and she added:
“I have no wish to bring insane children into this world.”

Individuals who suffer from bipolar illness experience acute shame and humiliation for many reasons, including psychosis and resulting bizarre and inappropriate behavior or violence, financial irregularities, and sexual indiscretions, to name but a few. In the words of one patient, “No one who has not had the experience can realize the mortification of having been insane” (Reiss, 1910). Another patient (Graves, 1942) wrote:

While the intoxication of mania lasts, I for one have no disposition to embrace death. After the intoxication is over, my chief emotional reaction is shame and disgust with myself, and a wonder that my fear of death could be so wonderfully and idiotically twisted. That the facing of humiliation, despair, or deprivation should produce a desire for death is quite natural.

In portions of two letters to T. S. Eliot, Robert Lowell (cited in I. Hamilton, 1982, pp. 286, 307) described his embarrassment following two different manic episodes:

[June 1961] The whole business has been very bruising, and it is fierce facing the pain I have caused, and humiliating [to] think that it has all happened before and that control and self-knowledge come so slowly, if at all.

[March 1964] I want to apologize for plaguing you with so many telephone calls last November and December. When the “enthusiasm” is coming on me it is accompanied by a feverish reaching to my friends. After it’s over I wince and wither.

The widely varying reactions of others to a person who has bipolar illness include anger, concern, withdrawal, unrealistically high or low expectations, rejection, and denial of the illness.⁴ Robert Lowell (1977) wrote of the isolation, pain, and misunderstanding experienced during one of his hospitalizations for mania:

At visiting hours, you could experience my sickness only as desertion. . . .

Dr. Berners compliments you again,
“A model guest . . . we would welcome Robert back to Northampton any time, the place suits him . . . he is so strong.”

I am on the wrong end of a dividing train—
it is my failure with our fragility.

John Custance (1952, p. 115), a British writer and former naval intelligence officer who suffered from severe, psychotic manias and depressions, described the denial of others after his release from a psychiatric hospital. He also depicted his own denial and the gradual sealing-over process so characteristic of the recuperation period:

But once I get out of a Mental Hospital all this changes. I find myself in a totally different “atmosphere”. I cannot, however hard I try, get even my most intimate relatives and friends to understand or take any interest in what may or may not have happened to me during my “madness”. Gradually the vividness of my memory fades; like my relatives, I try to put the whole experience out of my mind, and in fact it does to a certain extent disappear into “lower levels of my Unconscious”. Then I find myself genuinely wondering whether these memories so far as they are conscious at all, are not “delusions”, “hallucinations,” as “unreal” as the actual technical hallucination I know I have had and have described earlier.

A different kind of denial, a “conspiracy of silence,” was described by Norman Endler (1982, pp. 148–149), a Canadian psychologist writing about his hypomania and depression and their effects on those around him:

In April 1977, when I first started getting depressed, not only did I deny it to myself but so did my friends and colleagues. My secretary and administrative assistant, as indicated earlier, asked me what was wrong. My gradual withdrawal from interaction, my lack of cheerfulness, and my quietness were interpreted by them as anger at something done wrong. After about four weeks my wife insisted that I should see a doctor. My children said nothing to me. My colleagues at York said nothing to me, and the professionals (psychiatrists, psychologists, and social workers) in the Department of Psychiatry, Toronto East General Hospital, said nothing to me. I’m sure that some, if not most of them, must have noticed that something was wrong with me. (If they had not, they shouldn’t be working in the mental health field.)

Why did my colleagues participate in an unintended “conspiracy of silence”? There are a number of factors to consider. First, suppose they commented on my depression and they were wrong. Suppose I wasn’t really depressed but only very tired. This would have been most embarrassing for them. Second, some people do not like

to interfere or intrude in the lives of others. Third, suppose it were true that I was depressed. How could they handle it without embarrassing me? The fact that I was chairman might have been another factor. Because the "show" was running smoothly, there was no need to question the chief executive officer. My guess is that my friends didn't say anything because they probably couldn't believe that it was true. . . . when I was hypomanic, none of my colleagues confronted me. Here, again, they were following the social norm of not interfering. Because I had previously been depressed, they probably perceived it as a recuperative period and gave me the benefit of the doubt.

The postpsychotic or recovery phase is an important but seldom-discussed aspect of bipolar illness. The transition from disturbed to normal thinking and feeling and the adjustment to the interpersonal, medical, professional, and financial consequences of mania and depression are usually slow, exhausting, frustrating, and partially futile experiences for patients.

Virginia Woolf (1910), writing from a hospital where she was confined for mania (letter to Vanessa Bell, July 28, 1910), described the slowness and subtlety of psychological recovery: "I have been out in the garden for 2 hours; and feel quite normal. I feel my brains, like a pear, to see if its [sic] ripe; it will be exquisite by September." She also described the gradual return from depression to normality: "I think the blood has really been getting into my brain at last: It is the oddest feeling, as though a dead part of me were coming to life."

The recovery period typically is filled with anxiety about things done, or left undone, during the preceding mania or depression, fears about the future, and concerns about the completeness of recovery. Uncertainty about the future, as well as confusion about the origins and meaning of the illness, was expressed by Joshua Logan (1976, p. 178):

Still, none of that shook off the dreariness of having an illness that didn't seem like one, of not knowing how or when I'd be rid of it, of not knowing even why it had happened to me, of having iron bars on the windows—even though those bars were fashioned like curlicued decorative devices. Was I ever, ever, going to get out? And if I did—what would I do? Where would I go?

Inevitable ruminations about behavior when ill, especially when manic, are part of the recovery phase (Lowell, cited in I. Hamilton, 1982, p. 218):

I've been out of my *excitement* for over a month, I think, now, and am in good spirits, though I don't feel any rush of eloquence to talk about the past. It's like recovering from some physical injury, such as a broken leg or

jaundice, yet there's no disclaiming these outbursts—they are part of my character—me at moments. . . . The whole business was sincere enough, but a stupid pathological mirage, a magical orange grove in a nightmare. I feel like a son of a bitch.

Lowell, born into an old-line Boston family where "Lowells talk only to Cabots and Cabots talk only to God," wrote poignantly of his fall from "pedigreed tulip to weed" in his painful recovery (Lowell, 1959, p. 84):

Recuperating, I neither spin nor toil.
Three stories down below,
a choreman tends our coffin's length of soil,
and seven horizontal tulips blow.
Just twelve months ago,
these flowers were pedigreed
imported Dutchmen; now no one need
distinguish them from weed.
Bushed by the late spring snow,
they cannot meet
another year's snowballing enervation.

I keep no rank nor station.
Cured, I am frizzled, stale and small.

Anger, Denial, and Ambivalence

History bears witness to the tendency of some people to resist with passion when cornered by fate—to, in the words of Dylan Thomas, "rage against the dying of the light." Others submit more readily to what may or may not have been inevitable. Such different reactions are understandable in individuals who face an uncertain future because of bipolar illness. Some patients resist for years, irate at their diagnosis, their treatment, and their physicians. Others accept the illness and its treatment with remarkable equanimity. Most fall between the two extremes.

Bipolar disorder can push patients to the limits of their resources. It is a complicated and frustrating illness, seemingly impossible to sort through. It takes a heavy emotional toll on family members and friends, the repercussions of which place further psychological stress on the patient. The illness often seems within the patient's control, but usually it is not. It frequently carries with it a psychotic diagnosis and an uncertain course, and almost always a lifetime sentence of medication. Especially when not treated early and aggressively, it is costly in loss of self-esteem, disrupted relationships, secondary alcoholism and drug abuse, violence, economic chaos, hospitalizations, lost jobs, years consumed by illness, and suicide.

Contending with such a reality understandably rouses patients to anger, which can be seen as natural and, up to a point, highly adaptive. Anger is useful because it drives

patients to question assumptions and to refuse to accept the unacceptable. At the same time, it often leads patients to reject irrationally an effective treatment or to direct their wrath—at times legitimately, but more often not—at the clinicians who treat the disease. Moreover, determining the extent to which anger is a symptom of the disorder can be difficult.

Bipolar patients also use denial to cope with their illness. Even in the presence of severe and obvious pathology, they deny the disorder's severity, the odds of its recurring, its consequences, and at times its very existence. Like anger, denial is a normal response to the unpleasant, the painful, the unpredictable, and the destructive in life. Not to deny some aspects of a serious disease such as bipolar illness would be unusual, even troubling. Denial clearly is an essential part of healing, allowing slow assimilation of otherwise overwhelming thoughts and feelings. Too much denial, however, can be dangerous.

Not surprisingly, patients' level of insight into their illness varies depending upon the predominant nature of their clinical episodes. Patients who experience pure mania generally show less insight than those who have mixed states (Dell'Osso et al., 2000, 2002; Cassidy, 2001), although Cassidy and colleagues (1998) had failed to find this difference in an earlier study. Depressed patients usually show greater insight than manic patients⁵; those with bipolar-II disorder appear to show less insight than those with bipolar-I (Pallanti et al., 1999). Poorer insight is also related to the presence of psychotic features (Yen, 2003), as well as residual subsyndromal manic symptoms (Dell'Osso, 2002; Yen, 2003). Although not well studied, there is evidence that impaired insight persists during remission for many patients (Varga et al., 2006); recent research on patients with schizophrenia suggests that neurocognitive deficits, which persist during remission, play a significant role in impaired insight (Aleman et al., 2006).

Symptoms of bipolar illness contribute to the process of denial. Patients' judgment is often suspended during episodes of acute mania, to the point that they become incapable of recognizing the destructiveness of their behavior (Jamison, 1995; McAlpin and Goodnick, 1998). Likewise, cognitive and other memory impairments during depression often are pronounced, producing problems of recollection even without denial. Repression, psychological distance, and the need to adapt to the realities of life frequently cause memories of depression to pale over time. The severity and nature of manic episodes similarly are frequently minimized or forgotten. This can be due to the relatively clearer perception of earlier, milder, and more enjoyable stages of mania; amnesia resulting from the cognitive fragmentation characteristic of manic psychosis; repression; and the sheer volume of thoughts, perceptions, behaviors, and feelings that occur during mania

and make storage of memories or good recall unlikely. Denial often leads to medication nonadherence, an issue discussed in detail in Chapter 21.

The treatment of denial, although not always successful, frequently becomes easier as time passes and the illness reappears too often to be disowned, even unconsciously. Denial can be dealt with effectively in psychotherapy by exploring the meaning and consequences of the illness for the patient. Ongoing education about the natural history of the illness, with emphasis on its high relapse rate, undercuts the process of denial as well, as do straightforward and informed discussions of the risks and benefits of medication.

Ambivalence is another common reaction among patients with bipolar disorder, especially when caused by the incongruence between the behavioral expression of the illness and its biological treatment. As a disorder of mood and behavior, bipolar illness has symptoms and consequences that are largely psychological and interpersonal in nature. At the same time, effective mood stabilizers can result in relatively rapid improvement. The treatment response is obvious and gratifying to the clinician, if not the patient, and lends credence to a strongly biological treatment program. This belief is further encouraged by the demonstrated inability of psychotherapy alone to relieve or prevent bipolar episodes. Also encouraging a biological focus is the fact that treatment with mood stabilizers is imbued with a medical ambiance and embedded in a highly structured medical regimen: the physician orders laboratory tests of serum levels of mood stabilizers, as well as kidney, liver, and thyroid functioning, and asks specific medical questions about side effects, usually somatic rather than cognitive in nature. This understandable focus of physicians on the medical aspects of bipolar illness often stands in a point-counterpoint relationship to the perspective of patients, who are likely to be more focused on the psychological aspects of their illness and its treatment. These disparate perspectives can easily lead to a quite arbitrary split between the biological and the psychological.

Conceptualizing bipolar illness as fundamentally a medical disorder has many advantages for the patient. It can decrease stigma, result in effective and specific treatment, and minimize unwarranted family and individual responsibility for the emergence of the illness. At the same time, however, it can discourage discussion of significant life issues and problems involved in adjusting to the illness and its consequences. An overly medical approach can also mean that psychological concerns about taking medication may be ignored. Furthermore, taking medication can create its own stigma because society and patients themselves often disparage the continuing need for psychiatric drugs.

Biological assumptions about the illness can also make it more difficult for patients to feel a sense of personal control.

Many, for example, maintain the belief that if only they changed their work, exercise, or dietary habits; if only they conducted their love affairs in a different way; if only they heeded more stringently the counsel of their priests, therapists, and consciences—in other words, if only they behaved as they think they should—they would be able to prevent recurrences of manic and depressive episodes. When treatment with mood stabilizers has beneficial results, some patients continue to believe that they ought to have been able to handle things without the medication. Some may attribute their improvement to a combination of their own efforts and the efficacy of the medication. Others believe the medication alone made the difference, and they had little or no control over the illness. Psychotherapy can help clarify the ambivalence that inevitably results from such beliefs, underscore the patient's role in the medication regimen, and identify psychological issues that are important and amenable to the patient's control. There is also evidence that psychotherapy can help the patient change irregular sleep habits and deal with family conflicts, as well as teach the patient to monitor mood, cognitive, behavioral, and sleep changes for incipient relapses or recurrences.

Disappointment and Frustration

Expecting the treatment of bipolar illness to proceed in a straightforward manner is likely to create problems. For many patients, mood stabilizers are an uncertain treatment imposed upon an uncertain illness, a problematic treatment for a problematic disease. For many, life before medication can be likened to a kite on a string in exceedingly unpredictable winds. Mood stabilizers allow some control over the winds, but often it is not complete, and therein lies much of the disappointment and frustration. Clinicians and patients frequently define successful control very differently. The clinician looks at certain types of evidence—fewer or no hospitalizations or little or no need for adjunctive mood stabilizers, antipsychotics, and antidepressants—and finds drugs to be effective. The patient who continues to experience disruptive and upsetting mood swings is likely to interpret the same evidence in much more equivocal terms. In essence, physicians focus more often on the successes of medication, that is, the contrasts with untreated illness. Patients, while living with those successes, live with the failures and disappointments of medication as well. The improvements achieved tend to be forgotten, and with time, the seriousness of the illness is denied. Day-to-day discontents then emerge as the compelling factor in feelings about medication. In the words of one P. G. Wodehouse character (Wodehouse, 1975), "I could see that, if not actually disgruntled, he was far from being grunted." Bipolar patients on medication are often far from being grunted.

The resentment patients feel at their partial cure is, in some respects, proportional to the severity of the illness and concomitant hope. Unrealistic expectations of medications and of physicians not only derive from the fragile hopes of patients, but also are rooted in the exaggerated claims of some pharmaceutical manufacturers and physicians. Paradoxically, the very existence of mood stabilizers as effective treatments has given rise to a new generation of patients with a new set of expectations. When lithium was first used in Scandinavian clinical trials, there was no alternative, and patients were generally "grateful for a treatment that revolutionized their lives" (M. Schou, personal communication). The availability and efficacy of a variety of mood stabilizers have made them a part of the pharmaceutical establishment, which in turn has created an inevitable groundswell of expanded expectations, disappointments, and criticism.

Perceived Losses Associated with Medication

The subtle and powerful clinician–patient alliance that is possible in pharmacotherapy is predicated on a thorough understanding of not only the benefits of the medications to the patient, but also the realistic and unrealistic fantasies of loss that many patients experience during treatment. These fantasies often focus on missing the highs of bipolar illness and cannot be adequately understood through the simplistic view that the patient is shortsighted, self-destructive, or escapist. Effective therapy with bipolar patients—whether it involves using drugs alone or in combination with psychotherapy—must address the reality of the patient's positive perceptions of the illness, as well as the altered states of perception induced by its occasional elevated-mood, high-energy phases (Jamison et al., 1979, 1980).

Patients may experience many different kinds of losses, realistic and otherwise, as a result of taking a mood stabilizer. These losses and their relationship to medication nonadherence are discussed in detail in Chapter 21. Here we present an overview of the psychotherapeutic issues involved.

Realistic losses are those undesirable changes brought about by medication. They can include decreased energy level, loss of euphoric states, increased need for sleep, decreased productivity and creativity, less interpersonal verve, and diminished sexuality. One patient described the subtle effects of lithium thus:

People expect that you will welcome being "normal," be appreciative of lithium, doctors, and modern science, and take in stride having normal energy and sleep. But if you are used to sleeping only 5 hours a night and now sleep 8, are used to staying up all night for days and weeks in

a row and now cannot, it is a very real adjustment to blend into a formal schedule which, while comfortable to many, is new, restrictive, seemingly less productive, and for sure less fun. People say, when I complain of being less lively, less energetic, "Well, now you're just like the rest of us," meaning, among other things, to be reassuring. What they don't realize is that I compare myself with my former self, not with others. Not only that, I always compare my current self with the best I have been, which is when I have been hypomanic. When I am my present "normal" self, I am far removed from when I have been my liveliest, most productive, most intense, most outgoing and effervescent. In short, for myself, I am a hard act to follow.

(Patient with manic-depressive illness¹)

The results of a study of bipolar patients in remission suggest that many patients feel their illness makes positive contributions to their lives in one or more important ways (Jamison et al., 1980). A substantial majority of the patients in this study perceived pronounced short- and long-term positive effects from their bipolar illness in addition to whatever disabling and dysphoric symptoms they may have experienced. Most patients reported increased sensitivity, sexual intensity, productivity, creativity, and social ease. Men and women varied considerably in what they regarded as the most enjoyable and important changes when hypomanic: for men it was increased social ease, whereas for women, increases in sexual intensity, productivity, and social ease were rated equally important.

In a recent, related study, Culver and colleagues at Stanford (2006) assessed benefit finding in 57 euthymic bipolar patients (42 percent bipolar-I, 46 percent bipolar-II, 12 percent bipolar—not otherwise specified [NOS]). They found that these patients commonly identified benefits associated with their affective illness; most frequently, they endorsed the beliefs that bipolar illness "made me more understanding of others who have problems"; "increased my self-awareness"; "helped me become a stronger person, more able to cope effectively with future life challenges"; "led me to be more accepting of things"; "taught me how to adjust to things I cannot change"; and "led me to want to help others." Benefit finding correlated significantly with the more effective use of coping skills.

Such attributions are important for several reasons. From a behavioral perspective, it is essential to realize the meaning, nature, and value of positive behavioral and mood changes (as well as negative ones) for an individual patient. Such euphoric states serve for some patients as powerful addictive states, providing significant benefits on the one hand and posing the risk of severe emotional and pragmatic problems on the other. The sense of loss that occurs when medication eliminates those states, if unaddressed,

may hinder the patient's adjustment to treatment. Moreover, the side effects of a medication can be difficult to separate from the medication's effect on hypomanic symptoms; they are also sometimes indistinguishable from symptoms of inadequately treated depressive episodes.

Treatment management under such circumstances is not straightforward. For example, adherence to a mood stabilizer regimen, which at best has a tenuous and delayed relationship to alleviation of the dysphoric features of bipolar illness, competes with behavior maintained by a highly positive and intermittent reinforcement schedule—an exceedingly difficult behavior pattern to modify. It is in some ways analogous to a drug self-administration paradigm in which a highly pleasurable and relatively rapid state can be obtained. For some patients, hypomania or even mania itself may represent, in effect, an endogenous stimulant addiction. Clinical experience suggests that patients may attempt to induce mania by discontinuing medication not just when they are depressed, but also when they face problematic decisions and life events. Because the negative consequences of such behavior are delayed, it is not always clear to the patient that the benefits of medication outweigh its costs. Thus the clinician must be aware of the positive features of mood swings to better understand and thereby treat the bipolar patient.

Other realistic losses include cognitive, perceptual, physical, emotional, or social changes that result from the side effects of medications, as well as negative social consequences, such as self-labeling or social stigma (Jamison, 2006). Among the more significant side effects from a psychotherapeutic point of view, described further in Chapters 20 and 21, are those detailed in early papers by Schou and Bastrup (1973) and Schou (1980): decreased energy, enthusiasm, and sexuality (all of which can be a factor in increased marital problems); curbing of activities; and the common perception that life is flatter and less colorful. Cognitive dulling and weight gain are also important—indeed, more important to many patients (Gitlin et al., 1989; Perlick et al., 2004). Moreover, the need to adhere to a regimented lifestyle, underscored by frequent monitoring of medical and psychiatric status, may trigger the patient's feelings of being controlled and hopeless (Jamison, 1995; McAlpin and Goodnick, 1998).

Unrealistic losses include circumstances in which medication and psychotherapy come to symbolize the patient's personal failures. In addition to experiencing the normal difficulties of adjusting to the need for treatment, patients occasionally project their other life failures, thwarted ambitions, and personal and professional inadequacies onto medication, which can thereby become the psychological scapegoat and represent a rationalization for other failures that predate the onset of the illness.

Fears of Recurrence

The worst fear for most bipolar patients is recurrence of the illness. Many patients maintain a deep and fatalistic pessimism, however entwined with denial and optimism, about again becoming manic or depressed. In a poem from *Day by Day*, Robert Lowell (1977, p. 31) wrote, “if we see a light at the end of the tunnel, / it’s the light of an oncoming train.” This is a sentiment to which many of Lowell’s fellow sufferers can relate only too well. Some patients become preoccupied with such fears of recurrence and are almost illness-phobic. They become unduly self-protective and hyperalert for signs of an impending episode. These concerns are often reflected in the process of learning to differentiate normal from abnormal moods and states (see the later discussion). A perceived decreasing tolerance for affective episodes is a concern that is usually secondary to the stress of the illness and to the large amount of psychological energy consumed by earlier bouts. Patients, often with good cause, fear that their families and friends will grow ever more intolerant with each new recurrence. Bipolar illness also takes a severe toll on other relationships, professional activities, finances, and patients’ ability to handle the emotional stress of their affective episodes. Thus Lowell wrote, “but the breakage can go on repeating once too often” (1977, p. 113). Likewise, in his autobiography, Joshua Logan (1976, p. 338) described a certain weariness after yet another manic attack: “I was only forty-five years old, but I felt exhausted by this last experience, hollowed out, as though I were a live fish disemboweled.”

Learning to Discriminate Moods

Problems with learning to discriminate normal from abnormal moods are common throughout the psychotherapy of bipolar patients. Because of the experience of their illness and the intensity of their emotional responses, many patients fear that a normal depressive reaction will deepen into a major episode and that a state of well-being will escalate into hypomania or mania. Many common emotions range across several mood states, spanning euthymia, depression, and hypomania. For example, irritability and anger can be a part of normal human existence, or can be symptoms of both depression and mania. Tiredness, sadness, and lethargy can be due to normal circumstances, medical causes, or clinical depression. Feeling good, being productive and enthusiastic, and working hard can be either normal or pathognomonic of hypomania.⁶ These overlapping emotions can be confusing and arouse anxiety in many patients, who may then question their own judgment and, as discussed previously, become unduly concerned about recurrences of their affective illness. Occasionally, patients become conservative or excessively conforming (Benson, 1976).

The need to help patients discriminate normal from abnormal affect is common in psychotherapy. Patients must learn to live within a narrower range of emotions, yet master the skill of using those emotions with greater subtlety and discretion. Closely related to the discrimination of moods is the slow, steady process involved in patients’ learning to disentangle what is normal personality from what the illness has superimposed upon it—turbulence, impulsiveness, lack of predictability, and depression. Patients whose premorbid temperament has been predominantly depressive may have unrealistic expectations about how much change can be brought about by medication. Likewise, those with an underlying exuberant temperament may have to become more finely tuned to discerning normal from pathological enthusiasms (Jamison, 2004).

Dealing with Developmental Tasks

Developmental tasks previously overshadowed by bipolar illness often become issues for patients in remission. Ironically, the illness can act as a protection against many of the slings and arrows of fortune encountered in normal life. Because late adolescence and early adulthood are the highest-risk periods for the onset of the illness, many of the developmental tasks of these periods—separation from parents and family, development of close personal relationships, romantic involvements, hurts and rejections, childbearing and childrearing, and career development—are impaired or postponed. (Conversely, these developmental transitions or crises can also precipitate the occurrence of episodes.) Once the illness is under control, patients often must deal with these problems, as well as those of a more general, existential nature, within the therapeutic relationship.

Concerns about Family and Other Relationships

Concerns about the effects of bipolar illness on family and other relationships can be profound. Patients report feeling guilty about things done while manic and those left undone while depressed. The most frequently voiced concerns center on the interpersonal consequences of the illness, effects felt strongly by family members, spouses, and friends. Unmarried patients are often unclear about when and what to tell people they are dating about their illness. Similar concerns arise in relationships with employers and coworkers. Psychotherapy can help encourage patients to suspend major personal decisions during episodes and to manage family and work crises associated with the illness. Interpersonal aspects of bipolar illness are covered more fully in Chapter 10.

Concerns about Genetics

Many patients worry about possible transmission of bipolar disorder to their children. They tend to overidentify with

any close family member who has the illness, particularly a parent. Occasionally, they feel guilty about receiving effective treatments that were not available to an afflicted parent. This latter phenomenon, although not common, is particularly striking in those patients whose parents committed suicide or were hospitalized for a long time. Similar guilt is sometimes seen in patients successfully treated with medication whose siblings or parents have refused treatment.

Recent advances in locating specific genetic variations involved in bipolar illness (see Chapter 13) are likely to increase such concerns, as well as the desire for information. Indeed, study results indicate a strong desire for counseling about prenatal susceptibility (Smith et al., 1996; Trippitelli et al., 1998; Jones et al., 2002). Trippitelli and colleagues (1998) at Johns Hopkins studied knowledge and attitudes among 90 bipolar patients and their spouses with regard to the possibility of inheriting bipolar disorder, genetic testing, and decisions about childbearing. Most said they would agree to take a test for bipolar disorder if it were available, but that knowing they or their spouse had a gene or genes for bipolar illness would not change their decision to marry or to have children. Most also said they would not consider abortion if they discovered the fetus had the gene(s) for bipolar disorder. In research conducted at the University of California, San Francisco (Smith et al., 1996), both bipolar patients and psychiatry residents stated that they would be much more likely to consider terminating a pregnancy if the fetus's bipolar illness were hypothesized to have a severe clinical course than if it were not; the residents were more likely to endorse abortion. As of this writing, these issues are still academic. As more precise information on the genetic etiology and risk of bipolar disorder emerges, such concerns will become more prominent in the psychotherapeutic management of the illness. Issues associated with genetic counseling for bipolar patients are discussed in Chapter 13.

Clinician Attitudes and Expectations

As noted earlier, many psychoanalysts who worked in the prelithium era found it frustrating to treat bipolar patients. The psychoanalytic literature addressed countertransference issues extensively and described in some detail the anger analysts felt toward patients for their seeming inconstancy and lack of insight (or desire for insight):

The extraverted, apparently unsubtle, manic depressive is a threat. . . . in several ways: In the first place, communicative efforts are a strain because of the lack of response. Secondly, the so-called healthy extraverted approach to reality is likely to fill the more sensitive, introspective person [the psychoanalyst] with self-doubts as to the possibility that he makes mountains out of molehills, reads meanings

in where none were meant, and so forth. . . . Thirdly, the therapist tends to dislike this sort of person and to think of him as "shallow." And, finally, the patient's difficulty in recognizing or discussing his or another's feelings or meanings throws the therapist into a situation of helplessness, since these things are the coin in which he deals.

(Cohen et al., 1954, p. 131)

English (1949, p. 126) stated succinctly what others have said at great length: "The manic-depressive rejects you because he seems to be unsure that he needs you at all."

Although many aspects of therapeutic work with bipolar patients have changed radically as a result of effective mood stabilizers, patients continue to elicit strong feelings from some therapists. One clinical team put it thus:

. . . bipolar patients, with their alienating behavior, incessant demands, opaqueness, and difficulty in adhering to medication regimens, are generally viewed as difficult to treat, providing a therapist with a sense of unease and minimal gratification. (Davenport et al., 1979, p. 33)

Other therapists who work with bipolar patients are frustrated by the inconsistencies patients display in their behavior and attitudes toward self, therapist, therapy, and medication during different mood states. Unstable moods can result in fluctuating levels of intimacy and trust within the therapeutic relationship, both from patient to therapist and from therapist to patient. The patient who appears at a session in an angry and irritable state may produce a reaction in the therapist, whose feelings may then persist longer than the patient's fleeting mood. Or the therapist may make a suggestion at one session, find the patient feeling better at the next, and attribute the improved mood to the suggestion—only to discover the patient is depressed again at the next session. If the therapist fails to understand that fluctuating mood is not a reliable signal, but rather is intrinsic to the illness, such situations can lead to a misperception of the role of therapy.

Anger and frustration can also be engendered in the therapist when the patient rejects an effective treatment. This situation may arise when the therapist fails to comprehend what the illness means to the patient or the patient fails to understand, usually through processes of denial, the consequences of rejecting such a treatment regimen. Greenson (1967) emphasized that the therapist should have a broad and rich background for empathy. A breadth of imagination is particularly relevant and useful to the therapist dealing with manic patients, whose emotions and ideas often are not from the same experiential base as that of the therapist (see Chapter 2). In addition to having the kind of personal background advocated by Greenson, a therapist can reduce feelings of being excluded from and

not understanding the patient's experience by having a solid grounding in the phenomenology of the illness.

Patients who stop their medication, or take it only fitfully and become ill again, can be an enormous source of frustration to their clinicians (see Chapter 21). The therapist often experiences anger and feelings of helplessness when the patient's denial leads to medication nonadherence and results in rehospitalization for manic or depressive episodes, suicide attempts, or exacerbation of hostile and aggressive behaviors. Even when the patient is adherent, feelings of inadequacy and failure can develop when the illness recurs (see the earlier discussion). Indeed, such feelings may be commonplace when therapists treat patients who are depressed, suicidal, or hypomanic (Fromm-Reichmann, 1949; Janowsky et al., 1970). Hypomanic and manic patients regularly show special sensitivity to vulnerabilities in the therapist, and this tuning in to the "jugular" is at the core of many therapists' acute and intense feelings of anger. Although such a pattern of interaction is most likely to occur during hypomania and mania, it is not uncommon during the depressive phase, when the patient's levels of paranoia, irritability, and hopelessness have increased. Patients under such circumstances are often exquisitely aware of feelings of frustration, annoyance, and impotence in the therapist. The anger and hopelessness a patient expresses at such times can have a significant impact on the already vulnerable therapist. Therapists, of course, must recognize their own attitudes and feelings and cope with them effectively to minimize repercussions for the patient.

Yet another potential problem with clinicians' reactions to their patients centers on misinterpretation of resistance in bipolar patients. We have already discussed such patients' difficulties in differentiating normal from pathological mood states and their fears of recurrence. Therapists occasionally assume that a patient's depression is a reaction to a particular environmental, interpersonal, or therapeutic event. The therapist's tendency to link depression to external events can be problematic. Even when depressions are not really endogenous, the patient is often frightened by the similarity between such thoughts and feelings and those experienced earlier in severe major depressive episodes. Therapists need to take a delicate approach in helping the patient differentiate various types of feelings, while at the same time recognizing when they themselves may have overlooked recurrence or to see psychological causality when little exists.

Problems can also develop when the therapist "acts out" through the patient. The therapist is in an unusual position to influence the patient by unwittingly encouraging both medication nonadherence and the behaviors linked to affective states. The special appeal of hypomania is particularly

relevant here. The seductive aspects of that state are often impossible to ignore. Guilt over depriving the patient of a special state may occur when the patient proclaims that he misses the highs of the disorder. Moods are contagious, and occasionally the loss of a patient's hypomania results in a corresponding, albeit lesser, loss reaction in the therapist. A few therapists may also romanticize "madness." This romanticization can range from a tendency to overvalue the positive aspects of bipolar illness and minimize the negative, painful ones to a conviction that psychopharmacological interventions are oppressive or contraindicated. The consequences of such romanticization are usually catastrophic.

Mood Charting

Before turning to a discussion of psychotherapy, we examine the role of other components of psychological care: mood charting, patient and family education, and self-help groups. Mood charting by patients can provide invaluable information about seasonal and premenstrual patterns of moods; psychological, environmental, and biological correlates of mood swings; and response to treatment, including possible worsening of the illness (e.g., increased cycling induced by antidepressant therapy; see Chapter 19).

Administration of a visual analogue scale is straightforward, requiring little time on the part of the patient (see Chapter 13 for further discussion). The patient is given sheets of paper, each with a 100 mm line, anchored by 1 ("worst I've ever felt") on the left or the bottom and 100 ("best I've ever felt") on the right or the top. The patient is then asked to put a mark across the line at the point most representative of his overall mood (or whatever other variable, such as energy or anxiety level, is being assessed) for the day. To control for diurnal variations in mood and behavior, ratings should be recorded at approximately the same time of day or evening. Significant life events and additional medications required are noted on the rating sheet. After completion, the dated form is set aside to avoid influence from earlier ratings. The results can then be graphed, with time plotted along the horizontal axis and mood ratings, from 1 to 100, along the vertical. In some instances, patients can do their own graphing.

Two other instruments have been developed for mood charting: the retrospective Life-Chart Method (LCM-r) (Leverich and Post, 1993) and the NIMH prospective Life-Chart Method (NIMH LCM-p) (Denicoff et al., 1997). The two follow the same guidelines but differ in the unit of measure—LCM-r is monthly, whereas LCM-p is daily. For LCM-p, patients are given a computer-readable form to take home once a month, with instructions to rate their mood and functioning each day, morning and evening. Self-ratings of mood are plotted along a 100 mm line with 25

points corresponding to a continuum from most depressed ever, to balanced (middle), to most manic ever. Functional impairment is rated as none, mild, moderate, or severe.

A third method of tracking mood fluctuations as they relate to daily social and circadian rhythms is the Social Rhythm Metric (Monk et al., 1991; Frank et al., 2000). This chart, completed by the patient at the end of each day, is used to assess 17 daily activities (e.g., waking up, first communication with another person, morning beverage, afternoon nap) as to the time of the day they occurred, whether they involved other people, and how stimulating they were. This daily mood rating can help the patient understand the relationship among changes in a regular schedule, stimulation induced by daily routines, and mood fluctuations. Using the results of this charting, the therapist collaborates with the patient to find realistic ways of stabilizing these daily rhythms. This charting method has been incorporated into interpersonal psychotherapy for bipolar patients, described later.

Mood ratings can be useful not only in identifying patterns of mood and treatment response, but also in giving patients a sense of control, instilling a sense of collaboration, and underscoring the importance of systematic observation. They also provide a relatively objective basis for persuading patients when treatment regimens require modification. At the beginning of treatment, other patients' charts may be used as examples of various patterns of mood fluctuation to illustrate the use of daily mood ratings in diagnostic and treatment decisions. Figure 22-1 portrays one such pattern, in which the time course and efficacy of antidepressant medications are demonstrated in a woman with bipolar-II disorder. The essential point for the patient to note is that there is an uneven, sawtooth nature to the recovery pattern. Predicting occasional serious

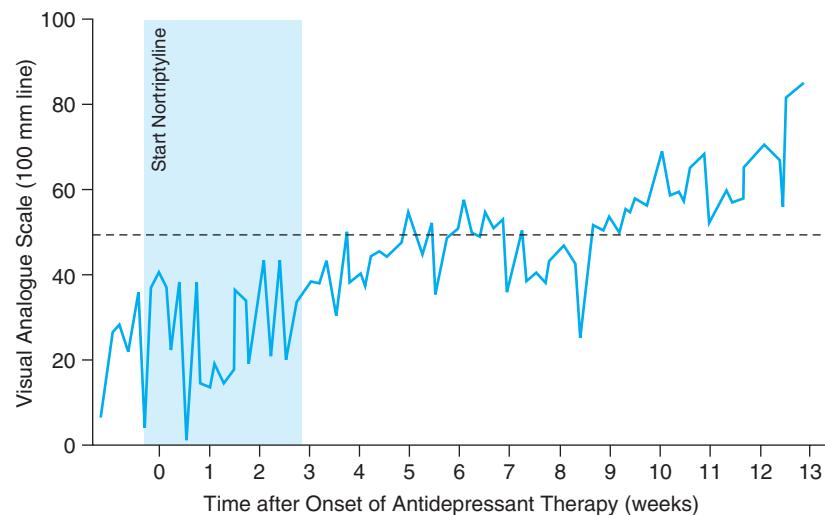

relapses on the way to remission is important in minimizing serious, potentially lethal discouragement in a high-risk (i.e., transitional) period. It also alerts patients to the potential danger of transitional and mixed states, which should be reported to the clinician.

Patient Education

"Am I manic-depressive?" "We don't use that term, but I would guess from the record that you are bipolar." "Which is a nice way of saying that yes, I'm manic-depressive? . . . that I'm lucky as all get-out to be a complete nut because we real bats get much more help from lithium than simple neurotics can—" "I've never heard it put just that way, but there is some truth in it." (Sloan Wilson, describing a conversation with his psychiatrist, 1976, p. 436)

Most affective disorder clinics and some practitioners routinely provide formal and informal education to patients and families through lectures, books, articles, pamphlets, discussion groups, videotapes, and ongoing communication between clinician and patient. Although this is the ideal scenario, it is not the prevailing one. Patients often express resentment at how little information they receive about bipolar illness and its treatment. Yet clinicians, in whatever setting, have an ethical and clinical obligation to engage patients in a continuing process of education, which clearly is integral to informed consent. Patients vary considerably in their ability to assimilate information about their medications and illness, and they need to participate actively in the treatment process. Too often a physician becomes a unilateral advocate of maintenance medication, and the result frequently is an adversarial rather than a collaborative relationship.

Figure 22-1. Course of recovery in a female patient with bipolar-II disorder treated with antidepressant medications.

The collaborative nature of the patient-clinician relationship is central to effective treatment. Not only must patients be taught about the natural course and symptoms of bipolar illness, but they should also be actively encouraged to question their clinicians about diagnosis and treatment, to discuss their concerns about undue delays in achieving the desired results, and to seek second opinions when appropriate. If the treating physician or psychotherapist disparages second opinions or consultations, patients should be encouraged to challenge this view and obtain the consultation anyway.

In the course of patient education, the chronic and highly recurrent nature of bipolar illness should be emphasized and reemphasized to the patient. Charts illustrating the relapse rate and worsening course of the untreated illness (e.g., Fig. 22-2) and the dramatic effect of a mood stabilizer can highlight these points for patients, as well as their families (Fig. 22-3). Patients should be encouraged to read about the illness and its treatment (suggested reading is listed in the appendix to this volume), including the potential neuroprotective effects brought about by lithium and other mood stabilizers (see color plates 1-4 and Chapter 14). They should also be given specific information about their medications and potential risks and side effects. The safety and efficacy of various treatments and the risks of no treatment should be outlined. Special attention should be paid to discussing the potential dangers of antidepressant use in bipolar patients, such as induction of mania or mixed states, worsening of the natural course of the illness (i.e., shortening of the cycle length), and severe agitation (see Chapter 19). Patients prescribed lithium should be advised that sudden discontinuance may substantially increase the risk of relapse and suicide (see Chapter 25). Education and informed consent do not end with a discussion of risks and benefits and the distribution of fact sheets, however. Ongoing talks between patient and clinician are essential, perhaps supplemented with lectures and/or videotapes.

Patients need to be alerted to the symptoms of impending episodes and, with the therapist's assistance, encouraged to identify their own individual prodromal patterns. These patterns have been studied extensively.⁷ Changes in sleep patterns are particularly important because they precede, exacerbate, and accompany mania, and because mania may be precipitated by sleep loss. As discussed in Chapter 16, environmental factors leading to insomnia (e.g., anxiety, excitement, grief), as well as other circumstances (e.g., hormonal changes, travel, drugs), can lead to mania through sleep deprivation. Wehr and Goodwin (1987) advised warning bipolar patients that a single night of unexplainable sleep loss should be taken as an early warning of possible impending mania. They further

suggested counseling patients to avoid situations likely to disrupt sleep and advised clinicians to consider prescribing hypnotics to prevent significant sleep loss. Factors leading to sleep reduction and their relationship to the precipitation of mania are illustrated in Figure 22-4. This illustration can be used in educating patients about the necessity of maintaining adequate levels of sleep. The importance of regularizing circadian rhythms by establishing patterns in meals, exercise, and other activities should also be stressed to patients.

Education regarding the impact of the disorder on interpersonal relations, employment, position in the community, and general health should also be provided. Patients often need guidance in dealing with the consequences of risky, illegal, or embarrassing behaviors that occur during mania, and in handling professional, family, or financial responsibilities during either depression or mania. For patients who experience significant employment difficulties as a result of the illness, the therapist can be helpful in recommending and exercising career counseling or vocational rehabilitation options.

A large amount of educational material on bipolar disorder can be found on the Internet. This material includes information on symptomatology, treatment options, support for patients and families, and referral sources; websites of discussion/advocacy groups; and reading matter. The quality of these materials varies enormously. Reliable sources include the NIMH, the Depression and Bipolar Support Alliance (DBSA; known until 2002 as the National Depressive and Manic-Depressive Association), the National Alliance on Mental Illness (NAMI), the National Foundation for Depressive Illness (NAFDI), and the National Mental Health Association (NMHA). In addition, Internet chatrooms provide bipolar patients and their families with a forum for the exchange of information and support, although some patients may find the information overwhelming and confusing. The appendix at the end of this volume includes various Internet sites and chatrooms relevant to bipolar disorder.

Finally, the ability to exercise informed consent, even for the well-educated patient, may be compromised when the patient is manic or depressed. In some states and countries, patients who know when rational and in a normal mood that they wish to have electroconvulsive therapy or be hospitalized when depressed (or manic) but that they are unlikely to consent in the midst of an episode can draw up "Odysseus" agreements (Joshi, 2003; Keefe and Pinals, 2004; Srebnik et al., 2005). Swanson and colleagues (2006) have shown that a 2-hour structured facilitation session, conducted by trained research assistants, is an effective way to help patients complete advanced directives so that they contain useful information about the patient's

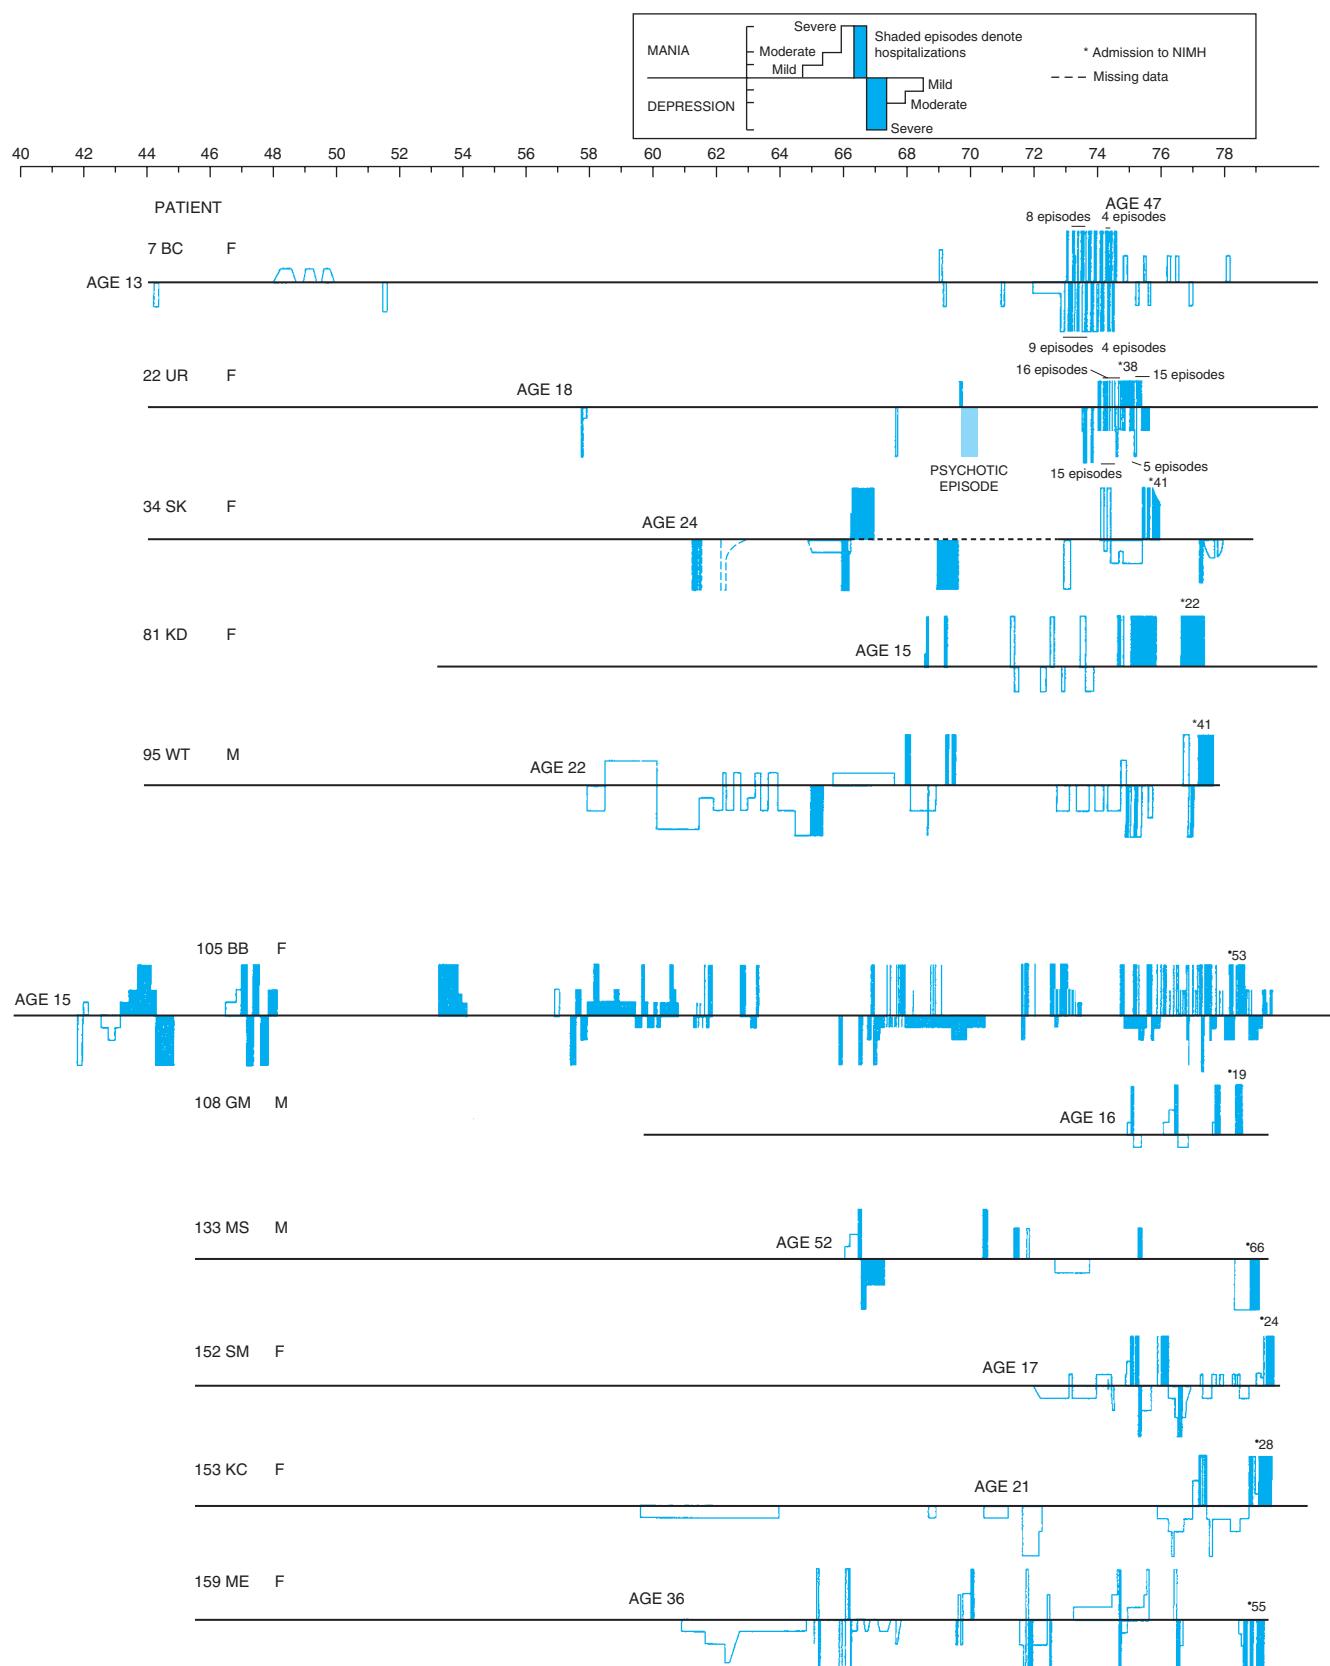

Figure 22-2. Life course of manic and depressive episodes in bipolar affective illness. Patterns of recurrent affective illness are illustrated in individual bipolar-I patients (those hospitalized for a manic episode). Manias are plotted above the line and depressions below. Hospitalizations are shaded, and dotted lines indicate uncertain or missing data. Note that most patients show a course of increased severity or frequency of affective episodes over time. NIMH = National Institute of Mental Health. (Source: Squillace et al., 1984.)

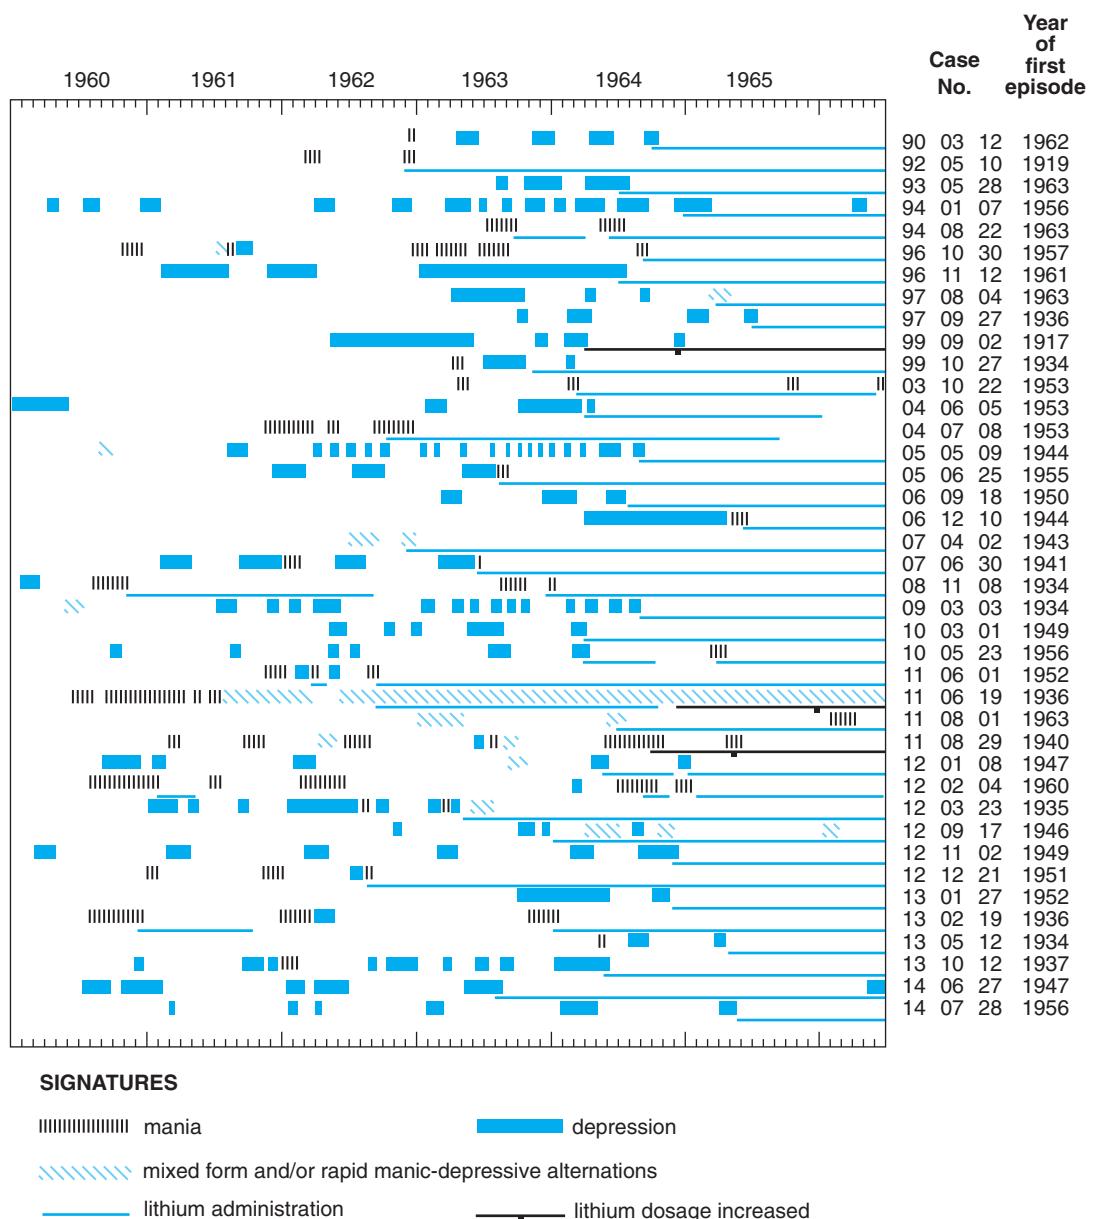

Figure 22-3. Effect of lithium in decreasing the frequency and duration of subsequent manic and depressive episodes. The patient records are arranged according to age; the first two digits of each case number indicate the year of birth. In the second column is shown the year when the first manic or depressive episode appeared. The diagram shows, for each patient, all psychotic episodes that occurred between January 1, 1960, and July 1, 1966. (Source: Baastrup and Schou, 1967.)

preferences for treatment. Derived from the same principle as that used by Odysseus when he sought protection from seduction by the Sirens, such agreements allow patients to consent in advance to certain treatments. General guidelines for drawing up advance directives are given in Box 22-1.

Family Education and Family Therapy

Family members and close friends often find that the educational information provided to patients is useful to them

as well. Families are, of course, in a unique position to observe the behavior and moods of bipolar patients. Education about the illness can increase family members' awareness and acceptance of the patient's condition and underscore their role in encouraging the patient to take prescribed medications and live sensibly. Waiting for symptom-free intervals between episodes to discuss the meaning and nature of bipolar illness allows for education and collaborative decision making in a less emotionally charged and more cognitively astute atmosphere.

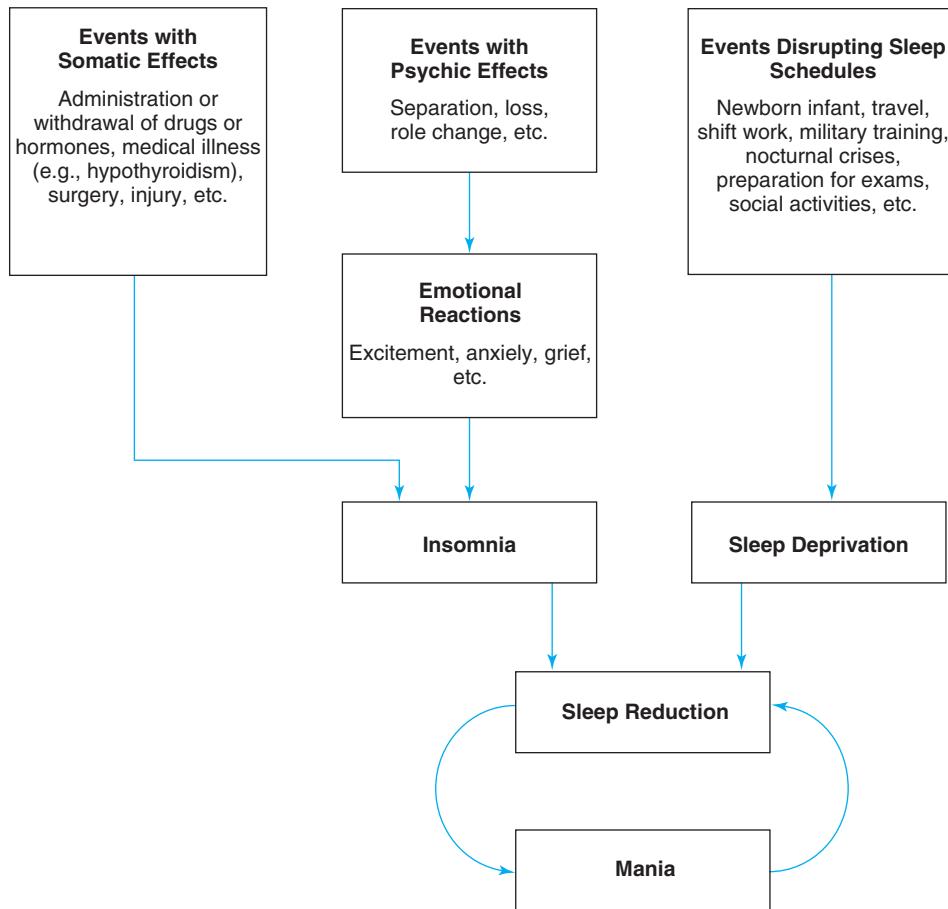

Figure 22–4. Diagram of the hypothesis of sleep reduction as the final common pathway of diverse factors thought to precipitate mania. (Source: Adapted from Wehr et al., 1987b. Reproduced with permission from the American Psychiatric Association.)

In addition to being educated about the illness and medications, family members should be informed about the importance of recognizing the early signs and symptoms of hypomanic, manic, and depressive episodes. Changes in sleep patterns, sexual and financial behavior, mood (expansiveness or undue enthusiasm, volatility, pessimism and hopelessness), and judgment, as well as involvement in excessive numbers of projects, are all highly characteristic of impending affective episodes. As noted earlier, such prodromes, as well as others more subtle or idiosyncratic (e.g., increased religious or political interest, avoidance of eye contact), can escape the patient's attention. These changes often are first noted by family members, who therefore can play a crucial role in early intervention, although Highet and colleagues (2005) found that many family members who care for patients with depression are able to recognize prodromal symptoms only in hindsight. In a comprehensive review of studies of early symptom identification by patients, Jackson and colleagues (2003) found that a median of 82 percent of patients could identify early symptoms of bipolar depression, such as changes in mood (48 percent) and psychomo-

tor symptoms (41 percent); prodromal sleep changes were far less easily identified (24 percent), however. The opposite was true for the prodromal symptoms of mania: the great majority of patients (77 percent) could identify sleep disturbance as an early symptom of mania, compared with 47 percent for psychomotor symptoms, 43 percent for changes in mood, and 34 percent for psychomotor changes. Overall, the prodromes of mania were of longer duration and easier to identify than those of bipolar depression.

If possible, strategies for contacting the clinician should be determined between patient and family during times when the patient is euthymic. To the extent feasible, general contingency plans and agreements should be formulated in advance to cover possible emergencies (e.g., suicidal thinking and behavior), hospitalization plans for mania or depression, and financial protection for patient and family during hypomanic and manic episodes.

The “relapse drill” is a roadmap to guide the family’s plans and actions should mania or depression recur (Marlatt and Gordon, 1985; Miklowitz and Goldstein, 1997). During the drill, the therapist identifies the prodromal

BOX 22-1. Advance Directives for Patients with Bipolar Illness

The Depression and Bipolar Support Alliance (2004) provides the following guidance on the use of advance directives:

One way to put self-knowledge and self-advocacy into practice is to create an advance directive—a written document outlining the treatment the patient would like to receive if his illness renders him incapable of making decisions. In your advance directive, you might choose to give another person the authority to make decisions about your treatment for you.

Advance directives for mental health are a relatively new development, and a few legal precedents are in place. Each U.S. state has a different set of laws governing the use and enforcement of advance directives. You may want to consult a qualified disability law attorney to be sure your advance directive is enforceable.

Using an advance directive may:

- Ease stress on you and your loved ones.
- Help you avoid treatment you know is not helpful.
- Help you get the right treatment when you need it most.

You must be mentally competent at the time you make your advance directive. Binding advance directives are usually signed by at least one witness and one physician who can verify that you are in good mental health at the time you write it. State what treatment you want, where and by whom, and under what circumstances. Your instructions may include:

Note: This information is not meant to take the place of consultation with a qualified legal professional.

symptoms of mania, hypomania, and depression and helps the patient and family develop plans for contacting the treatment team, dealing with practical problems that result from the relapse (e.g., parenting, financial arrangements), handling work and social responsibilities, and deciding when hospitalization is necessary and how to proceed. Realistic plans should be made with other adults (relatives or friends) who can support the patient's family during a crisis. The therapist can also formulate a mutually acceptable plan for helping the patient adhere to a medication regimen if he or she tends to skip doses.

Potential problems involving the violation of clinician-patient confidentiality are substantial and need to be discussed openly with both patients and their families. Szmukler and Bloch (1997) recommended that clinicians consider overriding the patient's refusal to involve family members only if harm (to the patient or family members) is probable and could be serious, if no acceptable alternatives are available, if the patient's decision-making ability is

- Emergency contact information for all of your health care providers.
- Medications (and dosages) that help you.
- Medications that have unpleasant side effects or do not help you.
- Treatments, such as electroconvulsive therapy, that you do or do not wish to be given.
- The facility or hospital where you prefer to be treated.
- Family members and friends who are authorized to make decisions about your treatment according to your written preferences.
- What you would like your loved ones to do if your symptoms cause you to be a danger to yourself or others.
- Things people can say or do to calm you or convince you to accept treatment.
- Warning signs that you may be in crisis.

You may also want to add instructions for legal professionals on how to assist you if you break the law and get arrested while you are ill.

Review your advance directive with your loved ones and health care providers. Give each of them an up-to-date copy. Check your advance directive periodically to be sure it still reflects your needs.

Having an advance directive does not guarantee your treatment will go smoothly. However, creating advance directives can be a beneficial addition to treatment. The entire process can be empowering. It can help you strengthen relationships with your health care providers and loved ones.

impaired, or if excluding the family could result in greater restrictions on the patient's rights and freedom. Whenever possible, however, patients should be strongly encouraged to involve their families in at least the early stages of treatment. (There are, of course, obvious if infrequent exceptions to this general guideline.)

Finally, family therapy, when indicated, can be a useful adjunct to treatment. Many issues arise in treating families with one or more members who suffer from bipolar illness (see Chapter 10). Specific studies involving family interventions are reviewed later in this chapter.

National and Local Support Associations

Both bipolar patients and their families can participate in excellent self-help groups, many of which operate under the auspices of DBSA. There are now approximately 1,000 such groups in the United States. The stated purpose of DBSA is "to provide personal support and direct service to persons with clinical depression or manic depression

and their families; to educate the public concerning the nature and management of these treatable medical disorders; and to promote related research." The importance of educating both the public and health professionals about early symptoms of bipolar disorder is underlined by DBSA's survey of members, in which half of bipolar respondents reported not having received any treatment during the first 5 years after the onset of symptoms (Lish et al., 1994).

Services provided by chapters of DBSA and other advocacy and support organizations, such as NAMI, include educational programs for patients, their family members, and the general public; self-help support groups for patients and families; determination of medication levels; Alcoholics Anonymous meetings; telephone hotlines for emergencies; newsletters; summaries of relevant research findings; employment counseling; and referrals to clinicians with expertise in treating bipolar and depressive illness. DBSA and NAMI work in collaboration, not in competition, with clinicians.

A survey of 2,049 members of DBSA support groups in 190 U.S. cities was conducted in three waves between 1997 and 1998. Among the survey respondents, 59 percent reported having bipolar disorder. The substantial majority (71 percent) of these respondents reported that psychotherapy was an essential part of their treatment. So, too, was participation in support groups. More than half (58 percent) of those who had experienced difficulty in adhering to treatment reported a significant improvement in adherence between the initial and follow-up surveys. The longer the patient had attended a support group, the lower was the chance of discontinuing medication against medical advice. Even those who had attended a DBSA group for less than a year reported a significant reduction in barriers to adherence (e.g., "problems in relationship with the doctor," "missing medication doses"). In addition, respondents who had attended a group for longer than a year reported significantly lower hospitalization rates. Although there is no clear cause-effect relationship between group attendance and better outcomes (members with more severe symptoms or functional impairment may be more likely to drop out of the groups), members cited the support, education, and advocacy of DBSA groups as important factors in dealing successfully with bipolar disorder and depression (Goodale and Lewis, 1999).

Although most major cities now have a branch of DBSA or a similar organization, 57 percent of respondents to a 1997–1998 survey of DBSA members reported not learning of the group's existence until more than a year after their diagnosis (Goodale and Lewis, 1999). Patients and their families should be encouraged to seek support from

their local DBSA, NAMI, or other such group. If there is no local branch of DBSA or NAMI, the organizations' national offices can be contacted for information about the nearest group (contact information is given in the appendix to this volume).

REVIEW OF THE LITERATURE

We have emphasized our belief that psychotherapy is important, often essential, in the treatment of bipolar illness, and have discussed a number of issues that can complicate overall clinical management and are the targets of such therapy. Until recently, however, scientific data from controlled clinical trials on the efficacy of psychotherapy in treating bipolar illness were nearly nonexistent.

At one time, the diversity of psychotherapeutic approaches discouraged research on psychotherapy for any disorder. Each psychotherapist was considered impenetrably unique, as was each patient, and there was little way to know what the therapist was actually doing in the office with a given patient. Psychotherapy was regarded as an art form that could not be addressed by science.

Over the past two decades, that view has changed. Methods have been developed or adapted for the testing of psychotherapeutic approaches, including the use of clinical trials, random assignment, and outcome measures that tap the areas of change one might expect as a result of psychotherapy. Most important among these new tools have been psychotherapy manuals that outline accepted procedures, provide technical specifications with scripts for intervention, and offer guidelines on what should be covered during treatment (Hibbs et al., 1997; Weissman et al., 2000). Such manuals can make psychotherapy a relatively uniform and therefore testable treatment. Audiotaping or videotaping of ongoing psychotherapy sessions provides an objective record of adherence to and delivery of the treatment set forth in a manual, and has been incorporated into numerous trials of psychotherapy for major depression and other disorders. Although bipolar patients have usually been excluded from these trials, possibly because medication has been viewed as the fundamental treatment for the disorder, this situation has begun to change.

The new psychotherapeutic approaches now being tested for treatment of bipolar disorder are different from the open-ended psychoanalytic approaches of the 1940s and 1950s, which focused on early-childhood experiences, transference, and dreams. Modern approaches are designed to be used as adjuncts to medication. They include attention to making a precise diagnosis; a psychoeducation component, with emphasis on medication adherence; monitoring of symptoms through symptom checklists; a focus on current problems; regulation of daily routine through life charts; and efforts to

improve current relationships to prevent relapse and build ways of coping with the consequences of the illness in work and family contexts. Bipolar disorder is viewed not as a character flaw, but as a chronic illness that requires varying levels of intervention over a lifetime. The norm is to employ psychotherapy as needed, rather than as an intensive treatment over many years. The family is an important ally, not an adversary, in the treatment. The emphasis is on the transactions between patients and their significant others, rather than the relationship between patient and therapist. The goal is not only gaining insight, but also learning to cope with having a chronic, usually devastating, and potentially lethal illness.

Not all of the new approaches have all these features. For example, some focus only on education, whereas others emphasize interpersonal and family relationships and use group or family modalities. The more comprehensive treatments—cognitive-behavioral therapy (CBT), interpersonal and social rhythm therapy (IPSRT), family-focused treatment (FFT), and the Life Goals Program—emphasize the achievement of functional goals through skills training and reduction of interpersonal conflict with significant others. These approaches include protocols for relapse prevention (the action plans in CBT and the Life Goals Program, the symptom monitoring and management plan for IPSRT, the relapse drill for FFT).

The new psychotherapeutic approaches appear to be consistent with the clinical reality of bipolar disorder. Whether they make a difference in altering patterns of relapse, however, cannot be known without further results from controlled clinical trials.

Tables 22–1 through 22–5 provide details of the interventions, study designs, results, and clinical observations of the clinical trials of various psychotherapeutic approaches conducted or ongoing as of this writing. It is obvious from these summaries that the samples have been relatively small, that many studies need to be replicated, and that only a few modalities have been tested. Tables 22–1 through 22–4 describe efficacy studies, and Table 22–5 ongoing effectiveness studies. The latter studies are designed to test psychotherapy in actual clinical practice among large, heterogeneous samples of bipolar patients. Such studies were recently initiated to compensate for the paucity of data on the psychotherapeutic management of bipolar illness. The following subsections review the most salient features and findings of studies addressing psychoeducation, CBT, IPSRT, and family/couples therapy (including FFT), as well as ongoing effectiveness studies.

Psychoeducation

Psychoeducation for bipolar disorder focuses on education about the illness, including symptoms (prodromal

and during the episode), treatment options, and the importance of sleep regulation and adherence to medication. An essential component of almost every new psychotherapy for bipolar disorder, it has also been tested as a specific method. Its purpose is to encourage the active and informed involvement of patient and family in the treatment process, following an “alliance, not adherence” philosophy (Frank et al., 1995; Toprac et al., 2000; Berk et al., 2004). In a recent survey, 500 British and American psychiatrists cited the education of patients as one of their most important clinical priorities (Roy and Williams, 2005). A Brazilian study of 106 bipolar patients found that level of knowledge about treatment, in this case lithium, was directly related to treatment adherence (Rosa et al., in press).

Psychoeducation deals with two of the most predominant problems in the management of bipolar disorder: nonadherence to medication and relapse despite adherence. Nearly one-half of patients with bipolar illness fail to adhere to their treatment (see Chapter 21); however, even highly adherent patients can suffer relapses (Keck et al., 1998). As discussed earlier, psychoeducation can help prevent relapses by teaching patients to recognize prodromal signs and symptoms and notify their treatment team and relatives. A summary of the results of studies examining the effect of psychoeducation and psychotherapy on medication adherence is presented in Table 21–5 in Chapter 21.

Various approaches to psychoeducation were employed in the studies listed in Table 22–1, including lectures; videotapes; group discussion; and fact sheets on symptoms, their management, and medication. Sometimes only the patient was included and sometimes key relatives, in individual or group settings. The length of the intervention varied from 2 to 6 weeks; all of the studies included follow-up at periods of 3 to 18 months. Outcomes ranged from improving knowledge and understanding and medication adherence to reducing rates of relapse. (Clinical trials of psychoeducation using CBT techniques are included in Table 22–2 and discussed in that section.)

In general, the results of these studies were modest. Some demonstrated significantly increased knowledge about the illness. Results varied regarding improvement in adherence to medication, and in some cases revealed improvement in relatives’ attitudes. The one study that assessed impact on clinical status found no effect of brief psychoeducation on relapse rate.

The most comprehensive psychoeducation program, the Patient and Family Education Program, was developed by the Texas Medication Algorithm Project (Toprac et al., 1998, 2000). The aim was to develop medication algorithms for the treatment of individuals with bipolar disorder, depression, or schizophrenia and to test the clinical and cost-effectiveness of these algorithm-driven treatments

TABLE 22–1. Clinical Trials of Brief Psychoeducation in the Treatment of Bipolar Patients

Study	Intervention	Study Design	Results	Clinical Observations
Haas et al., 1988	Inpatient family psychoeducation to increase acceptance and knowledge of BP in families (average 6 weekly sessions).	Families of BP patients randomized to psychoeducation plus standard hospital care ($n=12$) or standard inpatient care alone ($n=8$). Follow-up at 6 and 18 mo.	At 6 and 18 mo, female patients with BP who received the treatment had significantly better role functioning than female BP patients in the control group.	Family attitudes toward treatment improved in the psychoeducation group compared with the controls.
Peet and Harvey, 1991	Group psychoeducation involving a videotaped lecture on lithium action and side effects, followed by a home visit (2 sessions).	BP patients in remission randomly assigned to group psychoeducation ($n=30$) or a wait-list control group ($n=30$). Follow-up at 6 mo. Blood levels and tablet omission monitored to determine adherence.	At termination and follow-up, knowledge about lithium had increased significantly in the psychoeducation group. Improvement in medication adherence was significantly associated with improvement in knowledge about lithium.	Even short video psychoeducation increased knowledge about and adherence to lithium. Clinical status not assessed.
Van Gent and Zwart, 1991	Group psychoeducation with partners of BP patients (5 sessions). Focus on symptoms of the disorder, functioning, medication action, side effects, and hereditary factors.	Partners of BP outpatients randomly assigned to psychoeducation ($n=14$) or no intervention ($n=12$). Follow-up at 6 mo (partners) or 12 mo (patients).	Partners' knowledge about the illness, mood stabilizers, and coping strategies had increased significantly at termination and 6 mo. No difference in medication adherence was seen at 12 mo.	Clinical status not assessed.

Honig et al., 1997	Multifamily group psychoeducation (6 biweekly sessions). Focus on symptoms of BP, coping strategies, patient support and advocacy.	BP patient and a key relative assigned on a first-come, first-served basis to the psychoeducation group ($n=29$) or a wait-list control group ($n=23$). Follow-up at 3 mo.	No significant difference in relapse and medication adherence was observed in the two groups. Significantly more relatives in the psychoeducation group changed from high to low expressed emotion.	Even a brief intervention can result in changes in levels of expressed emotion in families.
Suppes et al., 2000	Psychoeducation as part of patient care in the Texas Medication Algorithm Project for BP, depressive, and schizophrenic patients.	Outpatient ($n=44$) and inpatient ($n=25$) BP patients received psychoeducation and algorithm-driven treatment. A large controlled trial is under way.	Both inpatient and outpatient groups experienced significant symptom improvement. Improvement in social functioning was significant for the inpatient group.	
Miller et al., 2004	Multifamily psychoeducational group therapy (6 sessions) or family therapy (average of 12 sessions), plus standardized pharmacotherapy.	BP-I patients randomly assigned to pharmacotherapy alone ($n=29$), family therapy plus pharmacotherapy ($n=33$), or group therapy plus pharmacotherapy ($n=30$).	No differences were found among groups in rates of recovery or time to recovery.	No measures of psychosocial functioning or recurrence of illness were used. The study involved a relatively small number of therapy sessions. The patient population may have been particularly refractory.

Note: Clinical trials of psychoeducation using cognitive-behavioral therapy are reviewed in Table 22–2.
BP=bipolar disorder.

TABLE 22–2. Clinical Trials of Cognitive-Behavioral Therapy for Patients with Bipolar Disorder

Study	Intervention	Study Design	Results	Clinical Observations
Cochran, 1984	Individual CBT for BP outpatients to enhance medication adherence compared with standard clinic care (6 weekly sessions). Targeted cognition and behavior that affect adherence based on Beck's model.	BP patients randomized to CBT ($n=14$) or standard clinical care ($n=14$). Follow-up at 3 and 6 mo.	The CBT group showed significantly greater adherence to medication at baseline and 6 mo follow-up (but not at 3 mo follow-up). Physician and independent evaluator reports showed improved adherence, whereas self- and informant reports did not. Although the two groups did not differ significantly in affective episodes, the CBT group had significantly fewer hospitalizations.	A brief intervention appeared to improve adherence to medication. The positive results disappeared at the 3 mo follow-up and reappeared at 6 mo, indicating the importance of long-term follow-up.
Hirschfeld-Becker et al., 1998	Group CBT (11 weekly sessions). Treatment included psychoeducation, cognitive approaches to depressive and manic behavior, preventive mood hygiene, medication adherence, problem solving around suicidality, and stress and conflict management.	BP patients randomly assigned to group CBT and medication ($n=15$) or medication only ($n=15$). Follow-up at 3 mo.	The CBT group had significantly longer periods of euthymia and significantly fewer new episodes than controls at both termination and follow-up.	A longer follow-up and a larger number of patients are needed to determine long-term efficacy.
Perry et al., 1999	Individual CBT psychoeducation for relapse prevention (7–12 sessions). Focus on early identification of relapse symptoms and a plan for seeking treatment.	BP patients with a history of relapse in the previous year but euthymic at baseline randomly assigned to psychoeducation combined with treatment as usual (TAU) ($n=34$) or TAU only ($n=35$). Follow-up at 6, 12, and 18 mo.	The psychoeducation group had significantly fewer manic relapses over 18 mo but no difference in the number of depressive relapses (in fact, the number slightly increased). Social functioning improved significantly. Adherence to mood stabilizers as indicated by blood levels did not differ.	This relatively short intervention resulted in a significant reduction of manic but not depressive episodes over a long follow-up period (18 mo).
Weiss et al., 2000	Group CBT for relapse prevention (12 or 20 weekly sessions) for patients with comorbid bipolar and substance-abuse disorders.	Euthymic BP (-I and -II) patients with substance abuse dependence within the past 30 days and taking a mood stabilizer enrolled in	The CBT group had significantly lower Addiction Severity Index scores and more months of abstinence from	Age was nonrandomly distributed. After controlling for age differences, reduction of mania symptoms in the

	In addition to psychoeducation and support, groups focused on identifying and coping with triggers, recognizing prodromal symptoms, and dealing with setbacks.	sequential blocks: BP patients ($n=21$) in group CBT in addition to any other psychosocial treatment compared with BP patients ($n=24$) who received assessment only. Both groups were assessed for mood, substance abuse, and medication adherence before, during, and after treatment monthly. Follow-up at 3 mo.	both drugs and alcohol. No significant differences in mood episodes or hospitalizations were seen.	CBT group no longer reached significance. At baseline, the therapy group had significantly more severe alcohol problems than controls, making results difficult to interpret. This is the only psychotherapy thus far for comorbid bipolar and substance-abuse disorders.
Lam et al., 2000	Individual CBT for relapse prevention (12 to 20 weekly sessions over 6 mo). Psychoeducation, CBT skills for coping with prodromal and residual symptoms. Emphasis on the importance of routine and sleep regulation.	Euthymic BP-I patients taking regular prophylactic medication with a history of recurrence. Random assignment to CBT plus TAU ($n=13$) or TAU only ($n=12$). Monthly mood and medication adherence ratings. Follow-up at 6 mo.	The CBT group had significantly fewer hypomanic episodes and a lower total number of episodes than the control group at follow-up. They also showed significantly fewer fluctuations in symptoms and higher medication adherence at termination and follow-up. They were significantly less depressed and hopeless at follow-up and showed significantly better social functioning and self-control behavior. Significantly fewer neuroleptics were prescribed in the CBT group.	Raters were not blinded to patients' status. CBT showed the best results at the end of follow-up, suggesting gains even after therapy had been completed.
Scott et al., 2001	Individual CBT (25 weekly sessions) focused on managing symptoms, altering dysfunctional thoughts and attitudes, managing barriers to adherence, and preventing relapses.	BP outpatients randomly assigned to CBT ($n=21$) or a 6 mo wait-list control group ($n=21$), followed by CBT. Medication prescribed by the preexisting treating physician. Follow-up at 6 and 12 mo.	The CBT group showed significant reductions in symptomatology and functioning at termination and follow-up (with a non-significant trend toward symptom increase at follow-up). Depressive symptoms were significantly reduced, and there was a trend toward fewer manic symptoms (self-rated manic	The authors suggest the need for a more extensive course of maintenance given the slight deterioration in symptomatology after termination.

(continued)

TABLE 22–2. Clinical Trials of Cognitive-Behavioral Therapy for Patients with Bipolar Disorder (*continued*)

Study	Intervention	Study Design	Results	Clinical Observations
Colom et al., 2003a	Group CBT psychoeducation for relapse prevention (21 sessions, 8–12 BP patients in each group). Focus on illness awareness, early identification of relapse symptoms, treatment adherence, and a plan for seeking treatment.	Euthymic BP (-I and -II) patients randomly assigned to psychoeducation group combined with medication ($n=60$) or unstructured group combined with medication ($n=60$). Follow-up every 2 mo up to 28 mo.	activation was significantly reduced). Hospitalization rates were also significantly reduced in the CBT group. The psychoeducation group had significantly fewer manic, hypomanic, and depressive relapses, as well as fewer and shorter hospitalizations, relative to the control group at termination and follow-up.	This is the only psychoeducation clinical trial that resulted in a significant reduction of manic as well as depressive relapses over a long follow-up period (28 mo).
Colom et al., 2003b	Group CBT psychoeducation for relapse prevention in adherent patients using the same treatment program as above.	Euthymic BP-I patients, adherent to medication, randomly assigned to psychoeducation combined with TAU ($n=25$) or TAU only ($n=25$). Follow-up every month up to 28 mo.	The psychoeducation group had significantly fewer overall recurrences and depressive episodes than the control group at termination and follow-up.	Because the patients were already adherent to medication, the positive results of psychoeducation seen in this study suggest that its therapeutic mechanisms extend beyond adherence enhancement.
Lam et al., 2003	Individual cognitive therapy (12–18 sessions during first 6 mo, 2 booster sessions during second 6 mo). Focus on preventing relapse, promoting social functioning, and monitoring mood and illness prodromes.	BP patients randomly assigned to cognitive therapy plus mood stabilizer ($n=51$) or control group ($n=52$), which received mood stabilizer plus regular psychiatric care. Monthly follow-up for 12 mo.	The cognitive therapy group had significantly fewer bipolar episodes, hospitalizations, and days affectively ill. They coped better with manic prodromes at 12 mo, and their medication adherence was better, although not significantly so.	It was more difficult to teach patients to monitor depressive than manic prodromes. There was no assessment of sleep routines or control for medication prescribed.
Lam et al., 2005b	18 mo follow-up of Lam et al. (2003) study.	Continuation of Lam et al. (2003) study design.	Over 30 mo, the cognitive therapy group had significantly better outcomes in terms of time to relapse. The effect of relapse prevention was seen primarily in the first year. Medication adherence was significantly higher in the cognitive therapy group.	The cognitive therapy group spent 110 fewer days in bipolar episodes (out of a total of 900 possible days) over the entire 30 mo and 54 fewer days (out of 450 possible days) for the last 8 mo. Booster sessions or maintenance therapy may be a helpful addition to treatment programs.

Ball et al., 2006	Individual cognitive therapy sessions (18–20) focusing on education, identification of early warning signs, establishment of stable routines, identification and modification of cognitions, and expression of emotions.	BP patients randomly allocated to a 6 mo trial of cognitive therapy plus mood-stabilizing medications ($n=25$) or medication TAU ($n=27$).	The cognitive therapy group had less severe depression scores, less dysfunctional attitudes, and a trend toward a longer time to depressive relapse. At 12 mo follow-up, the cognitive therapy group showed a trend toward lower mania scores and improved behavior control.	The study was the first to use emotive techniques systematically. The sample size was small, and the number of dependent variables was large. A single therapist administered the cognitive therapy, and there was poor adherence with blood testing in both groups. There was no significant difference between the groups in self-reported medication adherence. Clinical benefits diminished after the cognitive therapy was completed, suggesting that maintenance treatment or booster sessions may be advisable.
Scott et al., 2006	20 sessions of CBT, weekly until week 15 and then in reduced frequency until week 26. Two booster sessions offered (at weeks 32 and 38).	BP patients randomly assigned to CBT plus TAU ($n=127$) or TAU (medication plus occasional clinical contact) ($n=126$). Patients assessed every 8 weeks for 18 mo.	No significant differences between groups were observed in recurrence rates or medication adherence. CBT appeared to be more effective in those with a history of fewer episodes.	Interpretation of the findings is problematic because of heterogeneity of the patient population: 32% were in acute episodes, the remainder euthymic; 31% had a history of 6 or fewer episodes, 25% a history of 30 or more. Many (40%) of the CBT patients did not receive the entire treatment sequence; 16% of patients in both groups were not taking mood stabilizers.

CBT = cognitive-behavioral therapy; BP = bipolar disorder.

TABLE 22–3. Clinical Trials of Interpersonal and Social Rhythm Therapy for Patients with Bipolar Disorder

Study	Intervention	Study Design	Results	Clinical Observations
Frank, et al., 1999; Frank, 2000	Individual IPSRT plus behavioral strategies to help regulate patients' daily routines. Administered weekly in the acute phase until stabilization, biweekly for 12 wk during the preventive phase, monthly for 2 yr. Frequency increased in case of a new episode.	BP patients, acutely ill, randomly assigned to medication plus IPSRT ($n=45$) or medication plus clinical status and symptom review treatment (CSSRT), matching the frequency of IPSRT and including psychoeducation and treatment adherence training ($n=45$). After stabilization, patients were reassigned to either IPSRT or CSSRT for the preventive phase.	Preliminary results: patients in the IPSRT group had significantly more regular routines than those in the comparison condition. There was no significant difference in recovery time from manic and depressive episodes between the two conditions. IPSRT was associated with significantly longer periods of euthymia than the comparison condition. No such difference was found for manic/mixed versus euthymic states.	Changing treatment modality (whether IPSRT or the control treatment) was associated with significantly faster recurrence and worse symptomatology, suggesting the importance of stability in the treatment of BP.
Frank et al., 2005	Acute and maintenance IPSRT, acute and maintenance intensive clinical management (ICM), acute IPSRT followed by maintenance ICM, or acute ICM followed by maintenance IPSRT.	Acutely ill BP patients ($n=175$) randomly assigned to one of the four treatment strategies; 2 yr preventive maintenance phase.	No difference was found among treatment strategies in time to stabilization. Patients assigned to IPSRT in the acute treatment phase survived longer without a new affective episode.	Medically healthy married patients without comorbid anxiety disorders benefited most from treatment.

BP = bipolar disorder; IPSRT = Interpersonal and Social Rhythm Therapy.

TABLE 22–4. Clinical Trials of Family/Couples Therapy for Patients with Bipolar Disorder

Study	Intervention	Study Design	Results	Clinical Observations
Miller et al., 1991	Family group therapy (8–12 sessions) initiated during hospitalization and continued for 18 wk after discharge.	BP patients randomly assigned to standard treatment alone ($n=7$) or combined with family group therapy ($n=7$). Follow-up at 2 yr.	Significantly fewer hospitalizations and relapses had occurred in the family therapy group at 2 yr follow-up.	Although the number of patients was small, the significant results are promising.
Clarkin et al., 1998	Marital therapy with BP patient (either married or living with a partner for >6 mo); 25 sessions over 11 mo.	Euthymic BP patients randomly assigned to medication and marital therapy ($n=19$) or medication only ($n=23$). No follow-up.	At termination, medication adherence and overall functioning were significantly better for the psychotherapy group. There was no difference in symptomatology between the two groups.	The authors argued that aggressive treatment delivered earlier in the marriage could have been more successful.
Miklowitz et al., 2000	FFT including extensive family psychoeducation on BP, communication skills, and family problem solving; 21 sessions over 9 mo.	BP patients recruited during or immediately after an episode, randomized to either FFT for 9 mo ($n=31$) or standard psychiatric care ($n=70$). Follow-up at 3 mo intervals for 1 yr.	The FFT group experienced significantly fewer depressive relapses and longer interepisode intervals than the comparison group. The FFT group also showed an overall decrease in depressive but not in manic symptoms.	The effects of FFT were independent of medication adherence, although higher adherence in both groups was associated with greater stabilization of manic symptoms. FFT was associated with a more positive nonverbal interactional style, which partially mediated a more favorable outcome. BP patients from families with high expressed emotion showed the most dramatic symptom reduction.
Miklowitz et al., 2003	FFT as described above, 21 sessions, compared with crisis management (CM), 2 sessions. Both groups received pharmacotherapy.	BP patients randomized to FFT ($n=31$) plus pharmacotherapy or CM ($n=70$) plus pharmacotherapy. Follow-up at 3–6 mo intervals for 2 yr.	The FFT group experienced fewer relapses, longer survival intervals, greater reduction in mood symptomatology, and better treatment adherence.	FFT involved more extensive therapist contact. There was a lack of control over patients' medical regimens.
Rea et al., 2003	FFT as described above (21 sessions) or individual therapy focused on support, problem solving, and education (21 sessions).	BP patients randomly assigned to FFT ($n=28$) or individual therapy ($n=25$). Assessments at 3 mo intervals for 1 yr period of active treatment and follow-up at 1 yr after treatment.	The FFT group was much less likely to be rehospitalized or to have illness relapses during the 2 yr study period. Both groups showed high levels of medication adherence (no significant difference between groups).	The effect of FFT was strongest after completion of the treatment protocol. Patients with poor premorbid status were protected from relapse by FFT but not by individual therapy.

BP = bipolar disorder; FFT = Family-Focused Treatment.

TABLE 22–5. Effectiveness Studies Involving Psychotherapy for Patients with Bipolar Disorder

Study	Intervention	Study Design	Results	Clinical Observations
Sachs et al., ongoing	Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD). Clinical trials of interpersonal and social rhythm therapy (IPSRT), family-focused therapy (FFT), cognitive-behavioral therapy (CBT), or collaborative care (the control condition, psychoeducation) as adjunct to medication.	A multisite randomized effectiveness study. BP patients ($n=5,000$) to be recruited in 17 centers.	Not yet available.	Not yet available.
Callahan and Bauer, 1999	Life Goals Program: group psychotherapy with psychoeducation for relapse prevention (5 weekly sessions); individual behavioral treatment with social/educational goals.	Initial open trial with bipolar patients ($n=29$) at two Veterans Affairs (VA) Hospital sites.	69% of patients completed psychoeducation and showed increased knowledge of BP; 70% of these patients reached behavioral goals. Multisite open trial is ongoing.	The program is currently being evaluated against VA treatment as usual in a 12-site randomized controlled clinical trial.
Simon et al., 2005	An effectiveness trial of the Life Goals Program plus monthly telephone monitoring by nurses at a health maintenance organization.	BP patients ($n=441$). Clinical/functional status assessed every 3 mo for 12 mo.	Patients in the intervention group had significantly lower mania ratings and spent one-third less time in hypomanic or manic episodes. Mean depression ratings did not differ between the groups.	Those who completed five or more group sessions had better clinical outcomes but also had less severe symptoms at baseline. It is difficult to separate the effects of greater attention and support from those of specific intervention components.

BP = bipolar disorder.

compared with treatment as usual. The study cited in Table 22-1 tested only feasibility; a trial of this program is currently under way (Suppes et al., 2001). The psychoeducation in this approach has unique features. The program was developed mainly by a committee of members of patient advocacy and support groups, working in collaboration with clinicians. The educational material used during the acute phase of treatment is introduced by the physician and followed up by staff responding to patients' questions. When patients are less symptomatic, more complex material is presented to help with symptom recognition and to explore barriers to adherence to treatment (including side effects). Apart from individual meetings with the clinical team, patients and their families have the option to participate in group meetings that may include videotape presentations and consumer discussions (Toprac et al., 2000). The results of the ongoing trial, which includes a comprehensive consumer-guided educational program and large sample sizes, will provide important information about the effectiveness of this approach.

Cognitive-Behavioral Therapy

CBT, developed by Beck and colleagues (1979), is currently the most widely used and tested psychotherapeutic approach for which a manual has been created. It was originally developed for major depression but has been adapted and tested for numerous other conditions, including bipolar disorder. The underlying assumption is that depression-prone individuals possess negative self-schemata (beliefs), labeled the "cognitive triad." Specifically, depressed patients have negative views of themselves as worthless, inadequate, unlovable, deficient; of their environments as overwhelming, filled with obstacles and failure; and of their futures as hopeless, as though no effort will change the course of their lives. There have been far fewer studies of cognitive style in bipolar disorder than in major depression. The results of those that have been conducted suggest that cognitive styles in both mood disorders are similarly fragile and that negative self-esteem is a robust predictor of depressive and manic relapses (Scott et al., 2000; Scott and Pope, 2003; Jones et al., 2005). In administering CBT, the therapist is active and directive and, applying principles of logic and the scientific method, facilitates a rational approach to thinking with regard to the patient's current life circumstances. The patient's thoughts and assumptions are treated as hypotheses that can be tested to verify their accuracy.

To foster a spirit of collaborative empiricism, CBT therapists typically begin treatment by educating patients about their disorder. When a new technique is introduced, the therapist begins by presenting its rationale. In educating patients, the therapist builds the therapeutic alliance. To maximize rapid response to treatment, emphasis is placed

on homework outside of therapy sessions. By the end of each session, therapist and patient agree on at least one assignment the patient can complete to either test beliefs or build skills. Cognitive therapy focuses on understanding how patients interpret events in their lives. The therapy is based on the premise that if distorted thoughts and images can be changed, the accompanying negative emotional states and behaviors will change as well. In this cognitive model of emotion, affect and behavior are seen for the most part as mediated by cognition.

The CBT adaptation for bipolar disorder is based on the observation that stressful life events can interact with negative cognitive styles to precipitate manic and depressive symptomatology in individuals with the disorder (Alloy et al., 1999). Various studies (Hollon et al., 1986; Alloy et al., 1999) led to the somewhat surprising finding that many persons with bipolar illness exhibit cognitive styles as negative as those associated with unipolar mood disorders, suggesting that similar psychological processes may predispose to both manic and depressive episodes or that the underlying disorders may result in similar cognitive manifestations.

Antimanic cognitive techniques include early identification of manic thoughts, cognitive restructuring geared to realistic interpretation of events, and evaluation of plans before taking action. Behavioral techniques focus on coping with sleep disturbance and on increasing medication adherence (when the chance of discontinuation is high), such as by associating the taking of medication with certain daily routines. Also employed are methods of reducing risk-taking behavior, such as giving credit cards to a relative or friend permanently or at the first sign of a relapse to control spending, and the imparting of skills needed to prioritize and decrease the number and intensity of activities (Bauer et al., 1991; Basco and Rush, 1995; Scott, 1996). Cognitive and behavioral interventions during depressive phases include teaching behavior activation techniques to end the lethargy cycle (such as an increase in pleasant activities or assignment of tasks to reduce workload) and techniques for countering negative thoughts.

More than 10 efficacy trials of CBT in treating bipolar disorder have been completed (see Table 22-2). In addition, CBT is included in NIMH's ongoing Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) (discussed later). The CBT interventions studied were generally similar, but differed in the degree of structure of the manuals employed, as well as in the emphasis placed on cognitive or behavioral interventions and psychoeducation. Several studies used a group format (Hirschfeld-Becker et al., 1998; Weiss et al., 2000; Colom et al., 2003a,b). In most of the studies, CBT was conducted primarily on euthymic bipolar patients and was compared

with treatment as usual. The length of the interventions varied from 6 to 25 sessions.

The results of these studies suggest that CBT may be a particularly useful adjunct to medication for relapse prevention, and may result in increased medication adherence and fewer relapses (both manic and depressive). In one study, cognitive dysfunctional attitudes remained unaffected despite symptomatic relief by the end of the treatment (Zaretsky et al., 1999), and in another, the positive effects of CBT were greater by the end of follow-up (Lam et al., 2000), indicating that CBT for bipolar patients may need to extend over time. Other investigations also have found that "booster" psychotherapy may be necessary to maximize outcome (Scott et al., 2001; Ball et al., 2006). Results of a recent study by Lam and colleagues (2005a) suggest that the combination of cognitive therapy and mood stabilizers is superior to mood stabilizers alone with regard to not only clinical outcome, but also cost-effectiveness. The cost of adding cognitive therapy to a medication-only regimen was offset by reduced costs for other services, such as inpatient or community core programs. The most recent randomized control study of CBT (Scott et al., 2006) is the only study to show no significant differences between the CBT and treatment as usual groups, but its results are difficult to interpret. The results may be due to the heterogeneity of the patient population (one-third were in acute episodes, and there was wide variability in affective histories). Moreover, many CBT patients did not complete all of their treatment sessions, and nearly one of every five patients was not taking a mood stabilizer (see Lam, 2006, for a detailed critique of the study's methodology).

Several of the studies (Cochran, 1984; Perry et al., 1999; Colom et al., 2003a,b) used CBT techniques for psychoeducation to assist patients in changing their attitudes about adherence and in solving problems related to relapse prevention (see Box 22-2 for the content of the Barcelona Psychoeducative Program). Results of these studies showed significant changes in the clinical status of the patients or their number of hospitalizations as a result of extensive psychoeducation. In Cochran's (1984) six-session intervention, significantly fewer hospitalizations occurred in the CBT group (although no difference in mood episodes was found). The study by Perry and colleagues (1999) showed a reduction in manic relapses, whereas Colom and colleagues (2003a), who conducted the longest psychoeducational intervention, found a reduction in both manic and depressive relapses; thus it may take a longer intervention to help patients learn how to avoid depressive relapses. In addition, the study of Colom and colleagues (2003b)—a group psychoeducation study with adherent bipolar patients—sheds light on the possible mechanisms of action of psychoeducation: that it exerts its effect not

only through increased adherence (since the participants in that study were already adherent), but also through assistance provided to the patient in recognizing and managing the prodromal symptoms of a relapse. In a subanalysis of their data, Colom and colleagues (2005) found that mean serum lithium levels were higher and more stable in patients who had received psychoeducation than in those who had not (Colom et al., 2005). An individual treatment manual based on the CBT model of this study has been developed and is currently being tested in STEP-BD. This manual has optional sections that can be used to address comorbid disorders often associated with bipolar disorder (see Chapter 7).

Interpersonal and Social Rhythm Therapy

Interpersonal psychotherapy is a time-limited psychotherapy, specified in a manual, that was developed for major depression and has been modified for other disorders and tested in numerous clinical trials (Klerman et al., 1984; Weissman et al., 2000). It makes no assumption about the cause of illness, but makes use of the connection between onset of symptoms and current interpersonal problems. The approach deals with current rather than past relationships and the immediate social context of the illness. It attempts to intervene in symptom formation and social

dysfunction and not in personality. The initial phase includes a systematic diagnostic evaluation, psychoeducation, a review of medication, and an examination of current relationships and changes proximal to the emergence of symptoms. At least one of four problems (grief, interpersonal disputes, role transitions, role deficits) becomes the focus of treatment.

Frank and colleagues (1994) adapted interpersonal psychotherapy for bipolar disorder by adding a behavioral component to regulate patients' social rhythms and termed their approach IPSRT. The importance of regulating such rhythms had been demonstrated earlier in research conducted at NIMH (Wehr et al., 1987a,b). The focus of the method is on disruptions in interpersonal relationships that precede the onset of recurrence of an episode (manic or depressive). The four problem areas of interpersonal psychotherapy are also considered potential triggers of episodes in this adaptation. In IPSRT, grief includes not only grief for the death of a loved one, but also the mourning frequently experienced by bipolar patients over the loss of a healthy self that used to function productively (see Jamison and Goodwin, 1983; Jamison, 1991, 1995). Frank and colleagues (1994) argued that if this issue is not addressed, it may manifest itself in medication nonadherence and other self-destructive behavior. Interpersonal disputes are common among bipolar patients, especially in the manic phase, when angry and impulsive outbursts may alienate and frighten loved ones. Role transitions or life changes—such as starting a new job; relocating; having a new baby; experiencing the death of a spouse, family member, or close friend; or undergoing a divorce—may disrupt a routine that has provided a sense of familiarity and predictability, and may also disturb patients' sleep-wake cycle and daily rhythms. Interpersonal deficits are prominent in bipolar patients, as the damage and turmoil that follow manic episodes lead some patients to reduce their involvement in social relationships and work.

As noted earlier, major interpersonal disruptions may precipitate a manic or depressive episode. Based on findings from earlier research carried out by Wehr and colleagues (1987a,b) at NIMH, IPSRT postulates that the link between the patient's biological vulnerability and interpersonal events lies in the interplay between zeitgebers (events that stabilize the biological clock) and zeitstoppers (events that disrupt the biological clock) (see Chapter 16). Thus, the mediating mechanism that may lead to an episode is disruption of the patient's circadian rhythms and daily routines (Wehr et al., 1987a; Ehlers et al., 1988; Frank et al., 1994). Early in the treatment, the therapist introduces the Social Rhythm Metric to chart the regularity and stimulation of 17 daily activities (e.g., getting out of bed, having the first meal), as well as the patient's mood at the end of

each day. This procedure is intended to help the patient become more aware of the patterns of change in daily rhythms and life events and their relationship to mood.

IPSRT is conducted in four phases:

- In the initial phase, the therapist takes a thorough history of previous episodes and their interpersonal context; provides psychoeducation on bipolar disorder; introduces the Social Rhythm Metric, focusing on the most recent episode; and identifies the patient's main interpersonal problem area(s). The therapist is looking for evidence of disruption of daily rhythms that preceded episodes and educating the patient about the impact of rhythm dysregulation on mood.
- In the second phase, therapist and patient work toward regulating the patient's routine, as well as resolving the interpersonal problem areas relevant to episodes.
- The goal of the third phase is for the patient to become more independent and proficient in the use of IPSRT to address the links among events, biology, and mood.
- Termination is the fourth phase, with particular emphasis on enhancing the patient's independent functioning and developing strategies for relapse prevention.

Frank and colleagues conducted an efficacy study of IPSRT (Frank et al., 1999, 2000), comparing it with clinical status and symptom review treatment, a form of intensive clinical management (see Table 22-3). All patients also received medication. Preliminary results for 90 patients who participated in the preventive phase showed significantly more regular social/circadian rhythms in the IPSRT than in the comparison group. There was no significant difference in the number of episodes (manic or depressive) between the two conditions. However, IPSRT was associated with significantly longer periods of euthymia relative to the comparison group, which experienced more depressive symptoms over time. There was no difference between the two conditions in the proportion of manic/mixed and euthymic states over time (Frank et al., 2000). Preliminary findings also indicated that patients assigned during the preventive phase to a treatment different from that received during the acute phase (regardless of what that treatment was) were at higher risk for relapse, suggesting that stability in treatment delivery can be a regulating factor for bipolar patients (Frank et al., 1999). IPSRT is also being tested in the NIMH STEP-BD study (see the later discussion).

In a study of 175 acutely ill bipolar patients, Frank and colleagues (2005) compared two psychosocial interventions, IPSRT and intensive clinical management (ICM), in a randomized controlled trial involving four treatment strategies: acute and maintenance IPSRT, acute and maintenance ICM, acute IPSRT followed by maintenance ICM, and acute ICM followed by maintenance IPSRT. During

the 2-year preventive maintenance phase, they found no difference among the treatment strategies in time to survival. Those who had been assigned to IPSRT during the acute treatment phase survived longer without a new affective episode. As might be expected, the participants in the IPSRT group showed more regularity of social rhythms at the end of the acute treatment phase. Moreover, medically healthy patients without comorbid anxiety disorders derived greater benefit from treatment.

Family/Couples Therapy

Because bipolar disorder takes a considerable toll on marriage and family life, early psychotherapy studies focused on families and couples (see Chapter 10). It has been found that families with high levels of expressed emotion toward the patient, characterized by hostility, rejection, and overinvolvement, are associated with higher rates of relapse (Fallon et al., 1984; Miklowitz et al., 2004). Patients' sensitivity to such criticism is also predictive of poorer outcomes (Miklowitz et al., 2005). In an adaptation of behavioral family management methods tested with schizophrenic patients (Fallon et al., 1984), FFT was developed for bipolar patients recently treated for an acute episode as inpatients or outpatients (Miklowitz and Goldstein, 1990). Family attitudes, communication, and problem-solving style are the targets of treatment. FFT, lasting 9 months and usually delivered in 21 sessions, has five stages:

- In the “joining phase,” the therapist introduces the protocol to the family.
- The initial assessment phase focuses on evaluation of levels of expressed emotion in the family and on the quality of communication and problem-solving styles.
- Family psychoeducation consists of 7 sessions during which information on bipolar disorder is introduced, including the patient's particular patterns of onset for both manic and depressive episodes, symptom course, and suicidal ideation. A central component of family psychoeducation is the relapse drill discussed previously. The therapist also explores patient and family attitudes toward medication and emphasizes the importance of adherence, including regular monitoring of blood levels. A vulnerability–stress model is adopted, and the therapist identifies risk and protective factors that affect relapses. In this context, the entire family is encouraged to promote a regular, predictable, and low-stress environment.
- Communication enhancement training, lasting about 7 sessions, teaches family members skills of listening actively, expressing positive and negative feelings in an accepting and nonintrusive manner, and making nonjudgmental requests for change.

- Problem-solving techniques are addressed in about 5 sessions, in which participants learn to define problems, evaluate each option, and implement solutions. The family, with the help of the therapist, resolves problems concerning medication adherence, living arrangements, and resumption of previous social and occupational roles (Miklowitz and Goldstein, 1997).

There have been five efficacy trials of family/couples therapy with bipolar patients (see Table 22–4), which have varied in the number of participants (14–101) and length of follow-up period (from none to 2 years). A study conducted by Miller and colleagues (1991) had a very small sample and, despite the high probability of type II error, yielded significant results with regard to relapse prevention over 2 years. Clarkin and colleagues (1998) failed to show significant symptomatic change, but they did not conduct a follow-up evaluation and may have missed the delayed effect present in other studies. The largest efficacy studies conducted thus far (Miklowitz et al., 2000; Rea et al., 2003) showed that FFT led to a significant reduction in depressive relapses and symptomatology as compared with clinical management or individual therapy. The results of these studies suggest that therapy with some family involvement may be efficacious for bipolar patients, with a selective effect for depressive symptomatology. However, the variability in the treatments used in these studies limits conclusions about a specific type of family treatment. FFT is also included in STEP-BD (discussed later).

Psychotherapy for Children and Adolescents

Interest in the early presentation of bipolar disorder in children and adolescents has been growing (see Chapter 6). Since there are still so many unknowns regarding the early signs, diagnostic criteria, and comorbid conditions of pediatric bipolar disorder, it is no surprise that there are only a few tested mood stabilizers for this population and no proven psychotherapeutic approaches (Pavuluri et al., 2002).

Fristad and colleagues (1998) described a manual-driven, adjunctive, multifamily group treatment approach for youths aged 8 to 12 with bipolar and depressive disorders. This method includes psychoeducation about the disorders and the role of medications, training in communication skills to improve interactions between parents and children, stress management, and development of coping strategies. In a later study, Fridstad and colleagues (2002) showed that multifamily psychoeducation groups were characterized by increased knowledge about bipolar disorder and treatment options, better skills for dealing with the bipolar child, more active attitudes toward mobilizing resources to benefit the child, and an increased sense of support compared with a wait-list control group.

Miklowitz and colleagues developed a manual for adolescents aged 13 to 17 with bipolar-I disorder. This manual, an adaptation of the FFT model for bipolar adults, is designed to make the approach appropriate for this age group and to address clinical issues specific to juvenile bipolar disorder. In an open trial of 20 bipolar adolescents (mean age 14.8 years; standard deviation=1.6), this adapted approach was associated with improvements in depression and mania symptoms, as well as in behavioral problems (Miklowitz et al., 2004).

Greene (2001) developed a collaborative problem-solving model that focuses on parents' assistance to their children. This approach helps parents avoid engaging their children when the children are in the midst of a rage attack. Only after an attack subsides can the parent encourage collaborative problem solving. The approach is controversial since the model emphasizes no consequences for the rage behavior or associated actions.

Pavuluri and colleagues (2002) developed a treatment program that involves parent-and-child sessions for 8- to 12-year-olds with bipolar disorder, termed Child- and Family-Focused Cognitive-Behavioral Therapy. Central to this approach is building the youth's self-esteem and helping all involved parties understand that pediatric bipolar disorder is a neuropsychiatric problem of affect dysregulation, rather than willful misbehavior. Over 12 sessions, parents are trained as coaches while engaging in parallel therapy to address their own affect regulation in dealing with their children, restructure their thoughts regarding their effectiveness as parents, and learn to resolve conflicts with their children through empathy. Both parents and children are instructed in the use of "RAINBOW":

- R=the importance of a routine (including sleep hygiene).
- A=affect regulation/anger control (including knowledge about the disorder, medication, and life charts).
- I="I can do it" (positive self-statements).
- N=no negative thoughts (restructuring negative thinking)/living in the "now."
- B=be a good friend/balanced lifestyle (also for parents).
- O="Oh, how can 'we' solve it?" (letting the rages pass, interpersonal and situational problem solving).
- W=ways to ask for and get support.

The child's school receives a work folder documenting what has been accomplished in the individual sessions. In addition, a teleconference is held with school staff members to educate them in the use of the RAINBOW program. A preliminary investigation of 34 patients with pediatric bipolar disorder (mean age 11.3 years, standard deviation=3.1) found that the RAINBOW child- and family-focused intervention resulted in significant reductions in severity of symptoms of

aggression, mania, psychosis, depression, and sleep disturbance (Pavuluri et al., 2004).

Finally, an interpersonal psychotherapy-based preventive intervention for adolescent children of bipolar mothers is under way at New York State Psychiatric Institute (Verdeli, 2004). Seven adolescents whose mothers are receiving treatment for bipolar-I disorder and who themselves have subsyndromal bipolar symptomatology and/or mild functional impairment attend sessions of family psychoeducation about the mother's disorder and also receive individual interpersonal psychotherapy-based counseling (12 sessions). The intervention aims to (1) educate the adolescents and their parents/caretakers about bipolar disorder; (2) help the family make realistic plans in the event of the mother's relapse; (3) help the adolescents deal more adaptively with stressful interpersonal situations (including the mother's disorder); and (4) when necessary, help the adolescents regulate their circadian rhythms, social stimulation, and daily habits.

Ongoing Effectiveness Studies

The multisite STEP-BD effectiveness study being conducted by Sachs and colleagues should provide more definitive data on the relative value of the various psychotherapeutic approaches discussed here (see Table 22-5). This trial will be carried out over the next 5 to 8 years in 17 treatment centers and will include 5,000 bipolar patients. Data will be obtained on the effectiveness of CBT, IPSRT, and FFT in combination with pharmacotherapy treatment algorithms. Collaborative care, the control condition, is patient-directed in that the patients watch a psychoeducational videotape on bipolar disorder and receive a self-help workbook. The psychotherapeutic treatments are expected to improve remission of symptoms from acute depression, maintain treatment gains after recovery, and improve medication adherence. The large sample and the inclusion of psychotherapeutic approaches developed and/or adapted for bipolar disorder make this an important study. Early results suggest that intensive psychotherapy may be most helpful for those patients with the more severe forms of bipolar illness, whereas briefer treatment may be adequate for those who are less ill (Miklowitz et al., 2006).

The Life Goals Program encompasses a five-session psychoeducation phase followed by an individual behavioral treatment to improve functional status by working toward interpersonal/occupational goals identified by the patient (Callahan and Bauer, 1999). This program has been tested in an open trial in two Veterans Affairs (VA) sites with 29 bipolar patients, 70 percent of whom achieved their behavioral goal during the second phase of the study. Likewise, a 12-month effectiveness study based on the Life Goals Program, involving 441 patients at health

maintenance organization centers in Seattle, found that patients in the intervention group spent one-third less time in manic or hypomanic episodes (Simon et al., 2005). In an open study of 45 bipolar patients, Swiss researchers found that the great majority of those who completed the initial phases of the Life Goals Program were very satisfied with the information received and reported subjective improvements in mood stability, relapse prevention strategies, and methods of coping with relapse (de Andrés et al., 2006). The Life Goals Program is currently being compared against treatment as usual in 12 VA hospitals in a multisite randomized controlled trial.

In general, effectiveness studies are not initiated until there is evidence of a treatment's efficacy in homogeneous samples under the controlled conditions of an efficacy study. The push to conduct these large effectiveness studies reflects the relative paucity of data on the psychotherapeutic management of bipolar patients and the urgent need to close this gap.

Meta-analyses of Psychological Treatments

Scott and Gutierrez (2004), studied the overall efficacy of psychotherapeutic interventions for bipolar illness by conducting meta-analyses of randomized controlled trials of psychological therapies added to standard psychiatric treatment versus medication and standard psychiatric treatment alone. Most although not all of the psychological therapies used cognitive-behavioral techniques. Only studies that reported relapse rates during the treatment phase and a follow-up period of at least 6 months were included in the analysis. The analysis results, shown in Figure 22–5, clearly demonstrate that psychological interventions are effective in

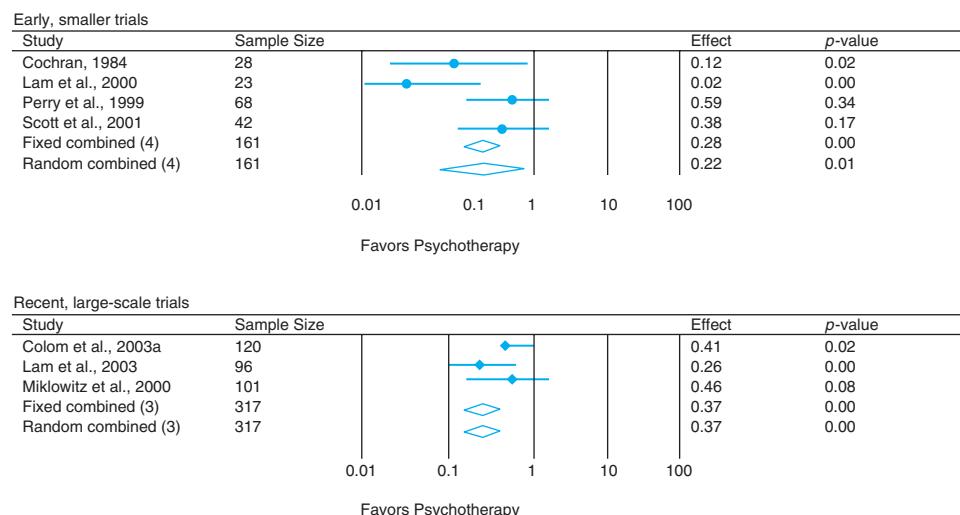

reducing the risk of bipolar relapse, although it is not clear which specific approaches are most efficacious. There is without doubt sufficient evidence to support the use of psychological treatments to improve the course and outcome of bipolar illness.

CONCLUSIONS

Both clinical experience and emerging evidence suggest that bipolar illness is treated most effectively with a combination of mood stabilizers or other medications and psychotherapy. Drug treatment, which is primary, frees most patients from the severe disruptions of manic and depressive episodes. Psychotherapy can then help patients come to terms with the repercussions of past episodes and comprehend the practical and existential implications of having bipolar illness. When medications are administered in an emotionally supportive atmosphere, patients are more likely to express their concerns, physicians are better able to assess the need for psychotherapeutic interventions, and medication adherence is enhanced. Moreover, educating patients and their families is essential because it aids them in recognizing symptoms of emerging episodes. It is also essential to informed consent for treatment, which is imperative for both clinical and legal reasons. Charting of moods appears to be useful to provide an objective record of patterns of mood and treatment response and to give patients a sense of control and collaboration in their treatment.

Although not all patients need psychotherapy, most may benefit from one of its many forms—individual, group, or family. Participation in a self-help group can supplement or, on occasion, supplant formal psychotherapy. Which option

Figure 22–5. Odds ratios of relapse in randomized controlled trials of psychological treatments for bipolar disorder. (Source: Scott and Gutierrez, 2004. Reproduced with permission from Blackwell Publishing, Ltd.)

is most appropriate can usually be determined by the psychiatrist or psychopharmacologist who supervises the patient's medications. No one psychotherapeutic approach, even among the newer techniques, has been shown to be uniformly superior for bipolar patients. The therapist must be guided by knowledge of the illness itself and its manifestation in the individual patient. In style and technique, the therapist must remain flexible to adjust to the patient's fluctuating moods, cognition, and behavior. The therapist must be especially alert to the emotions commonly engendered in clinicians who work with bipolar patients.

Psychotherapeutic issues are dictated by the character of the illness. Although reactions vary widely, patients typically feel angry, confused, and ambivalent about both the illness and its treatment. They may deny the existence of the illness, its severity, or its consequences; such denial may cause them to stop taking their medication. When treatment is not completely successful, patients are understandably disappointed and frustrated. Patients also may be disturbed at losing the energy and vitality that accompany mania. They fear recurrences. They have difficulty discriminating normal from abnormal moods. And they are concerned about relationships and the possibility of transmitting a genetic illness to their children.

During the 1970s and 1980s, research in psychotherapy for bipolar patients was characterized by small open trials, without the guidance of treatment manuals or attention to therapists' adherence to the treatment. Functional and symptomatic outcomes were not systematically assessed, and treatment randomization was rare. The empirical evidence for the efficacy or effectiveness of psychotherapy for bipolar disorder remains limited for adults and is virtually nonexistent for children and adolescents. In the 1990s, a number of randomized clinical trials of the efficacy of various psychotherapeutic approaches set the stage for multisite effectiveness trials now under way. Psychotherapy manuals, independent evaluators blinded to the treatment being given, and expanded outcome measures (including symptoms, social functioning, cost-effectiveness, and medication

adherence) are now the recognized tools for testing the new approaches. Of course, the demonstrable efficacy of manual-driven psychotherapeutic interventions does not rule out the efficacy of other, as yet untested types of psychotherapy.

Clinically, psychotherapy aimed at patient and family education and/or management of the consequences and environmental triggers of the illness makes sense, but there is still a gap between clinical wisdom and evidence. The results of ongoing trials should provide the strong base of empirical evidence that is needed to fill this gap.

NOTES

1. This passage, as well as others by "a patient with manic-depressive illness," was written by one of the authors, Kay R. Jamison. Some were modified slightly and incorporated into her memoir, *An Unquiet Mind* (Jamison, 1995).
2. For obvious reasons, psychotherapy has never been as integral or comfortable a part of the treatment of bipolar illness as it has been of unipolar illness. Clearly, the psychotic disorders and their empirically derived remedies long predate psychological treatments. Both history and necessity have embedded bipolar illness in medicine, much more so than other psychiatric disorders. Unipolar depressions, on the other hand, have had an easier alliance with psychotherapy, partly because they generally constitute a wider spectrum of psychopathology that shows a range of milder syndromes with prominent psychological factors. Because the concept of *depression* encompasses a relatively normal spectrum of emotions and feeling, it has traditionally stimulated counsel from priests, physicians, and friends.
3. For a more comprehensive discussion of the nature and methods of psychotherapy, see Jerome Frank's classic book, *Persuasion and Healing* (1961), and Phillip Slavney's *Psychotherapy* (2005).
4. Many of these reactions are discussed further in Chapter 10.
5. Ghaemi, 1995; Peralta and Cuesta, 1998; Dell'Osso et al., 2000, 2002; Pini et al., 2001.
6. G. Goodwin (2002) has described many of the difficulties that arise from attempts to establish clear boundaries between the manic states.

The prognosis of insanity in children must of course be very variable. . . . Judicious management, which is the most essential condition of amendment, is very difficult to obtain.

—D. H. Tuke (1892, p. 204)

Research on treatment in the field of child and adolescent psychiatry has been roughly a generation behind that in adult psychiatry. Several reasons explain this lag, such as the power and persistence of the analytic model in child psychiatry, concerns about pharmacological therapies interfering with a child's normal development, and ethical dilemmas in conducting pediatric clinical trials. Most important, diagnostic criteria for adults were not developed with children in mind, and children of different ages pose a variety of assessment challenges not encountered with adults. Because of these difficulties, there is a lack of consensus on what constitutes affective disorder, especially mania, in children (see Chapter 6).

Despite these barriers, however, research on treatment of manic-depressive illness in children and adolescents (virtually all of it focused on the bipolar subgroup) has been accelerating, spurred by a number of forces. These include incentives introduced by the U.S. Food and Drug Administration (FDA) in 1997 to stimulate industry-sponsored trials; research initiatives by the National Institute of Mental Health (NIMH); and, more recently, the activism of organizations such as the Depression and Bipolar Support Alliance (DBSA) and the Child and Adolescent Bipolar Foundation (CABF) in providing on-line support, de-stigmatization, and public education, especially their efforts to raise parents' awareness of the urgent need for more research.

We begin this chapter with a discussion of the unique diagnostic and other challenges posed by affective (especially bipolar) disorders in children and adolescents (sometimes referred to collectively here as youths or pediatric populations). We then turn to clinical management, presenting our recommendations for treatment, as well as for preven-

tion in at-risk youths. Next we review the literature supporting our recommendations for acute and maintenance pharmacological treatment, focusing on bipolar disorder (while there is essentially no literature on recurrent unipolar depression per se in this age group, we do discuss prepubertal depression and the frequency with which it evolves into bipolar disorder). In this section we also examine the literature on the offspring of adults with bipolar disorder, on psychiatric and medical adverse events, and on the use of electroconvulsive therapy (ECT) and psychotherapy in pediatric patients.

CHALLENGES POSED BY EARLY-ONSET BIPOLAR DISORDER

Diagnosis

"Classic" bipolar disorder is a recurrent condition in which mood and activity level are either significantly increased (hypomania and mania) or decreased (depression), with a return to premorbid levels of functioning between episodes. Our understanding of manic-depressive illness, especially the bipolar form, has emerged largely from the vast clinical experience of psychiatrists, such as Kraepelin, in recognizing the syndromal similarities among hundreds of patients over the course of time. By contrast, our understanding of the illness in youths, more specifically the bipolar subgroup, did not emerge from many years of intense study of the patients treated by child psychiatrists. Rather, it began with attempts to find in pediatric populations equivalents of what Kraepelin and others appeared to be describing (see Glovinsky, 2002; Carlson, et al., 2005). When early clinicians tried to do so, they

found that classic Kraepelinian manic-depressive illness did indeed exist in youths, but occurred mainly in adolescents. Anthony and Scott (1960) explored the question of classic “manic-depressive psychosis,” strictly defined, in preadolescents in a literature review and found it to be uncommon in this population, generally beginning to emerge with any frequency at about age 11 (see Chapter 6 for a comprehensive discussion).

When the bipolar form of manic-depressive illness was misdiagnosed in adolescents, it was because the psychosis in mania and depression was often very severe and was misattributed to schizophrenia (see, e.g., Carlson and Strober, 1978). In preadolescents, the diagnostic conundrum has been separating mania from a variety of behavioral disorders in children in which activation, short attention span, and irritability co-occur chronically. The essential question becomes whether the frequent and brief episodes of intense mood volatility and irritability that are being called “prepubertal mania” or “juvenile bipolar disorder” represent the same illness as that in adults (McClellan, 2005). The further one diverges from the description of bipolar disorder as it has been conceptualized for the past century, the more difficult it becomes to extrapolate those findings to children. At this point, it is unclear to what extent these children will evolve into adults with bipolar disorder as defined by the *Diagnostic and Statistical Manual* (DSM)-IV, let alone the classic form with clearly delineated episodes and good intermorbidity functioning (Biederman et al., 1998; Geller et al., 2004). Thus when people say bipolar disorder is much more common in children than heretofore believed, this statement is reflecting, at least in part, the broadening of the concept of the disorder.

Classic bipolar disorder is, at best, uncommon in children; however, the results of large retrospective studies of adult bipolar patients would appear to be at odds with this conclusion. In their recent review, Post and Kowatch (2006) cited retrospective data from two relatively large samples of adults with DSM-IV bipolar disorder—those of the Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) and the Bipolar Collaborative Network (BCN; formerly the Stanley Foundation Bipolar Network). In STEP-BD, 28 percent of adult bipolar patients reported their age at onset as younger than 13; in the BCN, 15 percent did so. Post and Kowatch also cited another finding from the BCN data: that the earlier the age at onset, the longer was the delay to first treatment (16.8 years for childhood onset, 11.3 years for adolescent onset, and 4.6 years for adult onset) and the worse the long-term outcome. In citing these data, however, the authors implicitly acknowledged the limitations of retrospective data: “The field is in agreement that prospective assessment and follow-up of large cohorts of children need to be conducted in order to better define initial diagnostic subgroups and their ultimate

trajectories into classic bipolar illness . . .” (p. 115). We certainly agree. We also agree that there are many children with markedly labile mood and episodic behavioral dyscontrol who appear to need and benefit from the mood stabilizers used in the treatment of adolescents and adults with bipolar disorder. But the relationship between these serious and very real syndromes in children and adolescent and adult bipolar disorder has not yet been clarified (see the discussion later in this chapter and in Chapter 6).

Furthermore, although DSM-III-R and -IV have been used to diagnose bipolar disorder in children as well as adolescents and adults, there is little uniformity in how these criteria are operationalized for children. Leibenluft and colleagues (2003) proposed an approach that requires strict adherence to criteria for mania in adults for a “narrow phenotype,” as opposed to an “intermediate phenotype” (based on the DSM-IV criterion for mania but with a duration of less than 4 days) and a “broad phenotype” (encompassing severe mood dysregulation that many believe characterizes what is being called “juvenile mania”). This approach, inherently inclusive, strikes us as quite sensible.

Geller and colleagues (2002a) have reoperationalized several of the DSM criteria (most notably euphoria and grandiosity) to make them what the authors believe to be developmentally appropriate for children. Not everyone agrees with this reformulation, however (Harrington and Myatt, 2003). In a recent cross-national study (United States and United Kingdom) of five cases of children with mood symptoms in whom bipolar disorder might have been a diagnostic consideration, disagreement on diagnosis occurred in three of the five cases. The reason for this appears to be differing interpretations of specific symptoms. DSM’s reliance on symptom counts (used in the United States) may result in a conceptualization that differs from the gestalt of bipolar disorder as described in the *International Classification of Diseases* (ICD)-10, used in the United Kingdom. Specifically, in a preadolescent patient with classic mania, agreement was close (96.4 percent of U.S. and 88.9 percent of U.K. physicians made a manic diagnosis). In the prepubertal child with both attention-deficit hyperactivity disorder (ADHD) and manic-like symptoms, however, 86.2 percent of U.S. child psychiatrists diagnosed mania, in contrast to only 31.1 percent of their U.K. colleagues (Dubbicka et al., 2005).

Other Challenges

Beyond diagnosis, other unique challenges posed by early-onset bipolar disorder ultimately have an impact on treatment. First, most clinical trials include only adolescents, or include mixed samples that are not large enough to permit separate analysis of children and adolescents. By our rough estimate, fewer than one-third of clinical trials discussed

later in our review of the literature involved solely children. That means most of our knowledge bears on adolescents rather than children. If childhood-onset bipolar disorder is a fundamentally distinct disorder, it is questionable at best to extrapolate treatments from adolescents to children. Further, even clinical trials of adolescents can be difficult to interpret because they often fail to distinguish the age at onset of the disorder, whether in childhood or adolescence. Some trials are of inpatients, some of outpatients. Inpatient trials more closely approximate adult “acute mania” studies. Outpatient trials usually address bipolar spectrum disorders or include subjects whose generally lower levels of severity allow them to be seen only monthly. These trials are reviewed later in the chapter.

Second, because Axis I-based structured interviews are used to assess bipolar disorder in most studies, developmental disorders, as well as conditions such as mild autism that used to be Axis II and that may occur in nearly two-thirds of bipolar children and adolescents (Towbin et al., 2005), are overlooked. Moreover, the presence of such children in a clinical sample may affect treatment response since adverse events are higher in these children (Carlson, 2005; Carlson and Mick, 2003).

Third, bipolar patients in whom the disorder started in childhood have more complicated developmental histories than those whose disorder started in adolescence or early adulthood (Carlson and Meyer, 2006). In an adult who has had many years to establish baseline functioning, recognizing the onset of something new and different is relatively easy. On the other hand, a child who enters kindergarten at age 5 and becomes disruptive may be manifesting the onset of bipolar disorder, suffering from an altogether different disorder, or simply having serious trouble adjusting to the academic and social demands of school.

Fourth, bipolar disorder in children almost never occurs without some other comorbidity (see Chapter 6). When manic symptoms are superimposed on or coexist with other kinds of psychopathology (e.g., ADHD, conduct disorder, anxiety disorder), episodes become more difficult to distinguish and to treat. Moreover, the meaning of comorbidity is unresolved. The hope in the field has been that the underlying comorbidity is actually a manifestation of bipolar disorder and with adequate treatment will resolve. Although this may turn out to be true once better treatments have been identified, the current armamentarium does not sufficiently treat underlying comorbidities. That is, a child with mania in addition to ADHD or conduct disorder usually continues to have the latter two conditions, although ratings of hyperactivity may improve with antimanic treatments. It appears that early onset and comorbidity interact and may change both the course of bipolar illness and its response to treatment. Two studies have found that the duration of the index

episode increases with younger age at onset (Carlson et al., 2002; Geller et al., 2004), and underlying comorbidity appears to predict poorer functional outcome (Carlson et al., 2002). There are also data suggesting that the presence of ADHD worsens response to lithium (Strober et al., 1988, 1998; Kafantaris et al., 1998).

Although the percentage of males and comorbid ADHD diagnoses both appear to decline with increasing age at onset of bipolar disorder, a history of ADHD can still be ascertained in 10 to 20 percent of patients with adult-onset bipolar illness (Carlson et al., 2000). Moreover, adult-onset bipolar patients with comorbid substance abuse may well have had externalizing disorders (conduct disorder and ADHD) as children and adolescents (Carlson et al., 1999). This externalizing disorder comorbidity likely complicates treatment response as well. Finally, anxiety disorders co-occur with bipolar disorder at high rates in youth and adults. Several selective serotonin reuptake inhibitors (SSRIs) (fluoxetine, fluvoxamine, clomipramine) have established efficacy for treating anxiety disorders, including obsessive-compulsive disorder, in children and adolescents (Reinblatt and Walkup, 2005). However, the same risks that complicate the use of SSRIs for treatment of bipolar depression (see the later discussion) obtain here as well.

Fifth, early onset of bipolar disorder is associated with increased genetic loading (see Chapters 6 and 13). The level of complexity of bipolar disorder may be heritable as well, and this, too, has an impact on treatment. For instance, there is suggestive evidence that parental response to medication may select a more homogeneous group of bipolar subjects (Duffy et al., 1998) and that offspring of lithium-responding bipolar parents have a milder condition¹ than offspring of bipolar adults with comorbid conditions (Biederman et al., 2000b).

Finally, severe emotional and behavioral lability in children and adolescents is significantly impairing but may be nonspecific. Several longitudinal studies have identified “bipolar symptoms” in children that did not evolve into bipolar disorder later on (e.g., Johnson et al., 1999; Lewinsohn et al., 2000; Hazell et al., 2003), although mood symptoms (depression and anxiety) did persist. While children with these “bipolar” symptoms certainly need treatment and may well respond to mood stabilizers, this fact alone does not clarify the relationship between these states and classic bipolar disorder.

CLINICAL MANAGEMENT

Overview

The American Academy of Child and Adolescent Psychiatry (AACAP) has developed practice parameters, the most

recent of which were published in 1997 and are being updated as of this writing. In the interim, given the immediate need to have something more current available for treatment of the manic, depressive, and maintenance phases of bipolar disorder in pediatric populations, a consensus conference was convened in July 2003, initiated and supported by the CABE. Experts in child and adolescent bipolar disorder summarized recommendations for the field based on interpretation of existing information (Kowatch et al., 2005). Our treatment recommendations, which follow, integrate our own views with those consensus recommendations.

Adequate assessment of bipolar disorder in a child or adolescent takes several hours and may require multiple visits (Youngstrom et al., 2004). The assessment should include interviews with parent(s) and child, as well as information gathered from other observers of the child (e.g., teachers). The information thus obtained should encompass not only symptoms of mania and depression, but also symptoms of other psychiatric disorders that may be confused with or co-occur with bipolar disorder. Standardized rating scales and interviews are often useful adjuncts. Evidence of psychiatric disorders in the youth's immediate family is essential not only because it can provide important genetic information, but also because such evidence can bring into focus issues that need to be addressed in psychotherapy. A developmental history, including ascertainment of social, academic, and family functioning, is necessary as well. Psychoeducational testing is often extremely helpful in formulating a treatment plan for school. Decisions regarding the impairment produced by mood symptoms can be addressed by the "FIND" approach (Kowatch et al., 2005), encompassing frequency (symptoms occur most days during the week), intensity (extreme disturbance caused in two or more settings), number (symptoms occur three or four times a day), and duration (symptoms occur a total of 4 or more hours a day, not necessarily contiguous). The information obtained should include whether the predominant mood is mania or depression and whether there are comorbidities in addition to the mood disorder. If there has been a positive response to medication treatment (or lack thereof), it is important to know the details, such as the dose and the length of the trial. It is equally important to determine what adverse effects may have occurred.

After assessment, psychoeducation of the patient and family members is important, and it should accomplish the following:

- The education of all concerned about the nature of the disorder(s) being treated (not only what is known about child, adolescent, and adult bipolar disorder, but also the comorbidities that may exist).

- Clarification of the advantages, limitations, and risks of medications, as well as the consequences of not using them:
 - Discuss the importance of following the exact prescription and of keeping medications secure.
 - Anticipate that a number of different medications may be used, so as to spare the patient multiple blood draws, and cover all bases by establishing a baseline: complete blood count (CBC), platelets, fasting blood sugar, liver and renal functioning, cholesterol, lipids, and thyroid functioning (specifically thyroid-stimulating hormone [TSH] and free thyroxine [T_4] by direct measure).
 - Obtain baseline ratings for the major symptoms being addressed (e.g., aggression/irritability, psychosis, hyperactivity, inattention, anxiety, depression, shifts in mood/behavior) to make it possible to track and quantify any response or worsening.
 - Establish the priority of drugs for trial, and inform other members of the treatment team, patient, and family. The fact that a parent says "we've tried that" may not mean that an adequate trial has taken place.
 - Tell parents to allow each dose adequate time to work.
- Address any aspects of the disorder and its treatment that have an impact on the family and functioning in school. This can involve cognitive-behavioral therapy for the child, training of the parent(s), neuropsychological testing, and academic intervention; it can also include treating any family members with psychiatric disorders that have an impact on parent-child functioning.

It is important to remember that any comorbidities warrant their own psychoeducational focus. If ADHD coexists with bipolar disorder, for example, the clinician must explore with patient and parent(s) all of the comorbidities that can occur with ADHD, including learning, language, and motor coordination problems. These latter comorbidities are likely to require an individual educational plan that accommodates them, such as smaller classrooms with higher teacher/pupil ratios. Depending on the severity of the mania, depression, or comorbidity, the child may also need a day program, periods of hospitalization, or even long-term residential treatment.

Children/adolescents and their parents need to understand the complexities of the conditions involved; the importance of adherence to treatment; and the need to stabilize the environment, aspects of which may be exacerbating the disorder. Information sources for parents are noted in the appendix at the end of this volume.

The reality that early-onset bipolar disorder is genetic means other family members with whom the child lives may need treatment for their own mood disorders. This observation is especially important for the patient's caregiver. Care

of a bipolar child is, to say the least, challenging. A depressed or manic parent afflicted with the dysfunctions that can accompany the condition poses additional management problems.

A candid discussion of medication risks is also necessary. If side effects of a particular medication are minimal and treatment efficacy is clear, it obviously makes sense to continue treatment. If adverse events appear to be worse than the condition being treated, the medication should be slowly discontinued or a lower dose administered. The decision to try another, similar medication or the same medication at a lower dose must be made on a case-by-case basis. The reason it is necessary to establish a clear baseline of symptoms and functional impairment is to be able to make such decisions with greater confidence. With respect to treatment for ADHD and/or antidepressant use, it remains prudent (1) to warn parents about hypomania/mania and nonspecific activation/agitation (including suicidal or other self-harm behaviors) as potential side effects of antidepressants, and activation/agitation as a side effect of stimulants; (2) to obtain as part of the family history information on any medication responses and intolerances; and (3) to provide careful follow-up (see the discussion later in this chapter).

It is unclear whether the absence of a classic presentation of bipolar disorder in prepubertal children hinders response to medication, or whether there are developmental differences that influence the medication response of young children, or both. Until this question can be answered, we believe the confidence one has in extrapolating treatment data from adults to children should be directly proportional to how closely the child's history and presentation correspond to a pattern of clear episodes of mania, depression, and euthymia. The following is an overview of treatment choices for the various phases of bipolar disorder:

- *Mania/hypomania/mixed episodes*—Given that the evidence base is rapidly changing, an evidence-based approach (see Chapter 17) requires the clinician to monitor closely the results of published studies. As of this writing, lithium,² divalproex, and atypical antipsychotics are supported as monotherapies and, when monotherapy is inadequate, in combination.
- *Mania and ADHD*—Mania is treated first, followed by treatment for ADHD if symptoms have not remitted. There is no consensus on cases in which the differential diagnosis is unclear. We advise discussing with parents the risks and benefits of using atypical antipsychotics or mood stabilizers first versus starting with treatment for ADHD (see the later discussion). There are many more years of experience with stimulant medication than with atypical antipsychotics or mood stabilizers. If the patient

becomes more irritable or aggressive with ADHD treatment, however, it makes most sense to switch to an atypical or a mood stabilizer, than retrying the ADHD treatment.

- *Bipolar depression*—One open trial of lithium monotherapy for hospitalized adolescents with bipolar depression found a reduction in depressive symptoms, although most of this amelioration occurred during the hospitalization. There has also been a positive open trial using lamotrigine alone or with other medication in adolescents. No placebo-controlled or otherwise randomized data exist, however. Thus for adolescents with clear bipolar depression, it may make sense to apply the findings from the literature on adult bipolar depression, which increasingly advocates the use of lamotrigine or quetiapine. The long-term use of quetiapine may be problematic, however, given the dramatic increase in obesity among adolescents, especially in the United States. This caution applies as well, of course, to some of the other atypicals, especially olanzapine and the olanzapine-fluoxetine combination.
- *First episode of depression with a bipolar family history*—This is another thorny issue on which there is no clear consensus, and for which it is necessary to have a discussion with family members of the risks and benefits of alternatives (Carlson, 2005a). In a young person at risk for a bipolar course, the clinician must weigh the risk that an antidepressant may precipitate mania or hypomania, versus the risk that a mood stabilizer alone may not alleviate the depression, versus the risk of using two drugs, one of which may not be needed. Adult data cited in Chapter 19 suggest that the beginning of an antidepressant response to lamotrigine is often evident by 3 weeks, which may help in the decision-making process. Regarding the use of traditional antidepressants to treat early-onset depression, there is as yet no consensus in child psychiatry on the importance of trying a mood stabilizer first or even on the need to combine the antidepressant with a mood stabilizer. We have seen young people destabilized by antidepressants, as well as others kept on mood stabilizers alone in the face of persistent depression. Regarding some mood stabilizers, moreover, it should be noted that children and adolescents may balk at taking medication at all if blood must be drawn or if there is a possibility of weight gain. Thus the clarity of a history suggestive of a bipolar diathesis (including a clear history of bipolar disorder in first-degree relatives), the reliability of parent observation and the patient's adherence to treatment, and family preference should all be carefully weighed in the decision-making process.
- *Maintenance*—Results of the few extant maintenance studies suggest that even with good medical follow-up,

young people with bipolar disorder have higher relapse rates than adults. It is unclear whether this is because children have higher rates of rapid cycling (and therefore are comparable to rapid-cycling adults) and/or because the higher rates of illicit drug use common in young people increase relapse; erratic sleep patterns or other factors may contribute as well. Both the available data and clinical experience suggest, however, that if remission is achieved on a particular regimen, that regimen should be continued as long as possible, and at least until the patient has navigated his or her most important developmental, academic, and social milestones.

In the following sections, we present in greater detail our recommendations for acute treatment of mania/hypomania, mania/ADHD, and bipolar depression in children and adolescents; maintenance and psychosocial treatments in these populations; and prevention in at-risk youths.

Mania/Hypomania

How one initiates treatment for bipolar disorder in children and adolescents depends on whether the patient is acutely manic or hypomanic. Evidence is best for adolescents with mania, for whom randomized, double-blind, controlled trials of atypical antipsychotics have shown clear efficacy, as have large open trials of lithium. In smaller samples of children and adolescents with mania, hypomania, and bipolar disorder-not otherwise specified (NOS) and/or those at risk for bipolar disorder, there are placebo-controlled data on lithium, which is the only antimanic medication approved by the FDA for adolescents. Lithium's approval was "grandfathered" from the FDA's requirement for efficacy and safety data specifically on children and adolescents. Data from open studies exist for anticonvulsants and atypicals.

The guidelines of Kowatch and colleagues (2005) (described earlier) include two treatment algorithms for use when the mania presents with versus without psychosis. Here again, what follows is an integration of our own recommendations with these guidelines. When a child or adolescent presents with manic or mixed symptoms without psychosis, monotherapy is generally preferred initially, for reasons of safety. Treatment can be initiated with lithium, a sedating anticonvulsant (the most data exist for valproate),³ or an atypical antipsychotic (such as olanzapine, quetiapine, or risperidone, for which the most data are available), while keeping in mind the adolescent's vulnerability to weight gain. If the clinical response is only partial, a drug of a different class should be used adjunctively (adding an atypical to a mood stabilizer or vice versa), with appropriate dose adjustments to minimize additive side effects. If there is no response to the initial monotherapy, we recommend switching to a drug of a different class (from lithium to an anticonvul-

sant, or from lithium or an anticonvulsant to an atypical). If the second agent fails to produce a satisfactory response, the evidence supports combined therapy (see the literature review below).

If the manic or mixed syndrome presents with psychotic features and/or prominent symptoms of severe agitation and aggression, we recommend that treatment be initiated with a combination of a mood stabilizer and an atypical antipsychotic. Based on data for adults, when a partial response is encountered under these circumstances, we recommend that a second mood stabilizer be added (for a total of three medications—an anticonvulsant, plus lithium, plus an atypical).

In the case of nonresponse (or intolerance) to the initial mood stabilizer/atypical combination, we recommend switching to an alternative mood stabilizer (lithium for anticonvulsant nonresponse/intolerance and vice versa). If there is still no response at this point, we recommend use of an alternative atypical agent or mood stabilizer.

For children and adolescents who have not responded to combination treatment involving three medications, we recommend clozapine. Haloperidol has also been used as an adjunctive treatment in several trials (Kafantaris et al., 2001). ECT is recommended for adolescents only, but for treatment refractory children with severe delusional depression, it may be justified (see the literature review below). Finally, although hospitalization is not a psychiatric medication, clinical experience suggests that some children and adolescents need the structure, decreased stimulation, or removal from stress that this intervention provides.

Differentiating Mania from ADHD

As noted earlier, it can be difficult to distinguish manic symptoms from those of severe ADHD in young people, particularly in the absence of clear *episodes* of mania. This is especially so in children, in whom mania tends to be chronic rather than episodic and is often comorbid with oppositional defiant disorder, a condition whose associated irritability and affective aggression are often indistinguishable from similar symptoms encountered in mania. Frequently, the classic manic symptoms of euphoria and grandiosity are not present. When they are, euphoria can be difficult to distinguish from the "class clown" antics of a child with ADHD, and grandiosity requires sufficient cognitive and linguistic maturity to understand the concept. Other symptoms of mania and ADHD overlap as well, such as talkativeness, hyperactivity-psychomotor agitation, and distractibility (Harrington and Myatt, 2003; Carlson et al., 2005). Although the specific criteria for ADHD appear to be different from those for mania (see Chapter 3), the overlap is heightened when ADHD-associated symptoms such as temper outbursts and mood lability are present (DSM-IV Text Revision [TR] p. 88).

The overlap between ADHD and mania raises three therapeutic questions. First, when both conditions occur, which should be treated first? Second, if it is unclear whether one is dealing with mania or severe ADHD and oppositional defiant disorder, which should be treated first? Third, if a child has an adverse response to a stimulant or atomoxetine, is that reaction suggestive of bipolar disorder? Some issues are clearer than others. When one is treating both mania and ADHD, results of clinical trials support treating the mania first, then proceeding with treatment for ADHD. Two small, systematic trials (Carlson et al., 1992; Scheffer et al., 2005) have examined combined treatment with a mood stabilizer and a stimulant. Neither found worsening of manic symptoms or significant side effects.

Atypical antipsychotics also appear to decrease rates of hyperactivity/impulsivity as measured by ADHD rating scales, although it is unclear whether this represents a non-specific sedating effect. Teacher ratings and other measures of academic impact, which are traditionally part of efficacy studies in ADHD, have not been obtained. The implication of studies involving atypicals is that they can improve ADHD behavior through their ability to enhance cognitive organization, but this effect has not been studied formally. Clinically, it appears that additional specific ADHD treatment is often necessary.

When it is not clear whether the clinical picture reflects mania or ADHD with oppositional defiant disorder (or when a positive family history of mania indicates a risk for the development of bipolar disorder), we believe the clinician should talk with family members to advise them of the various alternatives and their risks. While there is concern that ADHD treatments may hasten the onset of bipolar disorder in children with ADHD and some manic symptoms (DelBello et al., 2001; Soutullo et al., 2002), more definitive data are needed on this critical question.

There are two important treatment issues—efficacy and adverse events. With regard to efficacy, in outpatient children who clearly have ADHD and also display some mood lability (which some call manic symptoms), limited data suggest that both the ADHD and “manic” symptoms not uncommonly show a robust response to stimulants immediately, as well as over the next 14 months (Galanter et al., 2003). Moreover, the majority of inpatient children with ADHD and manic symptoms studied systematically by Carlson and Kelly (1998) improved with and could tolerate stimulants, though stimulants alone clearly were inadequate to treat severely disruptive children with multiple comorbidities.

In contrast to its effectiveness in treating mania, the available data indicate that lithium is ineffective for the treatment of ADHD and mood lability (Greenhill et al., 1973; DeLong and Aldershof, 1987; Carlson et al., 1992a).

Moreover, even if lithium provides some benefit in treating aggression (see Steiner et al., 2003 and Table 23–1), it must be administered for at least 1 month to achieve this effect. Data on the use of anticonvulsants to treat ADHD are lacking, although there is some evidence of their efficacy in the treatment of affective aggression (see Table 23–1). Of interest, risperidone appears to be effective in treating both irritability and ADHD symptoms in cognitively impaired, irritable, aggressive children (Aman et al., 2002); added to stimulant medication, it produces significantly better control than stimulants alone in these patients.

With regard to adverse events, some children do not tolerate stimulants (or atomoxetine). Given its clinical importance, the paucity of data on this issue is surprising. Children who develop rebound on stimulant medication (i.e., a worsening of behavior as the medication wears off) (Carlson and Kelly, 2003) do not appear to have higher rates of bipolar disorder than of other disorders, although more data are needed. In a follow-back study of children with minimal brain dysfunction/hyperkinesis who were reinterviewed in young adulthood, there was no evidence that treatment response differed in those with childhood manic symptoms or that treatment triggered the onset of bipolar disorder in childhood or young adulthood (Carlson et al., 2000). Follow-up studies of children with ADHD who were treated with stimulants (Mannuzza et al., 1998) have not shown increased rates of bipolar disorder compared with controls—which would be expected if 16 to 20 percent of children with ADHD were misdiagnosed as having mania, as has been reported in some clinics (Wozniak et al., 1995; Biederman et al., 1996, 1998). In addition, there is suggestive evidence that young children, especially those with ADHD (L.L. Greenhill, personal communication, 2006), as well as those with pervasive developmental disorder, may be more sensitive to behavioral toxicity in general, including mood and behavioral instability (Carlson and Mick, 2003; Carlson et al., 2005). In other words, young people with bipolar disorder may well worsen on stimulants, but not everyone whose behavior worsens on stimulants has bipolar disorder. Although it is prudent to discontinue a medication that worsens a child’s behavior, data are as yet inadequate to support the conclusion that acute behavioral toxicity predicts the development of a subsequent bipolar course.

In summary, then, for a child whose dominant symptoms clearly reflect ADHD (as distinct from a mood disorder), we recommend treatment with a stimulant first. If the child’s behavior clearly becomes worse, either on the medication or after it wears off, addition of a mood stabilizer or an atypical antipsychotic is advised. It should be noted that adjunctive atypicals cannot be recommended for long-term maintenance treatment in the same way that

TABLE 23–1. Controlled Studies of Aggression Lasting at Least 4 Weeks

Study	Sample Size	Age (yr)	Diagnosis	Medication	Duration	Measures	Outcome ^a
Lithium							
Campbell et al., 1984	61	9	CD/aggression (inpatient)	Lithium compared with haloperidol	6 wk	CPRS	Lithium and haloperidol both better than placebo
Campbell et al., 1995	50	9	CD/aggression (inpatient)	Lithium	1 mo	CPRS	Lithium better than placebo
Malone et al., 2000	40	12.5	CD	Lithium	6 wk	CGI, OAS	Lithium better than placebo
Divalproex							
Donovan et al., 2000	20	10–18	CD, ODD	Divalproex	12 wk	OAS, SCL 90	Divalproex better than placebo
Steiner et al., 2003	58 males	16	CD	Divalproex low vs. high dose	8 wk	CGI severity, CGI improvement	53% responders with high dose vs. 8% with low dose
Risperidone							
Findling et al., 2000	20	6–14	CD	Risperidone	10 wk	Rating of Aggression against People and Property Scale	Risperidone better than placebo
Buitelaar et al., 2001	38	Adolescent (IQs 36–84)	Disruptive behavior disorders	Risperidone	6 wk	CGI Severity Overt Aggression Scale-Modified Aberrant Behavior Checklist	Risperidone better than placebo overall and on hyperactivity scales

one would recommend mood stabilizers for youths with clear bipolar disorder.

Bipolar Depression

In young people, as in adults, there have been far more attempts to study treatment response in mania than in bipolar depression. The few studies in which lithium or adjunctive lithium was administered to depressed prepubertal children or adolescents with or without predictors of future bipolarity have demonstrated little or no efficacy. While further studies under controlled conditions are needed, recommendations for adults with bipolar depression appear to be relevant to pediatric populations, at least to adolescents. On the other hand, antidepressant responses in children do not necessarily mirror those in adults (placebo responses are more frequent, and drug responses may differ), so direct extrapolation becomes more tenuous.⁴

Emerging data on adults with bipolar depression suggest that mood stabilizers, such as lamotrigine, can stabilize primarily against depression (that is, “from below”; see Chapter 20), apparently without destabilizing the illness. In adults, bupropion is often cited as having advantages for the treatment of bipolar depression since it appears to have a lower switch rate (perhaps because it has little or no disruptive effect on sleep when given early in the day) and a favorable clinical profile for most bipolar patients (especially those with psychomotor retardation). Bupropion also has the most benign side-effect profile of any antidepressant. For this reason, it may be especially suitable for young patients, who tend to be more sensitive than adults to side effects. Thus in the absence of data, but based on clinical experience (including that with adults), the consensus panel (Kowatch et al., 2005) recommended using bupropion or an SSRI adjunctively with a mood stabilizer when treating bipolar depression in youths.

More problematic is treatment of depression when future bipolarity is uncertain. In adolescents, bipolar illness commonly starts with depression rather than mania, a fact that is troubling clinically because of the risk of precipitating a manic episode in a vulnerable patient by using antidepressants. This concern escalates in the case of a seriously depressed young person with a history of bipolar disorder in first-degree relatives. As with ADHD and mania, scant controlled data exist on which to base advice on the treatment of early-onset depression when the possibility of converting to a bipolar course is uncertain. Results of follow-up studies of clinical samples of children and adolescents with depression indicate that on average, 20 percent subsequently develop bipolar disorder, with a range of 6 percent (Weissman et al., 1999a) to 48.6 percent (Geller et al., 2001)⁵ (see Chapter 6). Thus the clinician using an antidepressant

without a mood stabilizer to treat young people with serious depression (or even dysthymia) must be mindful of the risk that they will develop bipolar disorder or at least mood/behavioral instability (sometimes referred to as “roughening”). Although the odds ratio for subsequent bipolar disorder in offspring of bipolar parents is higher than that for unipolar depression, this differential is influenced by the fact that rates of mania in the general population are much lower than those of depressive disorder.⁶ In fact, more offspring of bipolar parents develop depression than bipolar disorder (LaPalme et al., 1997; Meyer et al., 2004), although clearly the lengthy age range of risk for developing mania makes this statistic an unstable one.

The clinician, then, must weigh the modest but important risk of patients’ becoming bipolar against the greater likelihood of their having a nonbipolar depression (although the possibility of antidepressants inducing unipolar cycling, as has been suggested for adults with recurrent unipolar depression, should be kept in mind). For children and adolescents at risk for the development of bipolar disorder or destabilization, there are two questions embedded in the treatment dilemma. The first is whether to use an antidepressant even with a concomitant mood stabilizer. The second is how to understand psychiatric adverse events that may occur as a result of antidepressant exposure including manic symptoms (drug-induced mania), activation/disinhibition (which may be different from mania), long-term cycle induction, and suicidal behavior. Unfortunately, assessment of these events has not been well operationalized in medication studies in children and adolescents (Carlson, 2005).

To summarize some treatment implications for early-onset depression, a trial of lamotrigine may make sense when there is a strong suggestion of a bipolar diathesis. Other choices are combinations of an antidepressant with an antimanic mood stabilizer or with an atypical antipsychotic, although it has not been established that such agents protect against antidepressant-related mania and/or destabilization in pediatric populations (Baumer et al., 2006). If the parents and/or the child are especially concerned about the use of a mood stabilizer or antipsychotic, antidepressant medication alone may sometimes be used, provided that the child does not have both a bipolar first-degree relative and evidence of subthreshold bipolarity, and provided that there is adequate discussion of the risks and benefits involved, and that the child is monitored carefully.

Maintenance Treatment

Maintenance trials are generally undertaken after definitive acute studies have been conducted. Since data from acute trials of treatment of bipolar children and adolescents are just beginning to emerge, it is not surprising that information on

maintenance treatment in these populations is sparse. The one study designed to test lithium or valproate as maintenance monotherapy in children and adolescents who had been stabilized on the combination failed to establish the superiority of either drug. As discussed later, the relapse rate to mania was high with both medications (Findling et al., 2005).

Despite the lack of data on the efficacy of maintenance treatment, the consensus panel observed that, given the high lifetime recurrence rates for untreated bipolar disorder, medication should be recommended for the long term for patients with well-documented bipolar disorder (Kowatch et al., 2005). We would add that the foundation of maintenance treatment should be a mood stabilizer. Moreover, patients and families should be educated about both the high rate of relapse in young people and the especially noxious contribution of illicit drugs. When the prospect of lifetime medication appears overwhelming, we encourage patients to continue drug therapy until they have completed high school, college, or trade school or are beyond an anticipated major life stressor (e.g., starting a new job, getting married). If the patient and/or family insists on discontinuing medication, this should be undertaken very gradually and at a time when it will have the least impact on life, and ongoing monitoring and social support will be available to provide for prompt referral should an episode occur. The recommendation that any discontinuation be undertaken very gradually is based on evidence of an increased likelihood of mania (Suppes et al., 1991) and of severe suicide attempts among adults following after rapid versus gradual discontinuation of lithium (Baldessarini et al., 1999). In cases where the diagnosis is less clear, the decision on medication continuation should be based on how successful the treatment is in mitigating symptoms. Continuation of medications providing marginal benefit in the face of high rates of adverse events is not recommended.

Based on results of clinical trials in adults, the consensus panel supported the efficacy of lithium, lamotrigine, and olanzapine as maintenance treatments for youths (Kowatch et al., 2005). The advantage of lamotrigine is its benign side-effect profile, noted earlier. Agents with high side-effect profiles, particularly weight gain (e.g., olanzapine, valproate, and lithium) and neurocognitive impairment (e.g., lithium and valproate), are more likely to lead to poor adherence (and, in the case of weight gain, to medical complications).

When the diagnosis of bipolar disorder is more tenuous, the presence of baseline ratings of irritability/mood instability, depression, and executive dysfunction (all of which can occur in children with ADHD), along with periodic reassessment of those ratings, will help determine how effective mood stabilizer treatment is and therefore how vigorously

to maintain it. Obviously, the less robust the treatment response, the more reason there is to discontinue medications associated with significant adverse events. Recommendations for the use of antipsychotics to treat aggression in children and adolescents have been discussed by Schur and colleagues (2003) and Pappadapulos and colleagues (2003).

It is premature to draw conclusions about the clinical or pharmacological significance of apparent drug-related "activation" in young people because the data on this issue are so limited. How specifically to address the issue depends on what the symptoms are, how severe they are, and how effective the medication is. Choices obviously range from stopping the drug, to lowering the dose and/or changing the dosing schedule, to adding another medication that mitigates the unwanted symptoms. Before any medication is initiated, families should always be warned about the potential for psychiatric adverse events, with particular caution being exercised for young children; those with developmental disabilities; and those with preexisting problems involving severe emotional dysregulation, such as ADHD and bipolar disorder.

Psychosocial Treatments

Psychosocial treatments have an important complementary role to play in the treatment of bipolar disorder in young people. The reasons for this include (1) the impact of the disorder on overall functioning in school and within the family, (2) the high rates of comorbidity and treatment nonadherence in these patients (one study, for example, found nonadherence rates of 31 percent, even over a short, 6-week trial [Kowatch et al., 2000]), and (3) higher-than-normal rates of family psychopathology (see Chapter 22). Research supports the importance of both psychoeducation and approaches aimed at reducing "expressed emotion" within the family (i.e., destructive criticism that sometimes characterizes families with mental illness).

There are a number of common themes in three promising family therapy treatments developed for children (Fristad et al., 2003; Pavuluri et al., 2004a) and adolescents (Miklowitz et al., 2004). The underpinnings consist of psychoeducation and problem solving within a cognitive-behavioral framework. The premise of the former is that if parents are given information about the biology of bipolar disorder, they will be less likely to blame each other and/or their children, allowing a greater focus on positive solutions. Additionally, by educating families about aspects of the disorder that are worsened by environmental stresses (disordered routine, decreased sleep, harsh criticism, parental fighting and inconsistency) and by helping families develop constructive ways of solving problems, many aspects of the illness can be brought under more effective control.

Prevention in At-Risk Youth

Do early intervention and treatment ameliorate the course of bipolar disorder? The potential for preventive intervention has been raised by the emerging hypothesis that bipolar disorder is a progressive neurobiological process (see Chapter 14). However, clinical research has not yet reached the point of testing pharmacological and/or psychological therapies for their preventive potential. One first step would be to develop a reliable means of identifying children and adolescents in the prodromal phases of bipolar disorder. In the meantime, two trials involving children of adults with bipolar-I and -II disorder have been completed. One small, open trial conducted by Chang and colleagues (2003) showed promise for the use of valproate in children who were experiencing mood and behavior difficulties, but not yet bipolar disorder. In the other trial, Findling and colleagues (2001) failed to demonstrate the efficacy of valproate, although improvement was suggested in children whose parents both had bipolar disorder. While this is a vitally important issue, it is not possible as yet to recommend evidence-based, specific clinical management strategies beyond those that would be recommended for children with known psychopathology in a population not “at risk.”

REVIEW OF THE LITERATURE

In this section we review the literature behind the clinical management strategies recommended above. Our focus, by virtue of the nature of the available evidence, is on clinical trials of pharmacological treatments for acute mania—lithium, anticonvulsants, and atypical antipsychotics—as well as drug combinations; we also touch briefly on the efficacy of these treatments for aggression in pediatric populations. We then discuss in turn the findings of the literature on treatment of bipolar depression, maintenance treatment, offspring of adults with bipolar disorder, psychiatric adverse events, medical adverse events, ECT, and psychotherapies.

Treatment of Acute Mania

As discussed previously, the overall evidence base for treating pediatric bipolar disorder in general and acute mania in particular is sparse when compared with the extensive database from studies of adults, as reviewed in Chapter 18. There have been a few placebo-controlled studies of lithium involving a small number of children or adolescents, most of whom had conditions other than acute mania (see the later discussion). Five industry-sponsored clinical trials of medications for children and/or adolescents with acute mania have been completed: topiramate versus placebo

(DelBello et al., 2006); quetiapine versus divalproex (DelBello et al., 2006), oxcarbazepine versus placebo (Wagner et al., 2006), olanzapine versus placebo (Tohen et al., 2006), and divalproex-extended release (ER) versus placebo (data on file, Abbott Laboratories, December 2006). The largest lithium studies have been open trials, some involving hospitalized adolescents with acute mania (Kafantaris et al., 2004) and some involving outpatient children and adolescents with mania/hypomania or bipolar-NOS or children considered at risk for developing bipolar disorder. Placebo-controlled trials of other atypical antipsychotics (risperidone, aripiprazole, ziprasidone) and anticonvulsants (valproate) approved for adults are ongoing as of this writing. There have also been open and discontinuation studies. As noted earlier, there has been one controlled trial of maintenance therapy (Findling et al., 2005).

Table 23–2 summarizes the currently available information for children and adolescents on drugs used to treat mania in adults, organized by the level of evidence. As noted in the table, safety data are available for several other medications (anticonvulsants) because they are approved for the treatment of convulsive disorders in youths. Placebo-controlled trials in mania have not yet established efficacy for any of the anticonvulsants or the atypical antipsychotics; hence they have not been approved by the FDA for this purpose. The FDA has requested that drug sponsors conduct more clinical trials in youths, and NIMH is also supporting treatment trials. Although the following summary reflects considerable advances since the first edition of this text was published, the evidence base, including placebo-controlled trials, is expected to grow considerably over the next decade. In addition to the traditional randomized, placebo-controlled designs, there is a need for more practical, “clinician-friendly” trials (see Chapter 17), such as crossover and randomized open comparative studies that can assess differences in tolerability (and perhaps even efficacy) (Post and Kowatch, 2006). As Post and colleagues pointed out (2002), such designs are more likely to be accepted by parents, especially when very young children are involved.

Lithium

Early Lithium Trials. The earliest studies of lithium in young people were case reports involving episodic illness. Annell (1969) noted: “We began using lithium at the Department of Child and Youth Psychiatry in Uppsala in 1965 . . . for older adolescents and for typical manic conditions; but as time went on, we began giving it to younger patients and for conditions other than typical mania. All . . . had severe mental complaints and all showed sudden changes in their conditions during the course of the year.” The 12 youths on whom Annell reported were aged 9 to 18,

TABLE 23–2. Summary of Evidence for Drugs Used to Treat Mania in Children and Adolescents

Drug	Status as Treatment for Bipolar Disorder
Lithium	U.S. Food and Drug Administration (FDA) approved for treatment of mania in adults and in youths aged 12 and above. Placebo-controlled trials in samples that included some children and adolescents with acute mania, but acute mania was not specifically studied; results mixed. Otherwise, open and discontinuation trials with mostly positive results.
Divalproex	FDA approved for treatment of mania in adults. Safety data in youths because of approval for treatment of seizures. For mania in children and adolescents, positive open trials, discontinuation trials, add-on trial, and randomized comparator trials. The one placebo-controlled trial (divalproex-extended release [ER]) was negative.
Carbamazepine	Off label in adults and children. Safety data in youths because of approval as anticonvulsant in children and adolescents. For mania, open randomized trial and case reports in children and adolescents with positive results.
Topiramate	Off label in adults and children. Some safety data because of approval for partial-onset seizures in children aged 2–16 years. For mania, one placebo-controlled trial in children and adolescents aged 6–17 years; inconclusive results because underpowered.
Oxcarbazepine	Off label in adults and children. Some safety data in youths because of approval as adjunctive treatment for partial complex seizures in youths aged 4–16 years. For mania, case reports.
Risperidone	FDA approved for mania in adults. Chart review series, positive open trials, positive add-on trial, placebo-controlled trials in children with irritable aggression associated with conduct disorder and autism, ongoing industry-sponsored randomized controlled trial for youths aged 10–17 years.
Olanzapine	FDA approved for mania in adults. In children and adolescents, 10 positive open trials and case reports. Randomized controlled trial found olanzapine significantly better than placebo.
Quetiapine	FDA approved in adults for treatment of mania. In adolescents, positive add-on study and randomized comparison with divalproex; ongoing randomized controlled trial for youths aged 10–17 years.
Ziprasidone	FDA approved in adults for treatment of mania. In children and adolescents, chart reviews and small case series. Randomized controlled trial under way in youths aged 10–17 years.
Aripiprazole	FDA approved in adults for treatment of mania. In children and adolescents, chart reviews. Randomized controlled trial under way for youths aged 10–17 years.
Clozapine	FDA approved only for treatment-resistant schizophrenia in adults. Off label for mania in adults. In children and adolescents, case series.
Lamotrigine	FDA approved for maintenance treatment of adults with bipolar-I disorder to delay time to occurrence of mood episodes (depression, mania, hypomania, mixed states). Safety data in youths because approved for patients aged 2 and older with simple or complex partial seizures. For bipolar disorder, chart review and one positive open study for bipolar depression in adolescents.
Symbax (combined olanzapine and fluoxetine)	FDA approved for treatment of bipolar depression in adults. No studies of bipolar depression in children and adolescents, although fluoxetine is FDA approved for treatment of major depression in children and adolescents.

although onset had occurred at ages as young as 7.5 years; 25 percent of the sample ($n=3$) were younger than age 12. Of the 11 youths for whom follow-up data were available, 7 responded very positively; the responders consisted of both children and adolescents. Only 2 responders showed typical mania (dominated by euphoria and grandiosity), but all had experienced the clearly demarcated onset of a condition distinctly different from their premorbid state.

Most had family members with manic-depressive illness. Not long thereafter, a much wider net was cast to find subjects with psychopathological conditions and a positive family history who might be responsive to lithium.

In an early summary of the possible effectiveness of lithium in young people, most cases were not even considered bipolar disorder in today's terminology. Reviewing the extant case reports and studies, Youngerman and Canino

(1978) found 211 cases; of these, there was sufficient information for only 46 to allow tentative conclusions about the reasons lithium was used. Twenty-two patients were children: 2 had "manic-depressive illness," 2 had an "atypical mood disorder," 8 were hyperkinetic, and 10 had autism/childhood schizophrenia. Twenty-four of the 46 were adolescents: 9 had "manic-depressive illness," 13 had "atypical mood disorder," and 2 had hyperkinesis. Thus, there were very few studies of children or even adolescents who could be considered bipolar. Even placebo-controlled trials had heterogeneous subjects and few with classic bipolar disorder. Samples encompassed youths with a variety of psychotic-like and developmental disorders (Gram and Rafaelsen, 1972), hyperkinesis and equivocal stimulant response (Dyson and Barcay, 1970; Greenhill et al., 1973), and autism and schizophrenia (Campbell et al., 1972), as well as offspring of lithium-responding parents (McKnew et al., 1981).

Several observations can be made about these early studies of lithium in youths: (1) the rarity of classic bipolar disorder in children compared with adolescents; (2) the early interest in trying to find a symptom constellation, especially in younger children, that would be lithium responsive; and (3) the poor treatment response in these subjects, which may have deterred clinicians from conducting more studies. Early studies in adults, whose samples appeared equally heterogeneous, showed higher response rates. These results with adults were promising enough to encourage not just further investigation, but a whole revolution in treatment. The fact that the response rates were highest in adults with what is considered classic manic-depressive illness (bipolar disorder and recurrent unipolar depression) may explain why young people, whose presentation is less likely to be classic, were less likely to respond.

Placebo-controlled lithium trials that occurred prior to the first edition of this volume are summarized in Table 23-3. Those occurring since the first edition are listed in Table 23-4.

Lithium Treatment for Mania in Hospitalized Adolescents. Although lithium has been used in young people for more than 40 years, there have been no published randomized, double-blind, placebo-controlled studies of adolescents meeting DSM-IV criteria for acute mania. One placebo-controlled discontinuation study has been conducted (Kafantaris et al., 2004), and other studies are in progress. The largest open trial (Kafantaris et al., 2003) involved 100 adolescents initially hospitalized for mania and treated with lithium over 4 weeks; 55 percent were responders, as defined by a 50 percent reduction in scores on the Young Mania Rating Scale (YMRS). If the psychotic or aggressive manic adolescents received an adjunctive antipsychotic, the response rate improved to 65 percent. Of interest, 40 of

the responders to open lithium monotherapy were subsequently randomized under double-blind conditions to placebo or continued lithium and followed for 2 weeks (Kafantaris et al., 2004); both groups relapsed at about the same rate—52.6 percent of those on lithium and 61.9 percent of those on placebo. The adolescents who relapsed on lithium in the blind phase were subsequently restabilized on lithium under open conditions (V. Kafantaris, personal communication, 2006). It is likely that in the double-blind phase, the investigators tended to withdraw patients on blind lithium from the trial prematurely if they were showing even mild breakthrough symptoms (perhaps assuming that any given patient might be on placebo), and thus these lithium patients were scored as relapses even though they went on to respond to open lithium.

In an open study of manic adolescents, the response rate to lithium (defined as a 33 percent reduction in YMRS scores and a Clinical Global Impressions [CGI] rating of 1 or 2) was 53.5 percent; the presence of prior ADHD made no difference in the likelihood of responding to the drug (Kafantaris et al., 1998). On the other hand, psychotic features were associated with a significantly lower response rate. Subsequently, the same group treated 42 hospitalized manic adolescents with both lithium and antipsychotic medication. Ultimately, of 28 adolescents who completed at least 4 weeks of treatment, only 14 were judged clinically stable enough to discontinue their antipsychotic medication. Of these 14, only 8 maintained their response on lithium monotherapy for an additional 4 weeks (sustained responders). The other 6 experienced a clinically significant exacerbation of symptoms on lithium monotherapy and resumed treatment with their adjunctive antipsychotic (Kafantaris et al., 2001).

There have been two systematic case series of hospitalized manic adolescents. Strober and colleagues (1988, 1998) found response rates of 67 to 80 percent in adolescents with classic mania, while response rates in manic adolescents with a prior history of ADHD were lower (33 to 40 percent). An 18-month naturalistic follow-up study of adolescents who had discontinued lithium (because of nonadherence) after inpatient stabilization revealed that 90 percent had relapsed, compared with only 37.5 percent of those who had remained on lithium (Strober et al., 1990). Whether this result reflects the effectiveness of lithium or simply the difference between adherent and nonadherent youngsters cannot be determined for this nonrandomized study.

Lithium Treatment for Mania in Hospitalized Children. There have been two clinical trials of lithium in hospitalized children with mania or manic-like symptoms. In the first, 11 patients with bipolar-NOS were treated with lithium and tested by a trained rater, teachers, and nursing staff at baseline, 4 weeks, and 8 weeks (7 of these children also

TABLE 23–3. Early Placebo-Controlled Trials of Lithium in Children and Adolescents with a Variety of Conditions

Study	Sample	Psychopathology Addressed	Methodology	Results	Comments
Gram and Rafaelsen, 1972	N=18; ages 8–22 yr; 13 males, 5 females; pupils at a special school in Denmark	“Psychosis or pronounced psychotic traits”; 7 with autism/pervasive developmental disorder, 2 “borderline,” 2 psychosis, 1 personality disorder, 1 speech and language disorder	2 groups: lithium for 6 mo, then placebo, and vice versa; parent/teacher ratings on 11 items: hyper- or hypoactivity, elevated or depressed mood, anxiety, obsessive behavior or stereotypies, speech disturbances, aggression to others/ self, concentration, school performance	8 unchanged; 1 best on placebo, 9 best on lithium, 7 worsened when lithium stopped; significant improvement by chi square $p < .001$; “no patient became totally free of symptoms”; symptoms improving included aggression, depressed/elevated mood, speech disturbances and stereotypies in school	In current nosology, these youths had autism or psychotic spectrum disorders; none were bipolar, but mood component was important anyway; response rate 50%, meaning improvement but not cure
Campbell et al., 1972	N=10; ages 3–6 yr; inpatients	Severely disturbed preschoolers; developmental quotient < 60 in 50%; mostly autistic/pervasive developmental disorder; 2 “hyperkinetic,” 1 “organic” with “withdrawn reaction”	Children matched on hyperactivity and hypoactivity; lithium compared with carbamazepine; 7–10 wk for each drug, 4 wk drug free before the crossover; lithium levels .25–1.19 mEq/L; carbamazepine about 90 mg	Using global improvement: lithium—1 with marked, 4 with slight, 5 with no improvement and 1 worse; carbamazepine—3 with marked, 6 with slight (1 received thiothixine), 1 with no change; $p = \text{not significant (ns)}$; lithium may have improved explosiveness, aggressiveness, hyperactivity, psychotic speech	“Margin between toxic and optimal” doses small; improvement did not outweigh toxicity; a very difficult population to treat, however
Greenhill et al., 1973	N=9; ages 7–14 yr; hospitalized for study at National Institute of Mental Health, then outpatient for 6 wk	Hyperactive children unresponsive to stimulant medication by parent history; 2 “unsocialized aggressive,” 5 hyperactive-immature-inadequate labile type, 2 no diagnosis stated but looked equally labile and hyperactive by case report	Conners rating scale by nurses/teachers; “blind” psychiatrist-made global ratings; 2 stages: (1) 1 wk single-blind placebo, dextroamphetamine, lithium; (2) randomly alternating 3-wk trials of each condition; parents also raters; children seen at home, school, outpatient department visits	On dextroamphetamine: 3 improved, 3 slightly improved, 3 worse (including one delusional); on lithium, 5 worse, 1 no change, 1 dropout, 2 markedly improved (with deterioration after lithium was stopped), but improvement not sustained over the next 3 mo; Conners scale failed to detect differences	No attempt to call these youths bipolar, but addressed whether very hyperactive youths with a history of poor stimulant response would improve on lithium; they did not

DeLong, 1978	<i>N</i> =12, although only 4 were placebo controlled; ages 4– 14 yr; outpatient	Disruptive, nonpsychotic behavior problems, rages/ aggression, or cyclical behav- ior patterns	Open trial involving 12 children; all improved by parent ratings; 4 who had been stable for 9–21 mo had a placebo crossover	All 4 deteriorated on placebo and improved when lithium was resumed	A discontinuation study of children who had already improved
McKnew et al., 1981	<i>N</i> =6; ages 9–12 yr; outpatient	Offspring of lithium-respond- ing parents: 2 with bipolar-II, 2 unipolar (1 mother, 1 grandmother), 2 with bipolar-I (1 mother, 1 father); parents all comorbid; chil- dren: 2 with bipolar mixed, 3 with attention-deficit hyperactivity disorder (ADHD) and mood prob- lems, 1 with recurrent major depressive disorder (MDD)	Double-blind crossover design; 16–18 wk with 2 placebo periods; seen weekly; rated on the Child Psychiatric Rating Scale and Children's Affective Rating Scale; Clinical Global Impressions (CGI) ratings using informa- tion from both parent and child	2 children with bipolar disorder definitely improved; 2 chil- dren improved on some ratings by some raters (i.e., equivocal response); 2 chil- dren, including 1 with ADHD and cyclothymia and 1 with recurrent MDD, did not improve	Very small, very heterogeneous sample; it did not appear that parent mood or re- sponse status predicted any- thing in this small sample

TABLE 23–4. Contemporary Placebo-Controlled Trials of Lithium in Children and Adolescents

Study	Sample	Psychopathology Addressed	Methodology	Results	Comments
Carlson et al., 1992a	N=11; ages 5 yr 11 mo to 12 yr 10 mo; inpatient	K-SADS ADHD/ODD; severe aggression; bipolar symptoms; YMRS scores 15–35 in 10 children, 1 child with YMRS score of 12 had “episodic ADHD”; inadequate response to stimulant or severe rebound or depression	11 children completed an 8-wk trial of lithium, with ratings by staff and teachers at baseline, 4 wk, and 8 wk; 7 children treated with methylphenidate (MPH) alone and with adjunctive lithium and MPH, with a placebo discontinuation phase at the end of the study	Lithium alone produced modest changes in YMRS and CDRS-R scores, but no relapse off lithium; adjunctive MPH appeared to act synergistically with lithium by nurses’ ratings of inattention, but lithium blocked MPH improvements on computerized laboratory measures	It was not possible to discriminate milieu response from lithium response because children did not relapse when lithium was stopped; over-all response modest compared with the psychopathology of the children
Geller et al., 1998	N=25; ages 12–18 yr; outpatient	Teenagers with any kind of substance abuse and comorbid bipolar-I, bipolar-II, or major depressive disorder with risk for developing bipolar disorder; specific mood state not mentioned	Diagnosis by K-SADS; CGI score improvement >65 was outcome measure; randomized trial, 6 wk, 4 wk on lithium; “interpersonal therapy” in both groups	21 subjects completed; 6/10 lithium group responded (60%) vs. 1/12 (9.3%) on placebo ($p=.046$); no measures of mood outcome	Although this is always cited as a double-blind, placebo-controlled study of lithium in bipolar disorder, it did not address the treatment of pure bipolar disorder per se
Kafantaris et al., 2004	N=40; ages 12–18 yr; initially inpatient	Met criteria for current manic episode; YMRS score >16	Open trial of lithium or lithium + antipsychotic for 4 wk, then lithium alone; 19 randomized to take lithium, 21 to placebo after a 3 day tapering off period	YMRS scores dropped from a mean of 25.62 (7.37) to 8.53 (5.53), CGI scores from 4.95 (.85) to 2.68 (.89) during open phase; 52.6% on lithium and 61.9% on placebo got “worse or very much worse”; no difference (i.e., no protection) with lithium	Discharge could have complicated findings; ethical concerns may have necessitated a quick stop to the study; or lithium may not work well in hospitalized teens

ADHD = attention-deficit hyperactivity disorder; CDRS-R = Children’s Depression Rating Scale-Revised; CGI = Clinical Global Impressions scale; K-SADS = Kiddie Schedule for Affective Disorders and Schizophrenia; ODD = oppositional defiant disorder; YMRS = Young Mania Rating Scale.

received adjunctive methylphenidate [MPH] between their first and second lithium testing periods, during which they received no medication, as well as placebo at the end of the study). Patients, nursing staff, and raters were blinded to the medication condition (Carlson et al., 1992b). Results were mixed. Improvement in YMRS scores at 4 weeks was not sustained at 8 weeks, while scores on the Children's Depression Rating Scale-Revised (CDRS-R) (depression) improved by 8 weeks relative to scores at 4 weeks (Poznanski et al., 1984). Greater improvement was seen in teachers' ratings of self-control (Teacher Self Control Rating Scale [Humphrey, 1982]) than in nurses' ratings at both 4 and 8 weeks. Since most improvement did not reverse when lithium was discontinued, nonspecific improvement due to hospitalization was believed to account for some of the improvement observed. The sample size was limited because of the advent of managed care (Carlson et al., 1992a). The second trial of lithium was open and involved 10 pre-pubertal children identified as acutely manic and psychotic. All showed a "positive clinical response" to the drug (Varanka et al., 1988).

Lithium Treatment for Mania in Outpatient Settings. An old but large *case series* of lithium-treated children and adolescents was reported by two research neurologists who collected data on 196 such patients over the course of 10 years. DeLong and Aldershof (1987) divided their outpatient sample into those with clear mood disorder and those with other disorders with manic-like symptoms. They determined response based on whether patients were continued on the drug over a 10-month period. The duration of follow-up was highly variable but appeared to average about 3.5 years. Two-thirds (39/59) of the "classic" bipolar youths remitted on lithium, and one-third of those who remitted remained well after lithium was stopped. Lesser responses were seen in youths with unipolar depression (5/29, 17 percent), ADHD with affective symptoms (3/8, 38 percent, with 5 considered "worsened"), and explosive/aggressive behavior (5/9, 56 percent). The children with ADHD and affective symptoms all discontinued lithium without further problems. A modest percentage (5/21, 29 percent) of rageful, autistic/developmentally or neurologically impaired young people improved, but at the expense of high rates of serious side effects.

Formal outpatient *trials* of bipolar children and adolescents are more common than inpatient trials, but the samples are somewhat more heterogeneous, both diagnostically and by age. Here we review only those trials that used a systematic assessment for diagnosis and had a large enough sample size to allow interpretation of treatment response. A 6-month open trial of either lithium or valproate in combination with risperidone was conducted by Pavuluri and

colleagues (2004b). The study included 37 subjects aged 5 to 18 with mania or mixed episodes of bipolar disorder. Using three outcome measures (YMRS, CGI-Bipolar [CGI-BP], and CDRS-R), the researchers found lithium in combination with risperidone to be as effective as valproate plus risperidone. Both combination therapies were well tolerated. In a double-blind, placebo-controlled study, Geller and colleagues (1998a) administered lithium over 6 weeks to 11 substance-abusing adolescents with various bipolar diagnoses (bipolar-I, bipolar-II, and major depressive disorder with "bipolar predictors"). Response was defined as a score of 65 or higher on the Children's Global Assessment Scale (Shaffer et al., 1983) (at study entry, the average score was 38). The response rate was higher in lithium-treated adolescents than in those receiving placebo.

Anticonvulsants

Several controlled and uncontrolled trials of valproate and other anticonvulsants have been conducted in various inpatient or outpatient populations (see Tables 23-5 and 23-6). A number of open studies and chart reviews of valproate had results encouraging enough to stimulate controlled trials in outpatients.⁷ The numbers studied were small, however, and the studies suffered from the usual methodological problems (see Table 23-5).

There have been several positive open-label trials with a reasonable sample size in which children and adolescents were treated with divalproex alone or in combination with other medications (see Table 23-6). One was a trial of divalproex in 40 children and adolescents, 61 percent of whom improved (>50 percent decline in YMRS score) over the 8 to 10 weeks of initial stabilization. However, the study had been designed as a discontinuation trial and was hampered by the fact that 23 of 40 subjects had to discontinue prior to randomization because of poor efficacy, inability to discontinue concomitant lithium or haloperidol as required, nonadherence, or refusal to continue in the study once stable (Wagner et al., 2002). Pavuluri and colleagues (2005) reported the results of an open trial of divalproex in 34 children and adolescents with mania or mixed mania. They found that 73.5 percent responded (≥ 50 percent decline from baseline YMRS score and ≤ 40 score on CDRS-R), and 52.9 percent remitted.

A randomized, open-label, 8-week trial compared the benefits of lithium, divalproex, and carbamazepine in 42 outpatient youths aged 8 to 18 (Kowatch et al., 2000). Twenty of the subjects had bipolar-I and 22 bipolar-II; 71 percent had comorbid ADHD, among other comorbidities. Forty-six percent of subjects responded to divalproex, 42 percent to lithium, and 34 percent to carbamazepine, with response defined as a 50 percent reduction in YMRS score and designation as improved or very much improved on

TABLE 23–5. Open Acute Trials of Divalproex in Children and Adolescents with Manic or Mixed States

Author	Sample and Type of Study	Diagnosis, Measures, and Duration of Trial/Study	Other Medications Taken	Doses and Levels	Response and Adverse Events
West et al., 1994	N=11; ages 12–17 yr; open add-on trial; mean age 14.5; 9 M, 2 F; inpatients accrued over 10 mo	DSM-III-R bipolar mixed state or mania diagnosed by SCID, mean YMRS score 19; 63.4% comorbid ADHD; duration: valproate treatment over 6–26 days	Haloperidol—63.4%, perphenazine—36.4%, thioridazine—9%, lithium—45.5%; divalproex added to these medications	Dose range 500–2,000 mg/day, mean 1068 mg; valproate levels 38–91 µg/ml	Mild improvement—18.2%, moderate improvement—54.5%, marked improvement—27.3%; sedation in 2 cases
Papatheodorou et al., 1995	N=15 (13 finished); ages 12–20 yr, mean age 17.3; 13 F, 2 M; open trial inpatient, then outpatient	Bipolar mixed state or mania diagnosed by K-SADS, Blackburn Mania Scale, MMRS, BPRS, GAS, CGI	Only Practice Research Network (PRN) chlorpromazine allowed	Dose range 750–2,000 mg/day; mean 1,423 mg; mean blood level 64.2 µg/ml	MMRS drop: 69.54 → 18.08; BPRS drop: 36.31 → 12.0; CGI impairment drop: 5.4 → 2.4; GAS increase: 30.0 → 55.0; valproate side-effect scale drop: 11.8 → 5.5 (subjects felt better, reported fewer side effects); adverse events: 1 transient liver enzyme elevation; 1 developed hypothyroidism (thyroid stimulating hormone 3.80–7.26 IU/l)
Deltito et al., 1998	N=36, 20 manic or bipolar mixed episode; ages 13–18 yr, mean age 15.6; no gender noted; inpatient chart review	Chart data recorded systematically; comorbidity not described	Milieu treatment on ward; duration of stay not described; PRNs allowed; specifics not described	Dose range 700–900 mg/day; levels not reported	For those with mania or mixed states, overall changes reported: 66–70% change in mania, 79% change in depression, 83–87% change in aggression, 70–74% change in mood fluctuation

TABLE 23–6. Controlled Acute Trials of Divalproex in Children and Adolescents with Manic or Mixed States (*continued*)

Study	Sample and Type of Study	Diagnosis, Measures, and Duration of Trial/Study	Other Medications Taken	Doses and Levels	Response and Adverse Events
Findling et al., 2005	<i>N</i> =60; ages 5–18 yr, mean age 10.7; 91.7% bipolar-I, 50% rapid cycling; subjects were remitted with prior treatment with lithium + divalproex; randomized double-blind to lithium + placebo or divalproex + placebo; maintenance trial	Mania or mixed state diagnosed by K-SADS PL or K-SADS E, YMRS, CDRS, CGI, CGAS; ADHD 63.3% ODD/conduct disorder 30%; most subjects from prior study; duration: 76 wk	Stimulant use 58.3%	End of study blood levels: lithium 0.84 (0.30) mmol/L divalproex 75.3 (29.4) µg/ml	Only 10% completed 76-wk trial: 56.7% exited because of relapse into mania/hypomania, 6.7% because of relapse into depression, 26.6% for other reasons (e.g., non-adherence, side effects); time to relapse for mood reasons: lithium—114 days (standard error [SE] 57.4 days), divalproex—112 days (SE 56 days); time to discontinuation for any reason: lithium—91 days (SE 30 days), divalproex—56 days (SE 19.9 days); no significant difference between lithium and divalproex; young age predicted relapse into mania; no other predictors
Pavuluri et al., 2005	<i>N</i> =34; ages 5–18 yr, mean age 12.1 (3.7); open trial of divalproex; visits monthly	Mania or mixed state diagnosed by WASH-U K-SADS, YMRS, CDRS, CGI-BP, Children's Global Assessment of Functioning Scale (CGAS); 76.5% ADHD, 55.9% ODD; duration: 6 mo	Other medications in study: methylphenidate (MPH) 38.2%; risperidone at some point 50%	Final dose: mean 950 (±355) mg/day; level 109 (±33) µg/ml	Response (≥50% change from baseline on YMRS; ≤40 on CDRS): 73.5%; remission (response + CGI-BP improvement ≤2; CGAS ≥51): 52.9%; mean change from baseline: YMRS—19.8 points, CDRS—27.4 points
Abbott Laboratories (data on file, Dec. 2006)	<i>N</i> =150; ages 10–17; randomized DB to placebo or divalproex-ER	DSM-IV-TR mania or mixed state diagnosed by WASH-U KSADS; minimum YMRS score 20 on entry; assessed by CGAS, CGI, CDRS-R; duration: 4 wk	Full information not yet available	Initial dose 15 mg/kg/day, titrated to maximum of 35 mg/kg/day (plasma levels of 80–125 mcg/ml)	No significant drug-placebo differences in YMRS scores or secondary outcome measures

ADHD=attention-deficit hyperactivity disorder; BPRS=Brief Psychiatric Rating Scale; CDRS=Child Depression Rating Scale; CGAS=Children's Global Assessment Scale; CGI=Clinical Global Impressions; DB=double blind; DSM-IV-TR = *Diagnostic and Statistical Manual*, 4th edition, text revised; ER = extended release; K-SADS=Kiddie-Schedule for Affective Disorders and Schizophrenia; ODD=Oppositional Defiance Disorder; PANSS-P=Positive and Negative Syndrome Scale; PRN=Practice Research Network; TR=text revised; YMRS=Young Mania Rating Scale.

the Clinical Global Impressions-Improvement (CGI) scale. The sample sizes in these studies were too small to permit comparison of responses by diagnostic subtype or age.

In the first randomized, double-blind, placebo-controlled trial of an anticonvulsant in treating pediatric bipolar disorder—a large multicenter study of oxcarbazepine as treatment for bipolar-I mania/mixed states⁸—Wagner and colleagues (2006) failed to find a significant difference between drug and placebo on the primary outcome measure, change in YMRS score over 6 weeks (drug=10.9, placebo=9.8). There was a trend for more of the oxcarbazepine patients to respond (at least 50 percent improvement in YMRS score): 42 percent of those on the drug versus 26 percent of those on placebo. The oxcarbazepine response rate, nearly identical in children (43 percent) and adolescents (41 percent), was very similar to the response rates reported from open trials of lithium, valproate, and carbamazepine in bipolar children and adolescents (Kowatch et al., 2000). Nineteen percent of the oxcarbazepine patients discontinued because of side effects (primarily dizziness, somnolence, diplopia, and fatigue), compared with 4 percent of those receiving placebo. Recently, 150 DSM-IV manic or mixed-state patients ages 10 to 17 (minimum YMRS score at entry: 20) were randomized to divalproex-ER or placebo for 4 weeks; there were no significant differences in the primary or secondary end points. The drug was generally well tolerated, although there was a significant increase in mean plasma ammonium levels (2.1 versus 18.6), which in 1 patient was associated with disorientation requiring hospitalization, data on file, Abbott Laboratories (December 2006).

The less-than-impressive performance of mood stabilizers as monotherapy prompted a variety of other trials of combined medications. In a subsequent study, for instance, Kowatch and colleagues (2003) randomized 35 outpatient child and adolescent bipolar-I and -II subjects into a continuation phase of treatment, which had been initiated with mood stabilizer monotherapy (lithium, carbamazepine, or divalproex). For the nearly half of the patients (17 of 35) who had not responded acutely to monotherapy, other medications were added. Twelve improved on a second mood stabilizer, antipsychotic, or antidepressant, while 12 needed stimulant medication as well.

With regard to other anticonvulsants, there have been scattered case reports and the one open randomized trial that included carbamazepine, described earlier. In addition, there have been seven case reports of young adolescents cited in three studies (Hsu and Starzynski, 1986; Woolston, 1999; Craven and Murphy, 2000). All but one of the seven responded to carbamazepine. The anticonvulsant gabapentin has not been studied specifically for treating acute mania in youths, although there is one published

case report on its utility (Soutullo et al., 1998). A placebo-controlled study of topiramate involving 56 manic and mixed-state adolescents was recently undertaken simultaneously with a trial involving manic adults as part of a registration study, but was halted because of a lack of antimanic efficacy in the adults. There was some suggestion of a positive treatment effect of the drug in the adolescents, however (DelBello et al., 2005). The mean total reduction in YMRS scores was twice as large for those adolescents treated with topiramate ($n=29$) as for those receiving placebo ($n=27$), but given the small number of subjects, this difference did not reach statistical significance. At the final visit, however, 34.5 percent of the topiramate-treated subjects versus 22.2 percent of the placebo-treated subjects had improved either much or very much on the CGI-I scale relative to baseline ($df=1, p=.310$).

Atypical Antipsychotics

Until recently, the available database on atypical antipsychotics as treatment for bipolar disorder in children and adolescents included only chart reviews for risperidone (Frazier et al., 1999), olanzapine (Soutullo et al., 1999; Chang and Ketter, 2000), quetiapine (Schaller and Behar, 1999), and clozapine (Fuchs, 1994; Masi et al., 2002; Kant et al., 2004). However, the status of atypicals in the treatment of child and adolescent bipolar disorder is evolving (Findling and McNamara, 2004). The strong incentive for the pharmaceutical industry to conduct trials to determine the safety and efficacy of the drugs in children and adolescents has been a major impetus for the emergence of a controlled database on their use in treating bipolar disorder in these populations. To this end, multicenter placebo-controlled studies are now under way within the broad framework espoused by the consensus conference discussed earlier (Carlson et al., 2003).

An 8-week open trial of olanzapine was conducted among outpatient children and adolescents aged 5 to 15, 61 percent of whom improved (Frazier et al., 2001). The definition of improvement in this study was problematic, however, requiring only a 30 percent decline in YMRS score or a CGI score of 3 or greater. Biederman and colleagues (2005a) conducted an 8-week open trial of risperidone as monotherapy among 30 youths with mania, mixed mania, and hypomania. Stimulants were used as needed. The authors reported a 70 percent response rate (CGI scores improved or very much improved). Other symptoms of psychopathology were also responsive. Data on clozapine are limited to a chart review that found decreases in mania, depression, and aggression ratings in 10 adolescents with mania/mixed episodes in residential treatment for whom other treatments had failed (Masi et al., 2002). With regard to aripiprazole, data from retrospective chart reviews

suggest that it may be effective and well tolerated in children and adolescents with bipolar disorder (Barzman et al., 2004; Biederman et al., 2005b). In a case series of three youths not responding to traditional mood stabilizers, some symptom alleviation was observed after a switch to ziprasidone monotherapy (Barnett, 2004).

A recent study of mania/mixed episodes in 50 hospitalized adolescents compared quetiapine (400–600 mg/dl) against divalproex (blood levels 80–120 mg/dl) in a randomized, double-blind design (DelBello et al., 2006). Within each treatment group, a statistically significant improvement in YMRS scores was seen from baseline to endpoint.⁹ There was no statistically significant difference in YMRS scores between the two groups over the 28 days of the study ($F[1,48]=1.0$, $p=.3$, Cohen's $d=.28$). Measures of depression and psychosis also improved significantly with both medications. Over a 4-week period, 72 percent of those treated with quetiapine and 40 percent of those receiving divalproex had an end-point YMRS score of 2 or less, a statistically and clinically significant change. The slopes of recovery indicated that adolescents randomized to quetiapine improved more quickly than those receiving divalproex. Other than higher rates of sedation in the quetiapine-treated youths (60 percent versus 36 percent with divalproex), there were no differences in side effects, although it should be noted that, as in virtually all comparative clinical trials, the study was not powered to detect smaller side-effect differences.¹⁰

The first study to emerge as a result of FDA approval of an atypical antipsychotic for treatment of adult acute mania was one involving olanzapine in adolescents aged 13 to 17 (undertaken before the inclusion age was lowered to 10). Preliminary findings of this study are encouraging (Tohen et al., 2006). This 3-week double-blind, placebo-controlled, multisite study included 107 olanzapine-treated and 54 placebo-treated adolescents given doses that ranged from 2.5 to 20 mg/day (average 8 to 10 mg/day). The retention rate was reasonable (79 percent for those receiving active medication), and the response rate (50 percent decline in YMRS scores and CGI severity < 3) was 44.8 percent with olanzapine versus 18.5 percent with placebo ($p=.002$); remission rates were 35 percent with olanzapine and 11 percent with placebo ($p=.001$). Ratings of aggression (on the Overt Aggression Scale of Yudofsky) and ADHD symptoms were significantly better with the medication, suggesting an overall calming effect and a decrease in activation.

Finally, regarding other medications with potential utility in treating mania, there have been case reports on the utility of verapamil (Kastner and Friedman, 1992), nimodipine (Davanzo et al., 1999), lecithin (Schreier, 1982), and melatonin (Robertson and Tanguay, 1997).

Drug Combinations

In an open trial of combined medications, 90 bipolar-I and -II children and adolescents who had not responded to either lithium or valproate were treated with a combination of both (Findling et al., 2003). Using a strict definition of remission (YMRS score < 12.5, with a mean score of 21.8 entering the study), 42 of the subjects (46.7 percent) remitted. It is of note that this remission rate is in the same range as “response” rates in the monotherapy trials, which require only 50 percent improvement. The dropout rate due to side effects or nonadherence was high, but if the subjects could tolerate the combination of medications, they appeared to improve substantially. It would be interesting to know whether a combination of less-than-full monotherapy doses of lithium and valproate (given the evidence that their postsynaptic mechanisms show some synergism and their side-effect profiles are somewhat different) would produce a more favorable ratio of benefit to side effects.

In a small placebo-controlled crossover study of seven inpatients with mixed manic symptoms and ADHD, Carlson and colleagues (1992b) found that measures of inattention and overactivity showed greater improvement with lithium and MPH than with MPH alone. Scheffer and colleagues (2005) examined 40 children and adolescents with bipolar mania treated openly with valproate and then randomized to added placebo or added dextroamphetamine (Adderall). The added stimulant led to greater improvement on the YMRS compared with the added placebo (i.e., valproate alone), and also was effective for the ADHD symptoms. The study did not find worsening of manic symptoms or significant side effects. In another study of combined treatment, Pavuluri and colleagues (2004b) examined the combination of risperidone (up to 3 mg/day) and either lithium or divalproex in a 6-month, nonrandomized open trial. The study included 37 subjects aged 5 to 18 with mania or mixed episodes.¹¹ Based on three outcome measures (YMRS, CGI-BP, and CDRS-R), divalproex in combination with risperidone was found to be as effective and as well tolerated as the combination of lithium and risperidone.

Finally, as part of a double-blind, placebo-controlled study of adjunctive quetiapine, DelBello and colleagues (2002) randomized 30 hospitalized adolescents with mania or mixed episodes to divalproex plus placebo or divalproex plus quetiapine. There was a significant decline ($p<.01$) in YMRS scores with divalproex plus placebo (i.e., divalproex alone) and significant additional improvement with quetiapine. The response rate (improved or very much improved on the CGI or 50 percent decline in YMRS scores) was 53 percent for divalproex. Adding quetiapine (versus adding placebo) raised the response rate an additional 15 percent, a statistically significant difference.

Treatment of Aggression

Although a thorough discussion of the treatment of aggression and conduct disorder is beyond the scope of this chapter, it is important to state that most of the medications approved for the treatment of acute mania in adults have also demonstrated some efficacy in treating affective aggression in pediatric populations (see Table 23–1). Ironically, far more children with aggression and conduct disorder than with mania have been studied using lithium under controlled conditions (Campbell et al., 1984, 1995; Malone et al., 2000). One randomized trial of divalproex found that a higher dose was better than a lower dose for treating conduct disorder (Steiner et al., 2003).

Antipsychotics have also proven effective in randomized, placebo-controlled trials involving more than 500 children with aggression associated with either conduct disorder/ADHD¹² or autism/pervasive developmental disorder (McCracken et al., 2002). For example, with a responder defined as a subject with an end-point rating of much or very much improved on the CGI scale, the percentage of responders in one study (Aman et al., 2002) was 53.8 percent for the risperidone group and 7.9 percent for the placebo group, a significant difference.

One problem with these studies is that outcome measures of irritability/aggression (Aman et al., 1985, 1996) include behaviors elevated in mania: temper tantrums; irritability; depressed mood; demanding behavior; crying over minor annoyances; rapid mood changes; deliberately hurting oneself; arguing; explosive behavior; being easily angered; getting into physical fights; and talking back to teachers, parents, or other adults (Biederman et al., 1995; Carlson et al., 1998; Mick et al., 2003). In trials involving bipolar children and adolescents in which both aggression and mania have been measured directly,¹³ the decline in aggression has been similar to the decline in “mania” scores.

Treatment of Bipolar Depression

As of this writing, no large, placebo-controlled clinical trials of medications for pediatric bipolar depression (including antidepressants) have been published or are currently under way. There has been one 6-week open trial of lithium involving 28 hospitalized bipolar adolescents. This study demonstrated a significant reduction in depressive symptoms (Patel et al., 2006), with 48 percent of the patients showing a greater than 50 percent reduction in CDRS-R scores (Poznanski et al., 1984) relative to baseline, although the baseline scores were so high that in fact only 30 percent met response criteria after 6 weeks (decline in CDRS-R scores <28 and CGI improvement <2). Interpretation of the apparent treatment response is complicated by the fact that there was no placebo control (depression

has a notoriously high placebo response in youths); moreover, the major improvement in mood symptoms took place within the first 2 weeks of treatment, during which 82 percent of the adolescents remained hospitalized. Indeed, 6 weeks is a brief time frame for measuring antidepressant response.

Current understanding of lamotrigine treatment in youth began with a study by Kusumakar and Yatham (1997) that included 7 adolescents among a sample of bipolar adults and found an improvement in scores on depression rating scales. Carandang and colleagues (2003) reported on a case series of lamotrigine (both as monotherapy and as an adjunct) in 9 adolescents with refractory depressive disorders, 6 of whom were bipolar. In this series, 8 of the 9 patients responded well (mean dose 142 mg/day), as determined by achieving a score of 1 or 2 on the CGI-BP scale. Finally, Chang and colleagues (2006) recently completed a study using up to 150 mg/day of lamotrigine over 8 weeks in youths aged 12 to 18. Remarkably, of 19 subjects, 16 (84 percent) were considered responders by virtue of achieving a score of 1 or 2 on the CGI-I-BP. Remission was achieved in 11 of 19 (58 percent) of the subjects.¹⁴

Quetiapine is another promising agent for adults with bipolar depression (see Chapter 19). A controlled study examining this treatment option is currently in progress.

Maintenance Treatment

The question of how long a child or adolescent with bipolar disorder should be treated is clearly important. Insofar as youths have a condition in which clear episodes of mania, depression, and euthymia are occurring, one can probably extrapolate from adult monotherapy studies. In broader pediatric “bipolar” populations, however, the limited data currently available suggest that maintenance with single mood stabilizers generally does not provide adequate coverage. For instance, using subjects from their sample of children and adolescents stabilized on combined lithium and valproate (and adding other subjects to form a sample size of 60), Findling and colleagues (2005) conducted a maintenance trial in which those patients who had responded to combined lithium and divalproex were randomized to monotherapy. The study hypothesis, based on an adult trial (Calabrese et al., 2005), was that divalproex would be superior to lithium as maintenance monotherapy in patients with rapid cycling (50 percent of the subjects). Outpatients ranging in age from 5 to 17 were first openly stabilized on combined lithium and divalproex for 20 weeks and then randomized under double-blind conditions to have one of the mood stabilizers withdrawn while continuing on the other. Relapses were frequent and rapid over the next 3 to 4 months, with only 10 of the 60 subjects completing the trial. Moreover, neither drug was found to be

superior. Interpretation of the study results is limited by the lack of a placebo control, and especially by the confound represented by the withdrawal effect (Findling et al., 2005).

In addition to this one controlled study, there have been some naturalistic studies of medication continuation. For instance, in a study of adolescents hospitalized with "classic" bipolar disorder who were treated with lithium and then followed for 18 months, those who discontinued lithium had a high rate of relapse compared with those who maintained the treatment (92 versus 37 percent) (Strober et al., 1990). Finally, in a naturalistic 4-year follow-up study contrasting bipolar patients first hospitalized in adolescence with those first hospitalized after age 30, the proportion remaining on maintenance medication through the follow-up was similar in the two groups (55 percent of the youths versus 59 percent of the adults) (Carlson et al., 1999). In the adolescent-onset group, however, those who remained on maintenance medication had a relapse rate of 67 percent, similar to the 70 percent among those who stopped treatment. As might be expected, comorbid behavior disorders and substance abuse in the adolescents complicated both medication adherence and relapse. Cessation of substance abuse was associated with fewer episodes and greater functional improvement at the 4-year point in this follow-up.

Offspring of Adults Treated for Bipolar Disorder

Using a family history of lithium response as the basis for trying medication in children with a variety of psychiatric symptoms, Dyson and Barcay (1970) studied two children with "hyperkinesis" who had a parent considered to be a lithium responder. One child responded to both dextroamphetamine and lithium; the second responded to lithium alone. McKnew and colleagues (1981) attempted to replicate this study with a slightly larger sample ($N=6$) of symptomatic offspring of lithium-responding parents or grandparents, but without success (see Table 23-3).

There have been two more contemporary studies examining the use of divalproex in children and adolescents believed to be at risk for bipolar disorder by virtue of their family history. In one open 12-week trial, 24 children with "mood symptoms" whose parents had bipolar disorder improved globally (Chang et al., 2003). In another study, 53 children or adolescents (aged 5 to 17) with a bipolar parent who themselves had mood symptoms not sufficient to meet criteria for mania or depression were randomized to divalproex or placebo. Median time until a mood event for those randomized to placebo (196 days, standard error [SE] ± 117.6 days) was not significantly different from the mean survival time among the youths randomized to divalproex (148 days, SE ± 137.1 days). Among those with more bipolar disorder among first-degree relatives, however, the

mood stabilizer was significantly superior to placebo (Findling et al., 2003a).

Finally, there have been two recent studies of quetiapine by the same group involving the non-bipolar-I offspring of a bipolar-I parent. In one, a 12-week open study of quetiapine monotherapy (mean dose 447 mg/day) in 25 adolescents with major depression, the score on the CDRS-R was reduced from 40 to 29 ($p<.0001$) (Barzman et al., 2006). In the other study, 20 adolescents with dysthymia, major depression, depressive disorder-NOS, cyclothymia, bipolar-II disorder, or bipolar-NOS were treated in a single-blind fashion (blind rater) with quetiapine (300 to 600 mg/day) for 84 days. Mean YMRS scores declined from 18 to 8 at end point ($p<.0001$), and CDRS-R scores fell from 38 to 27 ($p<.0006$) (Strakowski et al., 2006). The most common side effects were sedation (65 percent), dry mouth (40 percent) and headache (40 percent).

Psychiatric Adverse Events

The diagnostic and treatment implications of activation associated with medications (which may manifest as symptoms of mania) complicate clinical decision making in general and that for patients with bipolar disorder in particular. As detailed in Chapter 19, the frequency of manic symptoms in adults with bipolar depression within 2 months of initiation of a second-generation antidepressant is about 20 percent.¹⁵ Rates can vary widely, depending on rating criteria, cohort characteristics, duration of treatment with the antidepressant, possibly the type of antidepressant used, and whether a mood stabilizer is used concurrently (Post et al., 2003). Results of studies in adults appear to suggest that rapid-cycling bipolar patients are especially vulnerable to destabilization (Ghaemi et al., 2003; Post et al., 2003; Altshuler et al., 2003). This finding is relevant to pediatric bipolar patients, among whom the percentage with a rapid-cycling course ranges from 19 percent (Faraone et al., 1997) to 83 percent (Tillman et al., 2003), depending on the study.

There are as yet no prospective studies evaluating the frequency with which antidepressant-induced switching or cycle induction occurs. Biederman and colleagues (2000a) used multivariate analysis to examine 50 charts of child and adolescent outpatients with bipolar depression treated with SSRIs plus a mood stabilizer and found a three-fold increase in the relative risk (RR) for destabilizing the condition ($RR=3.0$, 95 percent confidence interval [CI]=1.2–7.8; $p=.02$). However, it should be noted that there was a greater likelihood of improving the condition ($RR=6.7$, 95 percent CI=1.9–23.6; $p=.003$). Although mood stabilizers (primarily lithium and valproate) ameliorated manic symptoms, they did not prevent the antidepressant-related increase in cycling as reflected by more episodes of bipolar

depression. Another chart review involving 82 children with a modified diagnosis of bipolar disorder found that 58 percent developed treatment-emergent mania shortly after receiving mood-elevating agents (Faedda et al., 2004). Baumer and colleagues (2006) recently published the first study to assess, by direct semistructured interview of both parent and offspring, antidepressant-related mania in adolescents and children who not only are at risk for bipolar disorder (i.e., at least one parent with a *Diagnostic and Statistical Manual* (DSM)-IV bipolar-I or -II diagnosis as determined by the Structured Clinical Interview for DSM [SCID-I]), but who also meet criteria for bipolar-I or -II disorder according to the Kiddie Schedule for Affective Disorders and Schizophrenia (K-SADS) or subsyndromal bipolar disorder (ADHD symptoms with a YMRS score of 12 or more or CDRS-R score of 30 or more). They reported that, in agreement with the findings of Faedda and colleagues (2004), 50 percent of the subjects experienced an antidepressant-related mania as reflected in YMRS ratings and in accordance with DSM-IV criteria (except that only 1 day of symptoms was required because most subjects stopped the antidepressant with 1 to 4 days of the onset of mania).

It has been estimated that psychotically depressed, hospitalized adolescents who became hypomanic on a tricyclic antidepressant had at least a 20 percent chance of developing a bipolar course (Strober and Carlson, 1982; Akiskal et al., 1985). DelBello and colleagues (2003) attempted to replicate this in a sample of 157 adolescents and adults who were hospitalized with psychotic depression and followed for a relatively short time (up to 2 years); they found that only 13 percent developed DSM-IV mania or hypomania (which, of interest, was independent of age at onset). However, 13 percent is probably an underestimate in light of the finding of Baumer and colleagues (2006), noted previously, that the antidepressant is generally discontinued as soon as manic/hypomanic symptoms appear, and thus not all of the episodes would have met DSM-IV durational criteria (at least 1 week for mania and 4 days for hypomania).

Rates of agitation/activation in short-term trials of seven antidepressant drugs used to treat children and adolescents were recently summarized by Cheung and colleagues (2005). They reported the relative risk of treatment-emergent agitation or hostility to be modest but significant ($RR=1.79$, 95 percent CI=1.16–2.76). In the Treatment of Adolescent Depression study (March et al., 2004), the rate of agitation/anxiety/irritability in fluoxetine-treated subjects was 5.5 percent, compared with 3.57 percent in those treated with placebo. The rate of mania/hypomania was 2.3 percent versus 1.7 percent for placebo over the 12-week trial; these drug-placebo differences become more sig-

nificant given that bipolar youths were specifically excluded.¹⁶

In longer-term studies, follow-up data on prepubertal depressed children do not suggest that tricyclic antidepressants precipitate mania in early-onset *nonbipolar* depressed children (Craney and Geller, 2003). Nor does that suggestion emerge from a meta-analysis of 13 clinical trials of tricyclics involving more than 500 young people (from which bipolar youths were excluded) (Hazell et al., 2002). However, in interpreting this literature, it is important to recall the point made earlier that because DSM-IV mania requires at least 1 week of symptoms (2 weeks in the study of Geller and colleagues [2002]), cases in which the mania was ameliorated by immediate antidepressant discontinuation would not be counted.

The most interesting study of young people and their response to antidepressants examined a large insurance database involving “real-world” patients and treatments. This study found that children and adolescents had higher rates of administration of mood stabilizers 3 months or longer after being treated with antidepressants compared with adults. Along with the use of mood stabilizers was an accompanying diagnosis of bipolar disorder. Although it is possible that the diagnosis was made to justify the change in treatment, the vulnerability of young people to psychiatric adverse events is sobering. Comparing rates of “conversion” in those unexposed versus exposed to antidepressants, the study reported the following: for children aged 10 to 14, 3.1 versus 12.7 percent; aged 15 to 19, 4.8 versus 10.9 percent; aged 20 to 24, 4.3 versus 7.6 percent (Martin et al., 2004). At a minimum, these data suggest that young people are particularly vulnerable to psychiatric adverse events that trigger the clinician’s choice to use a mood stabilizer.¹⁷ Unfortunately, the study did not explore whether antidepressants were stopped and/or the change in treatment approach was continued and led to improved outcomes. That is, had it been possible to follow the sample longitudinally, one could have seen whether mood stabilizer treatment continued and whether the frequency of visits declined.

The question of antidepressant-induced “suicidal behavior” has been a contentious and confused topic, perhaps primarily because the term “suicidal behavior” has had no clear definition, and its relationship to actual suicide or serious attempts is tenuous at best (see the detailed discussion in Chapter 25). In 24 pediatric trials of antidepressants, the FDA (2004) found an increased risk for suicidal behavior (overall $RR=1.78$, 95 percent CI=1.14–2.77): about 2 percent with placebo versus about 4 percent in SSRI-treated subjects (there were no actual suicides). These rates are, in fact, similar to those for activation/agitation. Unfortunately, the relationship of suicidal behavior to agitation was not examined as a primary outcome measure. Even if it had been, agitation and activation were measured in such inconsistent ways

(Carlson and Mick, 2003) that conclusions would have been impossible. The Columbia Reclassification Project, requested by the FDA to reexamine data from industry-sponsored trials of antidepressant treatment in youths, has substantiated the small but significant “signal” of increased suicidal behavior compared with placebo with short-term use of antidepressants in these patients. However, bipolar subjects are excluded from the FDA database, and results of the few studies of bipolar youths indicate that the frequency of antidepressant-related suicidality is considerably higher: 14 percent in the study of Faedda and colleagues (2004) and 25.5 percent in the study of Baumer and colleagues (2006). Although these findings have not translated into an increased risk for actual suicide, it is prudent to monitor young people closely, especially those with or at risk for bipolar disorder, when starting these medications. Information for parents and clinicians on this issue is provided at <http://www.parentsmedguide.org> (accessed September 19, 2006).

Medical Adverse Events

Adverse events associated with medications in adults are described in Chapters 17 and 20, and all of these findings are applicable to children and adolescents. Several additional concerns need to be emphasized, however, as reviewed by Correll and Carlson (2006):

- *Lithium and thyroid suppression*—Lithium’s thyroid suppression effect is well known. In a brief, 4-week study of adolescents conducted by Kafantaris and colleagues (2003), lithium produced only minor, transient elevations in serum TSH, which corrected spontaneously. In a study in which lithium was administered along with divalproex, however, a significant number (24 percent) of patients developed serum TSH levels greater than 10 mU/l (Gracious et al., 2004) within only 20 weeks. This much larger thyroid impact suggests a synergistic effect of valproate and lithium such that extra caution should be exercised in thyroid monitoring for young people receiving the combination.
- *Valproate and polycystic ovaries*—Polycystic ovary syndrome (PCOS)—chronic anovulation and hyperandrogenism with or without actual polycystic ovaries—is associated with oligomenorrhea, hirsutism, and acne. Given that menstrual irregularities are common in adolescents, it is important to obtain a baseline menstrual history when evaluating the impact of valproate. See Chapter 20 for a review of two recent large studies of bipolar adults, whose results indicate a very substantial divalproex-related increase in PCOS and menstrual irregularities compared with other mood stabilizers. These findings are especially important to the management of adolescents, considered to be most vulnerable to this adverse effect.

• *Atypical antipsychotics and prolactin*—As reviewed in Chapter 14, dopamine-2 (D₂) receptor antagonism is associated with elevated prolactin, as dopamine blocks the release of prolactin. The affinity of atypical antipsychotics for this receptor and thus their likelihood of causing hyperprolactinemia can be summarized as follows: risperidone > olanzapine > ziprasidone > quetiapine > clozapine > aripiprazole. Postpubertal children and adolescents may be more susceptible than adults to drug-induced prolactin elevations (Wudarsky et al., 1999). However, a rise in prolactin does not necessarily translate into a clinical problem. Moreover, the rise in prolactin appears to be relatively transient (Findling et al., 2003b), so it is unnecessary to measure prolactin levels routinely. Prolactin levels should be measured if, after initiation of an atypical, amenorrhea or oligomenorrhea develops in an adolescent who previously had regular menses. The clinical manifestations of hyperprolactinemia in adolescents include breast enlargement/engorgement and/or galactorrhea, failure to enter or progress through puberty, and the development of hirsutism.

• *Weight gain associated with atypical antipsychotics, lithium, and divalproex*—This is a concern for patients of all ages, and as detailed in Chapter 20, combinations of these drugs are likely to increase the risk. Some of the atypical antipsychotics have an especially significant tendency to promote weight gain, particularly in patients who have not had prior exposure to psychotropic medication (Correll et al., 2005), as is the case for young people. This point is relevant because the occurrence of the metabolic syndrome in young people predicts development of atherosclerosis and vascular disease early in adulthood, while obesity during adolescence predicts later coronary artery disease and colorectal cancer even more strongly than obesity during adulthood. Data on adults (Allison et al., 1999; American Diabetes Association, 2004; Casey, 2004) and from an ongoing large-scale naturalistic study involving children and adolescents (Correll et al., 2005) suggest the following rank order among the atypicals in terms of ability to promote weight gain and development of the metabolic syndrome: clozapine = olanzapine >> risperidone >> quetiapine > ziprasidone >/= aripiprazole. In addition, the prospect of weight gain is likely to affect medication adherence, particularly among adolescents, for whom appearance is especially important.

• *Lamotrigine and Stevens-Johnson syndrome*—This potentially lethal condition is quite uncommon in young people with appropriate dosing—according to the German rash registry, 1 in 1,700 for those under age 16 versus 1 in 10,000 in adults (most of the youths in the registry were being treated for epilepsy with multiple rash-producing

drugs).¹⁸ It is important for the clinician to follow carefully the gradual upward titration schedule outlined in Chapter 20.

Summary of Pharmacological Studies of Bipolar Disorder

Numerous problems beset pharmacological studies of bipolar disorder in young people. The relative rarity of DSM-IV bipolar disorder in prepubertal children limits the number of subjects available for systematic trials. Moreover, from the earliest studies, there has been a great deal of heterogeneity in the subjects involved; this has been the case even in studies involving only adolescents. And although more recent studies have used structured interviews and rating scales such as the YMRS, the high prevalence of comorbidities across studies makes their results too heterogeneous to be compared meaningfully. Comorbid conditions may well affect the action of mood-stabilizing medications as well. In the case of placebo-controlled studies, the study duration and the severity of symptoms among subjects are limited by ethical constraints. Outpatient studies suffer from major problems with adherence, interfering stressors, family crises, and high dropout rates (Carlson et al., 2003). Inpatient studies are expensive and, some would suggest, not as generalizable.

Despite the difficulties faced by placebo-controlled studies, treatment research in pediatric bipolar disorder is moving forward at an accelerating pace. Whereas just a short while ago there were few agents and little agreement among experts, today there are many agents and many more areas of consensus. We are encouraged by the number and scope of controlled studies currently under way. While we await their results, we must note that in the many areas in which placebo-controlled data are inadequate, experts are still able to reach substantial agreement on recommendations by drawing on results of open studies and clinical experience. Thus today, clinicians, patients, and families enjoy an expanded array of options, many of them supported by extensive observations in the “real world” of clinical practice.

Electroconvulsive Therapy

The body of knowledge on the use of ECT in young people has grown to the point that a practice parameter has been developed to provide advice to child and adolescent psychiatrists (Ghaziuddin et al., 2004). Several reviews have summarized the literature on ECT, including its successful use in treating mania in bipolar adolescents (at least those without comorbid personality disorder) (Rey and Walter, 1997; Walter et al., 1999; Walter and Rey, 2003). There have

been no controlled studies, but these reviews have identified 60 reports (63 percent of which were case studies) describing the use of ECT in 396 patients. Rates of improvement across studies were 63 percent for depression, 80 percent for mania, 80 percent for catatonia (which is often related to bipolar disorder), and 42 percent for schizophrenia. One study evaluated adolescents about 5 years after they had undergone ECT. Compared with carefully matched psychiatric controls, 11 adolescents given ECT for psychotic depression or mania were similar in school and social functioning. Bipolar disorder was the most common follow-up diagnosis, however, suggesting that for some, the antidepressant effectiveness of the procedure was accompanied by a switch into mania (Taieb et al., 2002). The only data on prepubertal children come from a report on 2 successfully treated patients with refractory mania (Hill et al., 1997) and 1 with severe depression with catatonic features (Russell et al., 2002).

Psychotherapy

Fristad and colleagues (1998) used a manual-driven, adjunctive, multiple-family group treatment approach for children aged 8 to 12 with bipolar and depressive disorders. This method includes psychoeducation about the disorder and the role of medications, training in communication skills to improve interactions between parents and children, stress management, and development of coping strategies. In a randomized controlled trial, this same group (Fristad et al., 2002) showed that multifamily psychoeducation was associated with increased knowledge about bipolar disorder and treatment options, better skills in dealing with the bipolar child, more active attitudes toward mobilizing resources to benefit the child, and an increased sense of support compared with a wait-list control group.

Miklowitz and colleagues (2000, 2004) developed a manual for adolescents aged 13 to 17 years with bipolar-I disorder. This manual is an adaptation of the family-focused therapy model for bipolar adults, designed to make it appropriate for this age group and to address clinical issues specific to juvenile bipolar disorder. In an open, 1 year observational study of 20 bipolar adolescents, the approach, in combination with mood stabilizers, moderately improved symptoms of depression and mania and behavior problems (Miklowitz et al., 2004). Greene and colleagues (Greene et al., 2003; Greene and Ablon, 2005) developed a “collaborative problem-solving” model that focuses on parents’ assistance to their children. Parents are encouraged to avoid engaging their children until after a rage attack subsides, at which point collaborative problem solving can be encouraged. This approach is controversial, however, since the model emphasizes no consequences for the rage behavior or associated actions. Pavuluri and colleagues (2004a)

developed a treatment program that involves parent-and-child sessions for 8- to 12-year-olds with bipolar disorder, termed child- and family-focused cognitive-behavioral therapy, described in detail in Chapter 22.

CONCLUSIONS

A serious psychiatric condition such as bipolar disorder that begins in childhood or adolescence does more than interfere with the patient's life: it also interferes with development. Thus it is encouraging that information on the treatment of bipolar disorder in children and adolescents, while still lagging behind that for adults, is improving. In the not-too-distant future, ongoing research is expected to resolve the dilemma of how to diagnose children (younger than age 12) more accurately and how to distinguish bipolar disorder in this population from a host of common comorbidities, including ADHD. Once consensus exists on how to classify children, more advanced treatment strategies for this age group can be pursued in clinical trials. In the meantime, most of our knowledge about treatment for children comes from open studies and clinical experience, combined with what is known from controlled studies of adolescents.

Although the evidence base is far from strong, this chapter provides clinical guidance on the use of medical and psychotherapeutic treatments for both children and adolescents. As of this writing, a number of clinical and industry-sponsored trials have just been launched, and their results can be expected to greatly increase the current knowledge base.

To summarize our treatment recommendations, mania should be treated with lithium, an anticonvulsant, and/or an atypical antipsychotic, depending on the clinical presentation. One common and perplexing question is how to treat a youngster whose symptoms of bipolar disorder may actually be symptoms of ADHD, or one who has ADHD comorbid with bipolar disorder. When a diagnosis of mania is clear, a mood stabilizer should be prescribed first, followed by treatment for the ADHD. When a mania diagnosis is less clear, we believe the ADHD should be addressed; if the child becomes more irritable, an atypical antipsychotic may be used and the ADHD readdressed as needed. With regard to a first depression in youths with a clear positive family history of mania in first-degree relatives, lamotrigine should be offered initially; if there is a family history of lithium response, lithium may be preferred over lamotrigine. An antidepressant can be added later if the response to the mood stabilizer is inadequate. If the clinical situation makes it appear unwise to wait, however, the antidepressant can be started simultaneously with the mood stabilizer. If the family or child resists a mood stabilizer or is simply unhappy with taking two medications,

an antidepressant may be initiated alone, but only if the patient can be monitored very carefully for any signs ofincipient mania or mixed state.

With regard to maintenance therapy for bipolar disorder, treatment guidelines in adults extrapolated to young people suggest the use of lithium or lamotrigine. The jury is still out as to whether olanzapine and aripiprazole, which have FDA "maintenance" indications, will prove to prevent new episodes (a prophylactic effect) as opposed to simply being effective continuation treatments following an acute antimanic response.

Psychosocial approaches are a vital component of treatment. They can improve social, academic, and family functioning, as well as promote adherence to pharmacological therapies. Evidence-based psychosocial therapies include psychoeducation and family therapy to help families devise constructive ways of problem solving.

NOTES

1. Duffy et al., 1998; Egeland et al., 2000, 2003; Shaw et al., 2005.
2. For the acute treatment of mania in children and adolescents, side-effect considerations appear similar to those in adults, although some investigators have noted fewer side effects in children (see McClellan and Werry, 1997). Lithium has a shorter half-life in children because of their more efficient renal physiology and, therefore will reach steady-state levels more quickly. Children may be more susceptible to the cognitive dulling seen in adults at higher serum levels (Silva et al., 1992).
3. The issue of a possible effect of valproate on female reproductive function is important for girls and young women who are taking the drug. Regular monitoring of reproductive function in female patients taking valproate is recommended, including questioning patients during visits regarding menstrual disorders, fertility, weight gain, hirsutism, and galactorrhea.
4. Compared with adult trials, ethical constraints make it more difficult to get seriously ill children admitted to trials with placebo controls. Therefore, placebo responses are often high, which can obscure an active drug effect.
5. The Geller and colleagues (1999) data emerged from a tricyclic antidepressant trial that found no relationship between antidepressant use and the development of subsequent bipolar disorder.
6. Odds and odds ratios are based on comparison of rates of bipolar disorder in the offspring of adults with the disorder versus another sample, usually a population sample. Rates of bipolar disorder are just over 1 percent, and of depression are nearly 10 percent. Thus if rates of disorder in bipolar offspring are 5 percent for bipolar disorder and 20 percent for unipolar depression, more have unipolar depression. But the rate of bipolar disorder is 5 times higher than that in the general population, whereas the rate of unipolar depression is only 2 times higher.
7. West et al., 1994; Papatheodorou et al., 1995; Deltito et al., 1998.
8. Oxcarbazepine is a 10-keto analogue of carbamazepine that apparently is without the parent compound's hematopoietic problems.

9. For quetiapine, the baseline mean was 35 (standard deviation [SD]=8), and the end-point mean was 12 (SD=11). For divalproex, the baseline mean was 36 (SD=7), and the end-point mean was 17 (SD=11).
10. Other potentially relevant information on quetiapine comes from an open safety trial in 10 adolescents with "chronic or intermittent psychosis" (i.e., not specified as bipolar) who were subsequently followed for 88 weeks (McConville et al., 2000). Doses of 300 to 800 mg/day were used, reportedly with minimal side effects.
11. As opposed to most studies of combined medications, these subjects were not selected on the basis of nonresponse to monotherapy.
12. Findling et al., 2000; Aman et al., 2002; Snyder et al., 2002; Turgay et al., 2002.
13. Frazier et al., 1999; ACNP, 2005; Biederman et al., 2005a.
14. The starting dose was 25 mg/day (12.5 mg in three subjects also taking valproate) for 2 weeks, 50 mg for 2 weeks, then 100 mg, 125 mg, and 150 mg, with a final mean dose of 132 mg/day. No rashes developed (Chang et al., 2006).
15. Clearly, if 20 percent of bipolar adults destabilize on antidepressants, 80 percent do not, as is suggested by other studies (Maj et al., 2002; Altshuler et al., 2003; Gijsman et al., 2004; Joffe et al., 2005; Carlson et al., 2006).
16. We can only assume that if some early-onset depressive patients are going to become bipolar but have not yet manifested mania, some will inadvertently be included in these trials.
17. The possibility that clinicians treating young versus older people are quicker to use mood stabilizers if they perceive that certain side effects are occurring cannot be ruled out.
18. The safety profiles of the anticonvulsants are well characterized for children and adolescents taking these agents for epilepsy. Younger patients may be at greater risk of rare idiosyncratic hepatic and dermatological reactions, as these problems have generally been reported more frequently in children than in adolescents and adults. The manufacturers of lamotrigine do not recommend its use in patients younger than age 16 years, except for special antiepilepsy indications, because of the apparently higher incidence of toxic epidermal necrolysis in the young.

—John Berryman (*cited in Haffenden, 1982, pp. 374–375*)

For most of the medical and psychiatric conditions that are comorbid with manic-depressive illness, a combination of psychosocial approaches and medication is optimal. Few controlled trials of pharmacotherapy have been conducted, however, despite the high prevalence of comorbidity in patients with manic-depressive illness, especially the bipolar subgroup. Most clinical trials aim for a “pure” presentation of the disorder being studied and therefore exclude patients with comorbid conditions. As a result, it is difficult to select treatment based on demonstrated efficacy in a specific comorbid population. Instead, the focus has tended to be on identifying treatment for the comorbid condition that will not destabilize the mood disorder.

Mood stabilizers that have been shown to be effective in noncomorbid bipolar patients are an obvious first choice for the treatment of comorbid illnesses because they can contribute to the stabilization of both conditions simultaneously. If additional agents are required, the first consideration is that they should not exacerbate depression, mania, or cycling. Thus the risk of the comorbid illness must be weighed against the risk of the adjunctive treatment. In practice, this type of risk assessment is difficult given the paucity of controlled studies available to guide the clinician. A realistic approach is to rely on clinical judgment and knowledge of a patient’s unique presentation while conducting regular assessments of the patient’s response to a given treatment. Such ongoing assessment will enable the clinician to detect any destabilization of the mood disorder in response to the treatment for the comorbid condition so that alternative treatment strategies can be pursued.

In this chapter, we review in turn what is known about the treatment of the following comorbid conditions commonly seen in patients with manic-depressive illness: substance abuse, anxiety disorders (panic disorder, social

anxiety disorder, obsessive-compulsive disorder, and post-traumatic stress disorder), eating and personality disorders, and general medical disorders (cardiovascular disease, obesity, and thyroid dysfunction). Since the management of comorbid ADHD involves primarily children and adolescents, it is covered in Chapter 23.

SUBSTANCE ABUSE

The first step in the treatment of any disorder is to conduct a comprehensive assessment. For patients with substance abuse comorbidity, an initial assessment must include an evaluation of the effects of the substance(s) on the patient’s affective stability. Differentiating mood changes brought about by affective illness from those brought about by alcohol or drug abuse can be a subtle and complex process.

In some cases, simple coincidence accounts for the co-existence of two disorders in the same individual, whereas in others, the alcohol and drug abuse may reflect genetically influenced behavioral traits that overlap the mood and addictive disorders (such as stimulus seeking and poor impulse control). Alternatively, the substance abuse may simply reflect an attempt at self-treatment of depression, mania, or especially mixed states.

Just as affective illness can mask substance abuse, the reverse is also true. Accurate diagnosis of both disorders is vital because it is the basis for important treatment decisions. For example, it is unnecessary and unwise to prescribe mood stabilizers or antidepressants for transient mood symptoms secondary to substance abuse that will spontaneously remit with abstinence. Many investigators (e.g., Schuckit, 1983; Driessen et al., 2001) have noted that with primary alcoholism and an apparent secondary affective disorder, affective symptoms usually remit within 2 to

4 weeks after cessation of alcohol use. Treating only substance abuse in the presence of an independent affective illness, on the other hand, risks persistence of the problems associated with mood disorders.

Adequate assessment of a patient with possible diagnoses of bipolar or recurrent unipolar disorder and substance abuse requires systematic inquiry using standardized diagnostic criteria. Family histories of affective and substance abuse problems, as well as a detailed chronicling of symptom onset, also are important. Such histories aid in teasing out the more probable or primary diagnosis; moreover, they assist the clinician in identifying and counseling the manic-depressive patient who has a family history of alcoholism, a history that makes the patient more liable to become an alcoholic (Morrison, 1975). It is also important to differentiate between adolescent-onset affective disorders and early-onset alcoholism, which, like the bipolar form of manic-depressive illness, can be associated with aggressive and impulsive behavior. Indeed, early-onset alcoholism tends to be associated with a high degree of comorbidity. For example, Famularo and colleagues (1985) diagnosed bipolar illness in 7 of 10 cases of alcohol abuse developing before the age of 13. Driessen and colleagues (1998) studied a sample of 250 hospitalized alcohol-dependent patients and found that the majority of late-onset subjects were either not comorbid at all or had Axis I comorbidity only. Early-onset alcohol dependence, on the other hand, was preferentially associated with personality disorders. Gender differences also play a role. Goldstein and colleagues (2006), in a large-scale study of data from the 2001–2002 National Epidemiologic Survey on Alcohol and Related Conditions, found that among those with comorbid bipolar-I and alcohol abuse disorders, the former was more likely to go untreated among males and the latter more likely to go untreated among females.

In addition to a comprehensive diagnostic interview, a urine screen for drugs is important, as indicated by the finding of Estroff and colleagues (1985, p. 38) that there existed “little relationship between patients’ self-reported patterns of drug abuse . . . and the results of the urine analysis.” On the other hand, another study that evaluated patients seeking treatment specifically for drug problems found that self-reports of drug use were generally reliable (Brown et al., 1992), as reflected in the .65 reliability coefficient (*kappa*) between self-report and urinalysis results for most of the substances studied.

As with comorbid conditions in general, there is a paucity of data on how best to treat patients with comorbid mood and substance abuse disorders. Unfortunately, alcohol and drug abuse disorders are among the most common exclusionary criteria for patients entering clinical trials. At the same time, studies of substance abusers generally

exclude patients with co-occurring psychiatric disorders. Clinicians must therefore rely primarily on their clinical acumen in addition to the sparse empirically derived data when determining which treatments are best for patients with co-occurring bipolar and substance abuse disorders.

Treatment for the two disorders can be structured in a number of different ways: selective treatment of only one of the comorbid conditions, sequential treatment of first one and then the other, parallel treatment of each, and integrated treatment of the two together. It is important to note that no pharmacological treatment for substance abuse has been shown to be effective in the absence of psychosocial therapy. Therefore, any strategy that involves treatment of the substance abuse disorder must have a psychosocial component, which should include Alcoholics Anonymous (AA), Narcotics Anonymous (NA), or their equivalent.

Because it is easy for one of the two diagnoses to be missed (usually the substance abuse), selective treatment of only one of the two conditions is common. In such cases, favorable outcomes and long-term stabilization are unlikely. Because substance abuse triggers and exacerbates bipolar and recurrent unipolar disorders (and vice versa), such an approach is analogous to the partial treatment of an infection; the untreated pathology reactivates the morbid process. In a minority of cases, it is conceivable that effective treatment of the mood disorder will attenuate the substance abuse disorder such that the patient is able to recover from the latter without professional intervention. Nevertheless, treatment of only the mood disorder results in significant numbers of patients being labeled incorrectly as treatment resistant. These patients, especially the bipolar subgroup, fail to stabilize despite multiple trials of mood stabilizers not because of some factor intrinsic to their mood disorder, but as the consequence of an unrecognized or inadequately treated comorbid substance abuse disorder.

When co-occurring illnesses are diagnosed accurately, some patients may receive treatment first for one and then for the other. Such sequential treatment may be the result of factors within the system of care. Some mental health clinics are unable to treat patients with active substance abuse problems, while some substance abuse programs require that co-occurring psychiatric disorders be stabilized prior to enrollment. Although it is not ideal, sequential treatment can be effective for some patients. Because the two illnesses interact in harmful ways, stabilization of one can facilitate improvement in the other, making remission more likely.

Parallel treatment involves addressing both disorders concurrently but independently. Thus comorbid bipolar disorder is approached in the same way as the disorder without co-occurring substance abuse. Such an approach, however,

fails to address the ways in which the two illnesses interact. Therefore, the best approach is an integrated one that takes the comorbid substance abuse into account in choosing a treatment for the affective disorder. The interactions between the disorders are considered in selecting both pharmacological and psychosocial treatments. Specialized programs that offer integrated treatment are rare, however, and for many patients, accessing such treatment is not possible. Integrated treatment is discussed in more detail below in the section on psychosocial therapies.

Most psychiatrists are familiar with the large body of evidence supporting the efficacy of available treatments for recurrent depression and bipolar disorder. There tends to be widespread pessimism, however, about the long-term efficacy of treatments for substance abuse disorders. There are a number of reasons for this unfounded pessimism. For example, clinicians may initially be exposed to the most seriously ill substance abuse patients, many of whom are seen in emergency rooms. These patients demonstrate poor adherence to treatment recommendations, have very limited support networks, and often show little motivation for change. Clinicians may come to view these intractable cases as typical of substance abuse disorders. Substance abuse in patients with good prognoses, on the other hand, may not be recognized because the pathology is more subtle. Such patients may be employed and have homes, and their substance abuse may not be diagnosed unless a clinician specifically inquires about it with both the patient and the family. Clinicians who believe that substance abuse disorders do not respond to treatment may neglect to ask patients and family members about them, fail to identify the most treatable individuals, and consequently develop only limited experience with those who successfully overcome their addictions.

Inappropriate measurements of efficacy also contribute to the belief that substance abuse treatment does not work. For patients with substance dependence, full abstinence is the long-term goal; achieving this goal is a gradual process, however, and improvement may occur only incrementally. Judging a treatment based on its ability to achieve this long-term goal rapidly can be misleading. Thus it is useful to think of substance abuse as a chronic relapsing illness, similar to diabetes or hypertension, for which it is not clinically meaningful to expect that treatment will lead in the short term to an asymptomatic state. In this respect, substance abuse and psychiatric disorders differ: many treatments commonly used in psychiatry demonstrate efficacy over a period of weeks to months, whereas substance abuse treatments may take months to years to be fully effective.

Despite the belief that substance abuse does not respond well to treatment, a study of 51 patients with comorbid

bipolar disorder and substance abuse found that the treatment for the addiction was more successful than the treatment for the mood disorder. Over the course of 3 years, symptoms of bipolar disorder improved only modestly, whereas 61 percent of the subjects were in full remission from their substance abuse disorder at the end of the study period (Drake et al., 2004). Successful treatment of the substance abuse in this study was associated with greater rates of independent living, employment, social contacts with non–substance abusers, and overall quality of life. Indeed, measuring psychosocial functioning is the most appropriate way to evaluate a behavioral intervention.

Before taking a more detailed look at pharmacological and psychosocial treatments for comorbid manic-depressive illness and substance abuse, we wish to reemphasize that although comparatively little is known about the most effective ways to treat these patients, recovery is unlikely unless both illnesses are addressed. Recognition of the substance abuse problem is the essential first step, and lack of recognition is a common obstacle to effective treatment. Substance-abusing patients with comorbid mood disorders are more difficult to treat, and long-term abstinence may take longer to achieve. Nevertheless, the extensive literature demonstrating that noncomorbid substance abuse disorder can be managed successfully with currently available treatments suggests the possibility, or even the likelihood, of good outcomes for appropriately treated manic-depressive patients as well.

Pharmacological Treatment

Although pharmacological treatment in the absence of psychosocial intervention is not an adequate treatment for substance abuse, effective medication can contribute to a positive outcome. This strategy may also allow the clinician to reduce the total number of drugs a patient must take, which may increase treatment adherence. Table 24-1 presents the results of open-label and placebo-controlled trials of mood stabilizers in patients with affective disorders and comorbid substance abuse (Levin and Hennessy, 2004).

Bipolar disorder in the presence of a comorbid substance abuse disorder may not respond well to lithium. A retrospective review of the medical records of 204 bipolar-I inpatients found that patients with substance abuse histories who received divalproex or carbamazepine remitted during hospitalization more often than did those who received lithium as the sole mood stabilizer (Goldberg et al., 1999). Additionally, an assessment of 44 patients using a structured interview found that dually diagnosed patients were more likely to be adherent to valproate than to lithium (Weiss et al., 1998). It may be that patients who are good lithium responders, that is, those with predominantly euphoric, or “classic” manias, may be less likely to use alcohol and drugs

TABLE 24–1. Open-Label and Placebo-Controlled Trials of Mood Stabilizers in Mood Disorders (Primarily Bipolar) with Comorbid Substance Abuse

Study	Substance (Sample Size)	Affective Disorder Diagnosed (Diagnostic Criteria)	Type of Trial/Setting	Medication/ Duration (weeks)	Concurrent Therapy	Affective Disorder Outcomes ^a	Drug Craving ^a	Drug Use ^a
Gawin and Kleber, 1984	Cocaine (16)	4 cyclothymia, 3 dysthymia, 2 major depressive disorder (MDD), 7 no diagnosis (<i>Diagnostic and Statistical Manual</i> , 3rd edition [DSM-III])	Open-label/outpatient	Lithium ^{b/12}	Weekly individual and group therapy	Not assessed	↓ for 3-year lithium-treated cyclothymic patients only; measured by a 20-point analog scale	Self-reported ↓ for lithium-treated cyclothymic patients only; urine drug screen (UDS) collected every 3 to 6 weeks during the trial
Nunes et al., 1990	Cocaine (10)	Hypomania or cyclothymia (DSM-III, revised [DSM-III-R])	Open-label/outpatient	Lithium/12	Drug counselor weekly	Improved hypomania in 5 patients as assessed by Cocaine Craving Scale Inventory (GBI)	↓ in 5 patients as assessed by Cocaine Craving Scale	3 patients cocaine-free for 3 weeks, as assessed by weekly UDS; of these, one achieved sustained abstinence
Brady et al., 1995	Alcohol, cocaine, or multiple substances (9)	Bipolar-I disorder (DSM-III-R)	Open-label/started medication inpatient, then followed outpatient	Valproate/24	None	↓ Hamilton Depression Scale (HAM-D) and Young Mania Rating Scale (YMRS)	Not assessed	↓ in days and amounts of substance used as assessed by Time-Line Followback (TLFB); UDS collected every other month

Geller et al., 1998	Alcohol (7); marijuana (2); alcohol and marijuana (14); inhalant (1); alcohol, inhalant, and cough syrup (1) (total of 25 adolescents)	Bipolar-I or -II disorder, or MDD with bipolar predictors (DSM-III-R)	Placebo-controlled/outpatient	Lithium or placebo/6 (13 lithium treated, 12 placebo treated)	Weekly interpersonal therapy modified for families	↑ Children's Global Assessment Scale (CGAS) ^c	Not assessed	Percentage of positive UDS significantly decreased in the lithium group compared with the placebo group ^c ; UDS collected weekly
Calabrese et al., 2001	Alcohol, marijuana, and/or cocaine (56)	Rapid-cycling bipolar-I or -II disorder (DSM, 4th edition, [DSM-IV])	Open-label/Outpatient	Lithium + divalproex/24	12-step-based intensive outpatient chemical dependency program	↓ HAM-D and YMRS, ↑ Global Assessment Scale (GAS) after 4 weeks of treatment; statistical/clinical significance not reported	Not assessed	14 patients met DSM-IV criteria for full remission of alcohol or drug abuse disorder after 6 months; no UDS
Brady et al., 2002	Cocaine (139: 57 with affective disorder [AD ^d], 82 with no affective disorder [NAD] ^d)	Lifetime diagnosis of bipolar-I or-II disorder, MDD, cyclothymia, dysthymia, or NAD (DSM-III-R)	Placebo-controlled/outpatient	Carbamazepine (CBZ) or placebo/12 (AD: 30 CBZ, ^d 27 placebo ^d ; NAD: 42CBZ, ^d 40 placebo)	Non-study-related, outpatient substance abuse treatment	Not significant (NS) ↓ HAM-D and Beck Depression Index (BDI) ^c but not YMRS for the CBZ/AD group	↓ for the entire sample, assessed by a 10-point Likert-type rating scale	Compared with other three groups, CBZ/AD group had NS trend toward ↓ percentage of positive UDS and significantly longer time to first cocaine use, as assessed by TLFB and Cocaine Use Inventory ^c ; UDS collected weekly

to self-medicate than those who have predominantly mixed states (and may therefore be more likely to respond to anti-convulsants).

As summarized in Table 24-1, only a few double-blind, placebo-controlled trials have included a substantial number of substance-abusing patients with affective illness (primarily bipolar disorder). A recent 24-week controlled study followed 59 patients with comorbid bipolar-I disorder and alcohol dependence who had been randomized in a double-blind fashion to receive either valproate or placebo in addition to standard therapy with lithium (Salloum et al., 2005). Patients who received valproate had significantly fewer heavy drinking days. Valproate plus lithium therapy also significantly prolonged the time to relapse to sustained heavy drinking—to an average of 93 days, compared with an average of 62 days for those taking lithium alone. Supporting the specific benefit of the anticonvulsant, higher valproate serum concentrations correlated with improved alcohol abuse outcomes. There were no statistically significant differences in mood symptoms between the two groups, reflecting the mood-stabilizing efficacy of lithium in both. This finding suggests that the reduced drinking observed in the valproate group was not simply the result of a more stable mood, and that a separate mechanism played a role in reducing alcohol intake.

Valproate enhances gamma-aminobutyric acid (GABA), which may be affected in substance abuse disorders. GABA neurons projecting to the nucleus accumbens, the reward center of the brain where addictive drugs have their effects, diminish the release of dopamine and may attenuate the reinforcing properties of these substances. Although the antimanic efficacy of valproate is well established, data on its use in patients with substance abuse disorders are limited. In one open-label study, the efficacy of valproate for acute detoxification of noncomorbid alcohol-dependent subjects was demonstrated. Valproate reduced the symptoms of withdrawal more rapidly and consistently than benzodiazepines (the current standard of care), and valproate-treated patients were abstinent at 6-week follow-up (Longo et al., 2002). Valproate is an attractive option in this population because, unlike benzodiazepines, it does not have abuse potential.

While the anticonvulsants carbamazepine and topiramate have not been examined in bipolar patients with comorbid alcohol abuse, both have been shown to have a place in the treatment of alcohol dependence. Carbamazepine has been used successfully to treat acute alcohol detoxification. In a study of 100 noncomorbid outpatients, carbamazepine was more effective than placebo in reducing symptoms of alcohol withdrawal, and patients taking it experienced a more rapid improvement in their ability to work (Bjorkqvist et al., 1976). In another study, carbamazepine was shown

to work more rapidly than a benzodiazepine in reducing symptoms of alcohol withdrawal (Malcolm et al., 2002). Carbamazepine was also found to be as effective as oxazepam—the standard of care in detoxification units—in a double-blind study, and by one measure it was superior. Subjects taking oxazepam showed an increase in global psychological distress from day 3 to day 7, whereas those taking carbamazepine exhibited a decline (Malcolm et al., 1989). After day 7, there was no difference between the two treatments.

Actively abusing patients generally require detoxification as a precursor to sobriety. However, detoxification is not a treatment for the underlying abuse disorder because by itself, it does not address the central issue of managing long-term craving and relapse. A 12-month study of carbamazepine provided evidence of its potential usefulness in preventing relapse. This double-blind, placebo-controlled study of 29 noncomorbid adult alcoholics found that carbamazepine decreased the number of drinks per drinking day and delayed the time to first episode of heavy drinking (Mueller et al., 1997).

Similarly, a double-blind, placebo-controlled trial of topiramate found a robust effect on the core symptoms of alcohol dependence. In this study, 150 subjects were treated over a period of 12 weeks with either placebo or an average of 300 mg/day of topiramate. Subjects receiving topiramate had fewer drinks per day, fewer heavy drinking days, and more days abstinent (Johnson et al., 2003). In another study, topiramate significantly reduced both alcohol consumption and craving in alcohol-dependent subjects (Johnson et al., 2003). On the other hand, while open-label studies have shown promising results for topiramate in the treatment of mania in noncomorbid patients with bipolar disorder, controlled trials have failed to confirm its antimanic efficacy (see Chapter 18).

Lamotrigine, an anticonvulsant with antiglutamatergic properties, is an effective mood stabilizer, especially against depression; that is, it stabilizes “from below” (see Chapter 19). We could find only one study of lamotrigine involving bipolar patients with comorbid alcohol dependence, that of Rubio and colleagues (2006). They gave open-label lamotrigine to 28 patients (21 bipolar-I, 7 bipolar-II, as diagnosed by the Structured Clinical Interview for DSM [SCID]) and assessed weekly changes in scores on the Hamilton Rating Scale for Depression (HAM-D), the Young Mania Rating Scale (YMRS), the Brief Psychiatric Rating Scale (BPRS), and a self-rated craving scale, as well as change in a biochemical indirect measure of alcohol consumption, carbohydrate-deficient transferrin (CDT). Significant improvement was noted in scores on all three mood scales ($p < .01$) and in both craving and consumption (as reflected in CDT) ($p < .001$).

Unlike mood stabilizers, other drugs that are effective in the treatment of substance abuse disorders may carry a risk of destabilizing a comorbid manic-depressive patient. For example, naltrexone has demonstrated efficacy in preventing relapse in noncomorbid alcohol dependence. However, some studies (Hollister et al., 1981; Latt et al., 2002), though not all (Chick et al., 2000), have raised the question of whether naltrexone causes depression when used to treat alcohol dependence, possibly by blocking the positive mood effects associated with opioid peptides. Two cases reported by Sonne and Brady (2000) illustrate the potential problems bipolar patients can experience when given naltrexone for comorbid alcohol dependence. Both patients experienced severe adverse effects after taking a single dose of naltrexone and refused to continue the medication. One experienced dysphoria. Both were hypomanic at the time of naltrexone administration, and the authors noted that mania may be associated with the production of higher levels of endogenous opiates (Olson et al., 1996), which would make individuals in this state exquisitely sensitive to the actions of an opiate antagonist.

Disulfiram may also be problematic in some comorbid patients. Under normal conditions, the prospect of the aversive alcohol-disulfiram reaction would discourage alcohol use. However, manic patients experiencing impaired judgment and impulsivity may not adequately appreciate the serious consequences of drinking while taking this drug.

Acamprosate is the most recently approved treatment in the United States for the maintenance of abstinence from alcohol. Unlike naltrexone, acamprosate does not reduce the reward associated with alcohol consumption, nor does it cause an aversive reaction as does disulfiram. Indeed, the mechanism of action of acamprosate in the treatment of alcohol dependence is not well understood. It is thought, however, that acamprosate affects both GABA and glutamate activity. Animal studies suggest it restores the normal balance between neuronal excitation and inhibition that is altered in chronic alcohol abuse (Bertón et al., 1998). A large multicenter trial comparing acamprosate and placebo in 455 alcohol-dependent adults found that the mean cumulative duration of abstinence was significantly greater in the acamprosate group (139 versus 104 days). At the end of the 1-year study, 41 (18.3 percent) of the acamprosate-treated patients and 16 (7.1 percent) of the placebo-treated patients had been continuously abstinent (Whitworth et al., 1996). None of the patients in the study had comorbid mood disorders, however. Similar results were reported by Sass and colleagues (1996), who found that over a period of 48 weeks, acamprosate-treated patients (with no comorbid mood disorder) were abstinent 62 percent of the days, compared with 45 percent for patients taking placebo.

Acamprosate is well tolerated; diarrhea was the most common side effect reported by Whitworth and colleagues (1996). Potentially relevant to the treatment of comorbid patients, however, are results of clinical trials showing an elevated risk of suicidality among acamprosate-treated patients compared with those taking placebo. Completed suicides were similar in the two groups: 3 (.13 percent) of 2,272 acamprosate-treated and 2 (.10 percent) of 1,962 placebo-treated patients (.10 percent). However, suicidal events, including attempts and ideation, occurred in 2.4 percent of patients who received acamprosate for at least a year, compared with 0.8 percent of those who received placebo. The clinical relevance of these numbers is not yet fully understood, however, and it is essential to weigh the long-term risks of the untreated illness against the potential risks of this demonstrably effective medication.

Cocaine abuse and dependence are also common among patients with bipolar disorder, in part because of the drug's short-term antidepressant effect and in part because it extends and heightens hypomanic periods. As with alcohol abuse, the antimanic anticonvulsant medications may be useful in the treatment of cocaine abuse. In one study of a group of adults with cocaine dependence, some of whom also had a major affective disorder, there was a trend toward fewer cocaine-positive urine tests for those taking carbamazepine compared with those taking placebo (Brady et al., 2002). More than half of the patients in this study did not have a concurrent mood disorder, however, and among these "pure" cocaine abusers, carbamazepine had no effect on cocaine use compared with placebo. The benefit, therefore, may have been mediated by carbamazepine's mood-stabilizing capability rather than by an effect on cocaine craving per se. This finding supports the possibility that comorbid patients who receive treatment for bipolar disorder alone may be better able to reduce their substance abuse. This finding also is consistent with the observation that periods of abnormal mood tend to be associated with increased drug use.

Open-label lamotrigine was found to produce a statistically significant improvement in mood and a significant reduction in drug craving (but not a reduction in drug use) in a group of 30 bipolar patients with comorbid cocaine dependence (Brown et al., 2003). In a subsequent extension of this study involving an additional 32 cocaine-dependent bipolar patients, Brown and colleagues (2006) replicated their initial findings of improved mood and reduced craving, and in addition were able to document a significant reduction in cocaine use, as reflected in money spent on the drug. In another group of such patients, reductions in craving and improvement in mood were reported with open-label quetiapine (Brown et al., 2002).

Psychosocial Treatment

The most widely known and used psychosocial program for alcoholism, AA, has more than 1 million members participating in more than 30,000 groups that convene in at least 70 different countries. Determining the program's efficacy and delineating the types of individuals for whom it is most beneficial are difficult in anonymous, self-help group settings, however. As Ogborne and Glaser (1985) pointed out, it remains unclear (1) what proportion of any population of problem drinkers would either accept or benefit from a referral to AA; (2) whether benefits derived from involvement with AA are greater than those gained from other substance abuse treatment programs; and (3) whether involvement with AA can have any detrimental effects on some of those who participate. A meta-analysis of the literature on AA found that the correlation between participation and drinking outcomes was more positive among outpatient than inpatient samples; better-designed studies were more likely to report positive psychosocial outcomes related to AA attendance. In general, however, studies of AA have lacked sufficient statistical power to detect relationships of interest (Tonigan et al., 1996).

While there is a paucity of well-controlled studies, our clinical experience supports the widely held belief that AA benefits many individuals at little or no cost to themselves or to society. The program apparently derives much of its success from the continuous support, hope, and help provided by peers; from exposure to successfully abstinent alcoholics; from the substitution of other AA members for former drinking companions; and from increased self-regard gained through helping others in like circumstances (Vaillant, 1978). On the other hand, not all alcoholics are attracted to or able to tolerate AA's self-examining approach or religious underpinnings. Of particular relevance to manic-depressive patients with drinking problems is the opposition expressed by some AA members to the use of "chemicals" other than alcohol, including mood-stabilizing medications. Yet AA neither endorses nor prohibits the use of psychiatric medications by its members. The pamphlet *AA: Medications and Other Drugs*, published by the AA General Service Conference, clearly distinguishes necessary and important prescription medications from self-administered drugs.

To assess systematically the attitudes of AA members toward the use of medications, 277 AA members were surveyed anonymously. They were asked about their attitudes toward the use of alcohol relapse prevention medication and their experiences with any psychotropic medications while in AA. Nearly a third (29 percent) reported personally experiencing some pressure to stop taking a medication (of any type); however, 69 percent of these individuals

continued taking the medication. Only 12 percent of respondents said they would tell another member to stop taking medication (Rychtarik et al., 2000).

Double Trouble in Recovery (DTR) is a 12-step self-help program specifically designed for persons with chronic mental illness and a comorbid substance abuse disorder. The program was started in 1989 and currently has more than 200 groups in the United States. DTR specifically supports both abstinence from intoxicating substances and adherence to psychiatric medication regimens. Indeed, a 1-year prospective longitudinal study of 310 participants in the program found that consistent attendance at DTR meetings was associated with better adherence to medication regimens (Magura et al., 2002). Although the study was not randomized, this relationship persisted after controlling for baseline variables that were independently associated with adherence (living in supported housing, having fewer stressful life events, and having a lower severity of psychiatric symptoms). A fifth of the patients in the study had bipolar disorder, a fifth had unipolar depression, and about half had schizophrenia.

More recently, 129 stabilized outpatients meeting *Diagnostic and Statistical Manual* (DSM) criteria for drug dependence (cocaine, heroin, or cannabis) and serious mental illness (55 percent affective disorders, polarity not specified) were randomly assigned to 6 months of Behavioral Treatment for Substance Abuse in Severe and Persistent Mental Illness (BTSAS) or to a manualized control condition, Supportive Treatment for Addiction Recovery (STAR) (Bellack et al., 2006). BTSAS entails a social learning intervention, including motivational interviewing, social skills training, and a urinalysis contingency. Participants were taught how to refuse drugs, engage in alternative social activities, and develop non-drug-using social contacts. The STAR program consisted of support groups, some education, and checking of urine samples, but with no systematic feedback. The BTSAS program was significantly more effective than STAR in terms of attendance at treatment sessions, clean urine test results, and survival in treatment. BTSAS participants reported a significant increase in general life satisfaction, were less likely than STAR participants to be hospitalized, and were less likely to be arrested.

Group therapy has been shown to be effective for treatment of both bipolar disorder and substance abuse disorders; however, few structured group therapies have been developed to address comorbid substance abuse and bipolar disorder simultaneously. An exception is Integrated Group Therapy (IGT), a manualized relapse prevention therapy that achieves an integrated approach by addressing topics that are relevant to both disorders and by highlighting common aspects of recovery from, and relapse to, each disorder (Weiss et al., 1999, 2007). A 6-month, nonrandomized

pilot study found that, compared with patients who did not receive group therapy, those who received IGT had significantly better outcomes on the Addiction Severity Index drug composite score, spent more months abstinent, and were more likely to achieve at least two consecutive abstinent months. The nonrandom design of this study did not make it possible to compare the efficacy of IGT and other forms of group therapy, however. A more recent, randomized study of 62 patients found that those receiving IGT had significantly less substance abuse (Weiss et al., 2007).

In contrast to the benefits of the manualized IGT, unstructured therapy does not appear to be helpful, and it may actually be harmful, for substance-abusing patients. Weiss and colleagues (2000) followed 24 patients receiving unstructured psychosocial treatment after hospital discharge. It was found that psychotherapy and AA attendance decreased over time among the study subjects, and the focus of patients' psychotherapy gradually became more general, so that decreasing emphasis was placed on their specific disorders. During this period, there was a trend toward more frequent drug use, while the patients' mood symptoms did not change significantly.

ANXIETY DISORDERS

Panic Disorder

Uncomplicated panic disorder is generally treated pharmacologically with selective serotonin reuptake inhibitors (SSRIs) or high-potency benzodiazepines. While the use of SSRIs in unipolar depression is relatively straightforward, in bipolar patients the risk of switches into mania/hypomania/mixed states and the risk of long-term destabilization must be taken into account (see Chapter 19 for a full discussion of these critical issues). The risk of switch/destabilization with antidepressants may be increased by substance abuse comorbidity. For example, in a sample of 48 bipolar patients, 20 of whom had comorbid substance abuse, the probability of having a history of an antidepressant-induced mania was seven times greater among the comorbid patients. Overall, 60 percent of the bipolar patients with comorbid substance abuse had become manic when given an antidepressant (Goldberg and Whiteside, 2002). Although comorbid panic disorder represents a case in which an SSRI may well be needed, it is critical to first optimize mood stabilization. Indeed, as noted later, some mood stabilizers themselves have been shown to have therapeutic effects in panic disorder that could obviate the need for an SSRI.

Benzodiazepines, which are also effective in panic disorder, are frequently used during acute mania. Although they may not possess inherent mood-stabilizing properties, they can be highly effective in helping to normalize sleep, which

is a central objective in the treatment of mania. Apart from some reports of alprazolam-induced mania (Goodman and Charney, 1987), benzodiazepines do not appear to destabilize bipolar disorder. Given the high prevalence of substance abuse disorders in this population, however, benzodiazepines must be used cautiously because of their potential for abuse.

The frequency with which panic disorder occurs comorbidly with bipolar disorder may reflect a common underlying etiology (see Chapter 7). Use of a mood stabilizer to treat both illnesses simultaneously can be an advantageous strategy. Unfortunately, lithium, for which there is the largest database demonstrating efficacy in bipolar disorder, has not been the subject of controlled studies in anxiety disorders. There are more data on antipanic/anxiolytic effects among the anticonvulsants. For example, valproate has been reported to have some beneficial effects in the treatment of panic disorder, possibly due to GABA agonism (Keck et al., 1993). An open-label study of the efficacy of valproate in rapid-cycling bipolar disorder found that 95 percent of patients with comorbid panic disorder reported improvement in their panic symptoms when taking the drug. On the other hand, a related anticonvulsant, carbamazepine, was not found to be effective in a small trial of 14 patients with non-comorbid panic disorder. Only one patient experienced marked and sustained clinical improvement on the drug, while 50 percent actually experienced an increase in panic attacks (Uhde et al., 1988). A double-blind, placebo-controlled study of gabapentin in 103 patients with panic disorder (Pande et al., 2000) found it to be no different than placebo. However, a post hoc analysis did reveal that gabapentin was superior to placebo among the most severely ill patients. With respect to bipolar disorder, placebo-controlled trials have failed to demonstrate efficacy in mania (Pande et al., 1999). Pregabalin, a novel anticonvulsant that binds to a subunit of certain calcium channels, is approved as an add-on in the treatment of partial seizures. It has been found to be effective in controlled trials of generalized anxiety disorder,¹ with a side-effect profile that is generally more favorable than that of comparators such as benzodiazepines or SSRIs. In a recent placebo-controlled, head-to-head comparison of pregabalin with venlafaxine in treating generalized anxiety disorder, only pregabalin achieved significant efficacy, as early as the first week, on all a priori primary and secondary efficacy measures (Montgomery et al., 2006). Pregabalin, 400 mg, was better tolerated than venlafaxine, as reflected in significantly fewer dropouts due to side effects. These results (if replicated), together with evidence that among the second-generation antidepressants, venlafaxine is associated with the highest risk of manic switch (Leverich et al., 2006), underscore the importance of evaluating the efficacy of pregabalin in the treatment of comorbid anxiety disorders in bipolar patients.

Atypical antipsychotics are playing an increasingly important role in the treatment of bipolar disorder. All have significant effects on the serotonin system; in contrast to the SSRIs, however, this effect consists of direct stimulation or inhibition of presynaptic and postsynaptic serotonin receptors. Results of some studies suggest that certain of these agents, as well as the typical antipsychotics, including trifluoperazine (Mendels et al., 1986), may have anxiolytic properties in general (Wilner et al., 2002; Gao et al., 2006) as well as in bipolar patients (Hirschfeld et al., 2006). To our knowledge, however, there have been no controlled trials of atypical antipsychotics in the treatment of panic disorder per se, so their utility for this purpose remains speculative.

For optimal results, psychotherapeutic interventions should generally be part of the comprehensive management of comorbid panic disorders. Cognitive-behavioral therapy has been shown to be effective in treating many anxiety disorders and is considered a first-line treatment.

Social Anxiety Disorder

Little is known about the pharmacological treatment of comorbid social anxiety disorder. Monoamine oxidase inhibitors (MAOIs) and serotonergic agents such as SSRIs are effective for noncomorbid social anxiety disorder, but as noted earlier, these medications can destabilize bipolar disorder. Although gabapentin has not been shown to be effective in bipolar disorder, one double-blind trial showed positive results in 69 patients with noncomorbid social anxiety disorder (Pande et al., 1999). Presumably, gabapentin would be less likely than antidepressants to cause destabilization in patients with comorbid social anxiety disorder. The role of some of the atypical antipsychotics in reducing anxiety symptoms in bipolar disorder has already been noted. As with the other comorbid anxiety disorders, cognitive-behavioral therapy should generally be part of the management strategy.

Obsessive-Compulsive Disorder

Serotonergic antidepressants are the most frequently used treatment for obsessive-compulsive disorder (OCD); benzodiazepines (Hollander et al., 2003) and antidepressants without serotonergic activity (Vulink et al., 2005) are not effective for patients with this disorder. The use of antidepressants carries risks for these patients, however. A study of 263 patients with OCD who had not been diagnosed with bipolar disorder nevertheless found that 13 percent had experienced a hypomanic episode, and that many of the hypomanias occurred after treatment with an antidepressant (Lensi et al., 1996). Only 1.5 percent had experienced full manias, a finding consistent with data showing that most patients with comorbid OCD and bipolar disorder have the bipolar-II type (Perugi et al., 1997).

As noted earlier, mood stabilizers such as lithium and the atypical antipsychotics have some degree of serotonergic activity, but the evidence supporting their efficacy in treating OCD is mixed. The findings of two controlled studies of lithium augmentation of SSRIs in the treatment of refractory OCD without comorbid bipolar disorder were negative (McDougle et al., 1991; Pigott et al., 1991). On the other hand, randomized, double-blind, placebo-controlled trials of atypical antipsychotics (risperidone and quetiapine) have shown some efficacy when these drugs are taken adjunctively by OCD patients resistant to SSRIs (McDougle et al., 2000; Denys et al., 2004).

Among patients with OCD, the degree of insight into the irrationality of obsessions varies along a spectrum. In the most severe cases, the degree of insight is low, and many such patients have psychotic delusions. These patients also tend to have less favorable responses to standard antidepressant treatment (Solyom et al., 1985). Antipsychotic augmentation of SSRIs has been studied in resistant cases of OCD, with mixed results. A small open-label study of risperidone augmentation showed beneficial effects (Saxena et al., 1996), but in a case series of six patients, risperidone actually exacerbated OCD symptoms while successfully treating psychotic symptoms (Alevizos et al., 2002). Antagonism of postsynaptic serotonin receptors is a hypothesized explanation for this detrimental effect. A double-blind study of olanzapine augmentation in patients nonresponsive to fluoxetine likewise did not show a positive effect (Shapiro et al., 2004).

The treatment studies described above all evaluated patients with noncomorbid OCD. Evidence suggests, however, that comorbid OCD is different in important ways and may respond differently to treatment (see Chapter 7). Some data suggest that the co-occurrence of OCD and bipolar disorder reflects variability in the expression of a single morbid process that is responsible for both the mood and anxiety disorders (Strakowski et al., 1998). This hypothesis would suggest that a focus on mood stabilization is the most effective way to address a comorbid patient's OCD symptoms.

A naturalistic study of 38 inpatients with comorbid bipolar disorder and OCD found that drug treatment with clomipramine and, to a lesser extent, with SSRIs was associated with hypomanic switches in these patients, especially those not treated concomitantly with mood stabilizers (Perugi et al., 2002). A combination of multiple mood stabilizers was necessary in 16 of the patients (42.1 percent), and a combination of mood stabilizers with atypical antipsychotics was required in 4 cases (10.5 percent). Overall, OCD–bipolar patients tended to show a less positive outcome with respect to both mood symptoms and general functioning (Perugi et al., 2002).

Post-Traumatic Stress Disorder

No controlled studies have specifically evaluated treatment for the comorbidity of bipolar disorder and post-traumatic stress disorder (PTSD). Because of the greater severity of pathology seen with this comorbidity compared with PTSD alone, effective treatments for noncomorbid PTSD may not work as well when used with bipolar patients. Nevertheless, there is substantial interaction between the two illnesses, whereby the symptoms of one can destabilize the other: abnormal mood states can decrease resilience and increase the risk of developing PTSD in response to a traumatic experience; conversely, both acute and chronic overarousal associated with PTSD can exacerbate mood states by increasing stress and interfering with sleep. Given this interaction, improvement of either disorder has the potential to reduce the symptoms of the other.

There is good evidence for the efficacy of both pharmacotherapy and psychotherapy in patients with noncomorbid PTSD. In particular, an international consensus group has identified SSRIs as an appropriate medication for PTSD because of the large database of randomized controlled trials supporting their efficacy (Ballenger et al., 2004). As with other anxiety disorders, however, the risks associated with PTSD must be carefully weighed against the risks of antidepressant treatment in patients with bipolar disorder, and other alternatives considered. It appears appropriate to attempt other strategies first, such as optimizing mood stabilizers.

With one exception, there are no data from controlled trials on any of the accepted mood stabilizers in treating PTSD. The exception is a double-blind, placebo-controlled trial of lamotrigine in 15 subjects with noncomorbid PTSD, which found a response rate of 50 percent compared with 25 percent for placebo (Hertzberg et al., 1999). With respect to lithium, it should be noted that bipolar disorder complicated by anxiety generally does not respond as well to the drug as does uncomplicated bipolar disorder; on the other hand, results of open trials and case reports suggest that lithium may be associated with a reduction in the arousal, anger, and irritability associated with noncomorbid PTSD (Forster et al., 1995). The results of open trials also suggest the efficacy of valproate in noncomorbid PTSD (Fesler, 1991). And open studies of carbamazepine have found reductions in intrusive memories, flashbacks, sleep disturbance, impulsivity, and violent behavior (Keck et al., 1992).

Various studies, both controlled and uncontrolled, have found adjunctive use of risperidone, olanzapine, and quetiapine to be effective in treating noncomorbid PTSD in patients not responding well to standard treatment (usually antidepressants) (Hutterfield et al., 2001; Hamner et al.,

2003; Monnelly et al., 2003). Benzodiazepines, commonly used in bipolar disorder, have shown efficacy in treating some anxiety disorders, but they can increase the likelihood of developing PTSD when used during the acute post-trauma period and therefore should be avoided at those times.

As with other comorbid disorders seen in manic-depressive patients, psychotherapy has the advantage of providing an evidence-based intervention for PTSD apparently without the risks of potentially destabilizing drugs. Nevertheless, it is important to note that in some cases, psychotherapy carries risks of its own, and therapies shown to be effective in uncomplicated PTSD may not be effective in patients with comorbid bipolar disorder.

A recent consensus statement identified cognitive-behavioral therapy as an appropriate treatment for PTSD, although usually in combination with an SSRI antidepressant (Ballenger et al., 2004). There is also evidence for the efficacy of cognitive-behavioral therapy when used alone (Najavits et al., 1998).

Imaginal exposure therapy, which involves repeated recounting of the traumatic experience, has been shown to promote habituation of pathological anxiety and subsequent improvement in symptoms and functioning (Tarrier et al., 1999b). Some reports have suggested that imaginal exposure can be clinically problematic, however (Tarrier et al., 1999a). In particular, reexperiencing a traumatic event may be accompanied by shame, guilt, and anger. On the other hand, Foa and colleagues (2002) found that temporary exacerbation of symptoms during the course of treatment occurred in a minority of patients and tended to disappear during long-term follow-up. Moreover, patients who experienced temporary symptom exacerbation benefited from the treatment relative to other patients in this study. Despite generally reassuring data, however, this type of psychotherapy has not been tested in patients with comorbid PTSD and bipolar disorder. Because emotional upheaval can trigger mood episodes in bipolar patients and may result in destabilizing sleep loss, the risk associated with this treatment may be greater in comorbid patients. Yet given the substantial amount of data supporting its efficacy, imaginal exposure should not be avoided in patients with comorbid bipolar disorder; rather, it is prudent to use extra care and to remain vigilant for any signs of exacerbation of the clinical picture.

EATING AND PERSONALITY DISORDERS

The most common medications used in the management of eating disorders are the antidepressants, especially SSRIs; mood stabilizers have not been well studied in these disorders. Nevertheless, there are some limited data on the use

of lithium to treat anorexia nervosa. A small double-blind, placebo-controlled trial of lithium in 16 young women with noncomorbid anorexia nervosa showed, not surprisingly, increased weight gain in the lithium group (Gross et al., 1981). The patients randomized to lithium showed significantly greater improvement on an item measuring “denial and minimization of illness.” On the other hand, a larger study of depressed bulimic women showed a sizable placebo response and failed to demonstrate superiority for lithium in decreasing bulimic behavior (Hsu et al., 1991). In both studies, lithium was well tolerated, with no reports of serious adverse events.

Given its tendency to cause weight loss, topiramate has received some attention for the treatment of eating disorders associated with overconsumption of food. A controlled trial designed to evaluate topiramate in the treatment of noncomorbid binge eating disorder randomized 61 outpatients to receive placebo or flexible-dose topiramate (25 to 600 mg/day). Compared with placebo, topiramate was associated with a significantly greater reduction in binge frequency (McElroy et al., 2003). A separate placebo-controlled study also found a significant reduction in number of binge days per week among patients with noncomorbid bulimia nervosa who were treated with topiramate (Hoopes et al., 2003).

As noted earlier, zonisamide is another anticonvulsant that has been associated with weight loss, and it may have utility in the treatment of eating disorders. An open-label 12-week study of zonisamide in patients with noncomorbid binge eating disorder found significant decreases in binge eating, weight, and body mass index among patients who completed the study. There was a high dropout rate, however, with only 8 of 15 patients completing the study (McElroy et al., 2004).

Medication that causes weight gain may be useful in the treatment of anorexia nervosa. A short open trial of olanzapine in treating noncomorbid anorexia nervosa followed 17 patients for up to 6 weeks. Olanzapine was associated with a significant reduction in depression, anxiety, and core eating disorder symptoms and a significant increase in weight (Barbarich et al., 2004). A somewhat longer study (10 weeks) also found overall weight gain; 3 of 14 patients with anorexia nervosa who completed the study achieved their ideal body weight. Surprisingly, however, 4 of the 14 lost an average of 2.25 pounds (Powers et al., 2002).

Eating disorders are frequently comorbid with personality disorders (Braun et al., 1994; Zanarini et al., 2004). So, too, is bipolar disorder (see Chapter 10). Relatively little is known about the treatment of comorbid bipolar disorder and borderline personality disorder, although the treatment course is more problematic (Swartz et al., 2005). Anticonvulsant medications play a useful role in treating some patients

with borderline personality disorder (Frankenburg and Zanarini, 2002; Bellino et al., 2005; MacKinnon and Pies, 2006), and there is evidence that some patients with both bipolar illness and borderline personality disorder show marked improvement with a combination of pharmacotherapy and psychotherapy (Bieling et al., 2003; Swartz et al., 2005).

GENERAL MEDICAL DISORDERS

Cardiovascular Disease

Patients with bipolar disorder and recurrent unipolar depression are at increased risk for cardiovascular disease; any evidence of such disease should be managed by a cardiac specialist. Beyond careful screening for conditions associated with heart disease, such as diabetes and dyslipidemia, treatment of these conditions is beyond the expertise of most mental health professionals.

Of significance, treatment with lithium may reduce excess cardiac mortality associated with bipolar disorder. An international multicenter trial found that cardiovascular mortality among patients who took lithium for 2 years or longer ($N=641$) was the same as or only slightly higher than that found in the general population. Conversely, cardiovascular mortality remained high among those who took lithium for less than 2 years (Ahrens et al., 1995). Patients in this study who subsequently dropped out of lithium treatment lost the positive effects, however, and had a standardized mortality ratio (which included suicide mortality) 2.5 times higher than that in the general population (Muller-Oerlinghausen et al., 1996). SSRI use has also been associated with decreased morbidity and mortality in cardiovascular disease (Taylor et al., 2005; Tiihonen et al., 2006).

Obesity

The efficacy of most treatments for obesity is modest at best, and often temporary. Short-term caloric restriction, in particular, can lead to weight cycling. From the perspective of mood disorders, weight cycling is associated not only with physiological problems but also with psychological problems, such as diminished self-esteem and life satisfaction and a more negative body image (Friedman et al., 1998). From a dietary standpoint, the most effective approach to weight control among bipolar and recurrent unipolar patients is carbohydrate restriction.

Most agents used in the treatment of bipolar disorder are associated with weight gain, as well as with other components of the metabolic syndrome, such as insulin resistance and atherogenic dyslipidemia (see Chapter 20). Among the atypical antipsychotics used in the treatment of mania, ziprasidone and aripiprazole are relatively weight-neutral.² It is important to note that with this class of drugs, medical

complications associated with obesity, such as insulin resistance, can occur even in the absence of obesity (Henderson et al., 2005). It remains to be seen whether the lack of weight gain associated with ziprasidone and aripiprazole is accompanied by a fully benign metabolic profile. Risperidone appears to cause fewer problems with glucose utilization compared with clozapine and olanzapine (Henderson et al., 2005). Among the established mood stabilizers, only lamotrigine does not cause weight gain, nor does it increase the risk of diabetes, atherogenic dyslipidemia, or other components of the metabolic syndrome.

As noted earlier, unlike many medications used in psychiatry, topiramate has been associated with weight loss rather than weight gain. Because so many mood stabilizers cause weight gain, topiramate may play a significant role as an antidote to iatrogenic weight gain in patients with bipolar disorder. A 6-month placebo-controlled, dose-ranging trial of topiramate for weight loss in obese patients found that all doses of the drug (64 to 384 mg/day) resulted in comparable weight loss, which was significantly greater than that observed with placebo. Mean weight loss from baseline to week 24 ranged from 4.8 to 6.3 percent of pretreatment body weight, compared with 2.6 percent with placebo (Bray et al., 2003). However, neurocognitive side effects, which are dose dependent, can interfere with patients' acceptance of topiramate; difficulty with memory, concentration, and attention were the most frequently observed of these effects.

Zonisamide has been associated with weight loss in patients with epilepsy; in a 16-week controlled trial involving 61 obese patients, zonisamide and a hypocaloric diet resulted in more weight loss than a hypocaloric diet alone (Gadde et al., 2003). The drug has also been reported to have therapeutic properties in a small number of open studies and case series of bipolar patients (see Chapter 18) (Kanba et al., 1994).

Bupropion was shown to be superior to placebo in facilitating weight loss in three controlled studies (Gadde et al., 2001; Anderson et al., 2002; Jain et al., 2002). In one of these, the weight loss was maintained for 48 weeks (Anderson et al., 2002). Moreover, in expert consensus guidelines, bupropion has been identified as a preferred antidepressant for patients with bipolar depression, although there is only limited supporting evidence from controlled trials.

Sibutramine, an antiobesity agent, is a serotonin–norepinephrine reuptake inhibitor that has been shown to improve depressed mood in patients with binge eating disorders (Apolinario et al., 2003). Although no studies have been done in patients with bipolar disorder, a dual reuptake inhibitor of this nature might be expected to lead to mood destabilization. Venlafaxine, an antidepressant dual reuptake inhibitor that has been associated with switches into mania, has not been associated with long-term weight loss. Duloxetine has not been formally evaluated for weight loss activity.

The most effective treatment for severe obesity is gastric bypass surgery, which leads to long-term loss of approximately 50 percent of excess body weight (Reinhold, 1994). This is a major abdominal surgery, however, associated with significant discomfort and medical complications. After the surgery, patients undergo extensive changes in their ability to tolerate food. They experience a drastic reduction in the amount of food they are able to consume, as well as a reduced ability to tolerate a wide variety of foods, including simple carbohydrates, foods with high fat content, and carbonated beverages. Patients who fail to follow a strict dietary regimen experience nausea, vomiting, and other aversive symptoms. The physical distress experienced by patients who do not adhere to the dietary rules may serve as a type of punishment, as characterized by the operant conditioning model, thereby facilitating long-term behavior change. It is interesting that despite the severity of the stress associated with this weight loss treatment, gastric bypass surgery has been found to lead to improvement in depressive symptoms (Dymek et al., 2001). This improvement is probably related directly to the treatment's success in bringing about long-term weight loss. Of course, with manic-depressive patients, especially the bipolar subgroup, the risks associated with major surgery (e.g., stress, disrupted sleep, temporary disruption of medications) need to be carefully weighed.

Thyroid Dysfunction

The thyroid gland produces two hormones—the prohormone thyroxine (T_4) and the more biologically active triiodothyronine (T_3). T_4 is partly converted into T_3 by deiodinases. Thyroid hormones enter the cell, bind to nuclear receptors, and alter the expression of specific genes that affect the synthesis of key enzymes required for neurotransmitter production, as well as glial cell proliferation and myelination.

As reviewed in Chapter 19, T_3 is used mainly in the adjunctive treatment of major depression and has been shown to accelerate the response to tricyclic antidepressants (Prange et al., 1969; Goodwin et al., 1982). Women in particular appear to benefit from the combination of T_3 and a tricyclic antidepressant. T_3 has also been used as an augmentation strategy in treatment-resistant depression (Aronson et al., 1996).

T_3 , the most active thyroid hormone, carries the risk of inducing a hyperthyroid state. Because T_4 is the prohormone, the homeostatic mechanism of reduced conversion to T_3 allows the body to maintain a euthyroid state more easily. Unlike T_3 , moreover, T_4 has not been associated with osteoporosis (Nuzzo et al., 1998).

Supraphysiological doses of T_4 were shown to be effective in the maintenance treatment of prophylaxis-resistant

affective disorder in a prospective open-label study of 21 consecutively enrolled patients. The mean T₄ dose at the study's end was 378.6±90.2 µg/day. In this study, subjects with bipolar disorder benefited more from the T₄ treatment than did subjects with unipolar major depressive disorder (Bauer et al., 2002).

Despite some doubts that have been raised regarding the relationship between hypothyroidism and rapid cycling (Post et al., 1997), several open studies have demonstrated beneficial effects of high-dose T₄ augmentation in patients with rapid-cycling bipolar disorder resistant to conventional prophylactic drugs (Stancer and Persad, 1982; Leibow, 1983; Bauer and Whybrow, 1990). Double-blind studies are needed to confirm these results. (For more detail, see Chapter 20.)

There is a significant body of evidence supporting the connection between subclinical hypothyroidism and a less favorable course of illness in mood disorders (see Chapters 7 and 20). Unfortunately, controlled studies of thyroid supplementation for such patients have not been conducted.

CONCLUSIONS

Given the frequency of occurrence of comorbid conditions in manic-depressive illness, especially the bipolar subgroup, clinicians should screen specifically for comorbid substance abuse, anxiety disorders, obesity, eating disorders, and general medical disorders. All illnesses should be addressed individually when a treatment plan is developed. Depending on the relationship among the comorbid diagnoses, the successful treatment of one disorder may lead to improvement in the others. Nevertheless, this is not always the case, and the goal should always be full remission of

each disorder individually. In the case of addiction, even if the substance abuse disorder was initially caused by symptoms of the mood disorder, the patient undergoes neurophysiological and psychological changes once the addiction is established that necessitate disease-specific interventions.

A mood stabilizer should always be initiated before other pharmacological options are considered. If the bipolar or recurrent unipolar disorder and the comorbid illness share some common pathophysiological processes, it is possible that the mood stabilizer will improve both conditions simultaneously.

For most of the comorbid disorders, the psychosocial component of treatment, ranging from 12-step programs for substance abuse to cognitive-behavioral therapy for comorbid anxiety, is a vital component of management. Further, psychotherapy alone can help some patients with comorbid anxiety disorders, enabling them to avoid the potentially destabilizing effects of antidepressants. Patients receive the most benefit from this kind of therapy once their bipolar disorder has been stabilized.

The pharmacological treatment of comorbid conditions requires careful weighing of risks and benefits. Treatment often involves using medications off label and venturing beyond the limited database of available evidence. Many patients are likely to require complex combinations of medications and psychotherapy for optimal response.

NOTES

1. Feltner et al., 2003; Pande et al., 2003; Pohl et al., 2005; Rickels et al., 2005.
2. Of these two atypical agents, ziprasidone is less likely to be associated with weight gain.

Lithium . . . is the lightest of the solid elements and it is perhaps not surprising that it should in consequence possess certain modest magical qualities.

—G. P. Hartigan (1959)

Manic-depressive illness carries the risk of suicide throughout its course (see Chapter 8). The precise timing of suicide cannot be predicted, but there are almost always warning signs in the preceding days to weeks. The challenge for clinicians is to discern, from a complex and fluctuating clinical picture, suicidal intent in a patient, and to assess the presence of various risk factors for suicide, which may manifest as symptoms, stressful situations, and/or comorbidities. Specifically, treatment of manic-depressive patients to prevent suicide has three key elements: (1) clinical assessment of intent and overall suicide risk; (2) intensive treatment of those acute symptoms associated with an increased risk of suicide; and (3) careful clinical follow-up of patients with suicide risk factors, with renewed attention to treating the patient's underlying affective disorder and comorbidities. While no approach is foolproof, treatment in a maximally supportive clinical environment can reduce the risk of suicide and save lives (Rucci et al., 2002; Knox et al., 2003; Bruce et al., 2004).

In 1999, the U.S. Surgeon General declared that suicide is a *preventable* public health problem (U.S. Public Health Service, 1999). This embracing of a public health perspective on suicide was prompted by compelling evidence that (1) mental illness was undiagnosed in about 50 percent of suicides (see Chapter 8), (2) inadequate treatment characterized the majority of those individuals who had been diagnosed (Isometsa et al., 1994; Isacsson et al., 1997; Oquendo et al., 1999), and (3) the majority of those who killed themselves had had some type of contact with the health care system in the months leading up to their death. In the final month before the act alone, according to results of more than 40 studies, nearly 45 percent of suicide victims had had contact with a primary care physician and another 20 percent with a specialist (Luoma et al., 2002).

These findings strongly suggest that many lives might be saved by educating physicians and the public in how best to recognize, accurately diagnose, and correctly treat those at risk for suicide.

In this chapter, we begin by reviewing the various aspects of assessment of acute and chronic suicide risk. We then address the clinical management of those patients assessed as being at high risk for suicidal behaviors. This is followed by a review of the literature on medical and psychological treatments used for acute clinical management of suicidal patients and for long-term suicide prevention. The final section presents conclusions.

ASSESSMENT OF ACUTE AND CHRONIC SUICIDE RISK

Communication of Suicidal Intent

The clinician's ability to discern a patient's suicidal intent, which includes suicidal ideation, plans, and behaviors, is one important component of any effort to prevent suicide. All too often a breakdown in communication occurs between clinician and patient during the months preceding suicide. Final contacts with clinicians are often filled with miscues, miscommunications, and missed opportunities for intervention. Clinicians frequently fail to ask explicit questions, and patients often evade such questions and disguise or deny their intent (Institute of Medicine [IOM], 2002).

This failure of communication is one of the most enduring and disturbing findings of the literature on suicide. It should be pointed out that most of the evidence on this phenomenon comes from retrospective studies, which have methodological limitations and biases (see Busch et al.,

2003). Nevertheless, the available retrospective evidence on recent health care contacts is widely interpreted as suggesting that suicidal patients, while often motivated to seek help, are reluctant to disclose their full intent and plans. Likewise, it is clear that many clinicians are reluctant to ask explicit questions about suicide.

In a now classic retrospective study, Barracough and colleagues (1974, p. 366) observed a trail of “unequivocal threats,” not “enlightened hindsight” after studying warnings of suicide in 64 depressed patients. The authors found that 30 percent of those who killed themselves had left a direct threat; when indirect communications were taken into account, the total reached 51 percent.

In another landmark study, Robins and colleagues (1959, 1981) found, in a retrospective evaluation of 134 consecutive suicides, that 69 percent had communicated their intent to commit suicide within a year of their death; 41 percent had done so through a direct and specific statement. Suicidal ideation was expressed more frequently to spouses, relatives, and friends than to physicians. Nearly half (47 percent) of the study sample had been diagnosed with manic-depressive illness, which included severe recurrent depression as well as bipolar disorder. None of these patients were manic at the time of their suicide, a finding borne out by subsequent research showing that classic euphoric mania is not an acute risk factor for suicide (see Chapter 8).

More recent studies likewise have documented communication barriers. Isometsa and colleagues (1995) conducted a large psychological autopsy study of everyone in Finland who had committed suicide during a 12-month period and whose last medical or psychiatric appointment had been within 1 month of their suicide ($N=571$). The investigators found that only 30 percent of psychiatric inpatients and 39 percent of outpatients had communicated their intent to mental health providers during their final appointment. The problem is even worse in primary care settings; one large study found that only 19 percent of patients treated in such settings who committed suicide had communicated suicidal intent to their medical providers (Isometsa et al., 1994).

In light of patients’ conflicting signals, it is no surprise that studies reveal the frequent failure of clinicians to identify those at greatest risk. Weeke (1979), studying clinicians’ evaluations of suicide risk in patients who later killed themselves, reported that only 13 percent had been assessed as “seriously suicidal”; clinicians had rated 58 percent as “suicide possible, not likely,” and 28 percent as “suicide quite unexpected.” In a study of 76 inpatient suicides, Busch and colleagues (2003) found that approximately 30 percent had been on “no precautions” at the time of their suicide in the hospital (an additional 15 percent had been on pass or

BOX 25-1. Points at Which to Repeat Suicide Assessments

- Prior to sustained therapeutic response—each visit
- First 6 months after hospital discharge—each visit
- In presence of a new, painful, or disabling medical condition
- In presence of a new or exacerbated comorbidity, especially anxiety, panic, or substance abuse
- At evidence of relapse or recurrence of symptoms
- At occurrence of major stresses, losses, threats, shame-inducing events
- With comorbid personality disorders: at times of vacations, reductions in treatment intensity (e.g., after hospital discharge), transfers of treatment or change of clinician
- On emergence of other acute risk factors not listed here (see Box 25-3)

recently discharged). This study also found that suicides occurred after suicidal intent had been expressly denied by patients. Fully 77 percent of hospital inpatients who committed suicide had, within 1 week of their suicide, denied suicidal ideation or intent in their last communication with physicians or staff. Similarly, a review of more than 30 cases of completed suicide revealed that in the majority of these cases, suicidal intent had been denied during the last communication to a clinician before the act was committed; the denial to the clinician had occurred despite earlier suicidal communications to a family member (J. Fawcett, personal communication, February 2004). Taken together, these studies suggest that many manic-depressive patients will not communicate, or will expressly deny, suicidal ideation or intent. This sobering reality means that the clinician must understand and be especially alert to other clinical risk factors, such as severe anxiety and panic, that are more predictive of suicide than expressed intent, at least in the short term, and that are amenable to direct pharmacological intervention (see the later discussion of acute versus chronic risk factors).

Goals and Timing of Suicide Assessment

The long-term management of affective illness requires that the clinician be constantly alert to the possibility of periods of increased suicide risk. We recommend that a complete suicide assessment be performed and documented during the initial evaluation of the patient and at certain points thereafter when suicide risk is likely to increase (Box 25-1). The initial suicide assessment should include family history of suicide, diagnosis, past history of suicide attempts, lethality, access to means, impulsiveness, substance abuse, and other areas of inquiry. The American Psychiatric

BOX 25-2. Questions That May be Helpful in Inquiring about Specific Aspects of Suicidal Thoughts, Plans, and Behaviors

Begin with questions that address the patient's feelings about living:

- Have you ever felt that life was not worth living?
- Did you ever wish you could go to sleep and not wake up?

Follow up with specific questions that ask about thoughts of death, self-harm, or suicide:

- Is death something you've thought about recently?
- Have things ever reached the point that you've thought of harming yourself?

For individuals who have thoughts of self-harm or suicide, ask:

- How often have those thoughts occurred (including frequency, persistence, obsessional quality, controllability)?
- How likely do you think it is that you will act on them in the future?
- What do you envision happening if you actually killed yourself (e.g., escape, reunion with significant other, rebirth, reactions of others)?
- Have you made a specific plan to harm or kill yourself? (If so, what does the plan include?)

For individuals who have attempted suicide or engaged in self-damaging actions, questions parallel to those in the previous section can address the prior attempts.

Additional questions can be asked in general terms or can refer to the specific method used and may include the following:

- Can you describe what happened (e.g., circumstances, precipitants, view of future, use of alcohol or other substances, method, intent, seriousness of injury)?

- What did you think would happen (e.g., going to sleep versus injury versus dying, getting a reaction out of a particular person)?

- How did you feel about surviving the attempt? Relieved? Disappointed? Indifferent?

- Did you receive treatment afterward (e.g., medical versus psychiatric, emergency department versus inpatient versus outpatient)?

For individuals with repeated suicidal thoughts or attempts, ask:

- About how often have you tried to harm (or kill) yourself?
- When was the most recent time?
- Can you describe your thoughts at the time you were thinking most seriously about suicide?

For individuals with psychosis, ask specifically about hallucinations and delusions:

- Have you ever done what the voices ask you to do? (What led you to obey the voices? If you tried to resist them, what made it difficult?)
- Have there been times when the voices told you to hurt or kill yourself? (How often? What happened?)
- Are there things that you've been feeling guilty about or blaming yourself for?

Consider assessing the patient's potential to harm others in addition to himself or herself:

- Are there others who you think may be responsible for what you're experiencing (e.g., persecutory ideas, passivity experiences)? Are you having any thought of harming them?
- Are there other people you would like to die with you?
- Are there others who you think would be unable to go on without you?

Source: Questions are selected from Table 3 of the American Psychiatric Association's *Practice Guideline for the Assessment and Treatment of Patients with Suicidal Behaviors*. See that table for additional questions. Reproduced with permission from the American Psychiatric Association.

Association's 2003 *Practice Guideline for the Assessment and Treatment of Patients with Suicidal Behaviors* gives examples of the kinds of questions that may be helpful to clinicians in inquiring about suicidal history and current intent (Box 25-2).

The goal of suicide assessment is to arrive at an overall qualitative estimate of the patient's risk of suicide in terms of both acute and chronic risk (Boxes 25-3 and 25-4, respectively). A risk estimate is a clinical judgment that integrates findings from the initial assessment with evaluation of risk factors and protective factors (Box 25-5). (Acute and chronic risk factors and protective factors are discussed in detail below.) Based in part on this assessment, the clinician should formulate a treatment plan for reducing the treatable risk factors, such as anxiety, insomnia, agitation, and psychosis.

Suicide assessment is not without its limitations. Research has failed to yield a set of criteria that predicts suicide risk in an individual patient.¹ Nor has any method of suicide assessment been adequately evaluated prospectively, in part because suicide is a statistically rare event (IOM, 2002). Assessment instruments are available, but no set of criteria can be sensitive enough to detect every patient at high risk while also avoiding a high false-positive identification rate. The current understanding of risk factors for suicide depends mainly on retrospective studies that lacked control groups and standardized measures of symptoms and behaviors; these studies may also suffer from bias introduced by the knowledge that a suicide occurred. Yet regardless of how imperfect clinical assessment may be, it can help prevent many suicides, and its imperfections cannot justify inattention or inaction on the part of the clinician.

BOX 25-3. Acute Risk Factors for Suicide in Manic-Depressive Illness

- Recent onset of mania, depression, or mixed states
- Cycling within an episode (rapid mood fluctuations)
- Recent hospital discharge
- Recent suicide attempt
- Severe psychic anxiety—fearful ruminations occurring most of the time*
- Panic attacks*
- Episodes of agitation, depressive turmoil, mixed states, angry outbursts, tantrums*
- Global insomnia—trouble initiating sleep, middle waking, early awakening*
- Recent alcohol abuse
- Severe anhedonia
- Recent or anticipated loss of close personal relationship or job, financial loss, legal or criminal proceeding
- Acute psychosis with command hallucinations or paranoid fears of punishment, delusional guilt*

*Risk factors that are usually and rapidly modifiable with treatment.

BOX 25-4. Chronic Risk Factors for Suicide in Manic-Depressive Illness

- History of frequent mood cycling
- History of mixed states
- Comorbidity—especially substance abuse and anxiety/panic; personality disorders (?)
- Family history of suicide
- Past suicide attempt
- Suicidal ideation—persistent, with specific plan and means
- Severe, sustained hopelessness
- Life dissatisfaction
- Few perceived reasons for living
- Absence of future orientation
- Loss of relationship, job
- Physical illness, chronic symptoms/pain*
- Firearms in the home*
- Help-rejection behavior
- Nonadherence to treatment
- History of impulsiveness and/or violence

*Risk factors that are usually and rapidly modifiable with intervention.

Evaluation of Patient History

A thorough history of the patient is an integral part of suicide assessment. In addition to the risk factors given in Boxes 25-3 and 25-4, the history should include the following points specific to the patient's illness:

BOX 25-5. Protective Factors against Suicide

- Restricted access to highly lethal methods of suicide
- Children in the home; sense of responsibility to family
- Pregnancy
- Strong religious beliefs
- Life satisfaction; reality testing ability
- Positive coping and problem-solving skills
- Positive social support
- Access and adherence to care, with a positive therapeutic relationship

Note: Most factors come from clinical experience rather than a strong evidence base, because very little research has addressed the specific factors that might be protective in manic-depressive illness.

Sources: Goodwin and Jamison, 1990; Malone et al., 2000; Jacobs et al., 2003.

- When in the *overall course of the illness* did past suicide attempts or severe suicidal ideation take place—in particular, how long after the onset of the illness, diagnosis, and preliminary treatment? The early stages of bipolar illness carry a significantly elevated risk of suicide (see Chapter 8).
- When in the *sequence of episodes* did attempts or ideation take place? For example, did the patient attempt suicide in a depressive episode that preceded or followed a manic episode?
- When in an *individual episode* did the patient appear to be most vulnerable to suicide?
 - In the transition from manic to depressive, depressive to manic, or manic to euthymic state? Were these states characterized by acute agitation?
 - Did increased suicidality occur relatively soon after the beginning of a depressive episode, well into it, or during the recovery period?
- How severe was the patient's suicidal ideation at the worst point in the illness?
- On the basis of past episodes (if any), when might the patient reasonably be expected to begin recovery? Has this period been associated with increased agitation and suicidality?
- If the patient is female, when in the menstrual cycle might the patient be in special jeopardy (e.g., in the premenstrual phase during a depressive or mixed episode)?
- When, in general, might the patient be at increased risk for suicide—for example, in the postpartum (puerperal) period, seasonally, or during transitions from one mood state into another?

The life-charting approach to recording data relevant to course (see Chapters 4, 11, and 20) is useful in tracking this information.

Acute versus Chronic Risk Factors

We recommend that assessment of suicide risk distinguish acute from chronic risk factors. By acute, we mean risk factors operating over days to months, whereas by chronic, we mean risk factors operating over months to years. The terms are somewhat overlapping and inexact, however; no precise lines can be drawn to demarcate when the acute period ends and the chronic one begins.

The importance of distinguishing acute from chronic risk factors was revealed in one of the few (and the largest) *prospective* suicide studies ever conducted, involving nearly 1,000 patients with major affective disorders followed for an average of 4 years, over which time 25 suicides occurred. Fawcett and colleagues (1987, 1990) observed that certain factors evaluated at study entry (e.g., severe psychic anxiety, panic attacks, global insomnia, alcohol abuse) were associated with a significantly higher suicide risk within 1 year of study entry (acute risk factors), while others (e.g., severe hopelessness, ideation) were correlated with higher risk within the second to tenth years (Table 25-1). Suicidal ideation and suicide attempts, contrary to the conventional

wisdom based on retrospective studies, were not found to be acute predictors of suicide. Findings of other studies support mixed states, panic attacks, and agitation in the presence of depression and bipolar disorder as acute risk factors for suicide (Coryell, 1988; Busch et al., 2003). The main conclusion of the National Institute of Mental Health (NIMH)-sponsored prospective study of Fawcett and colleagues was that most standard suicide assessments, which focus on ideation, attempts, and hopelessness, are at best of limited value, and at worst are misleading because they overlook very real acute risk factors, most of which are treatable.

In bipolar disorder, mixed states, which are marked by intense irritability and agitation, heighten suicide risk (see Chapter 8). These states warrant particular attention because the criteria for the diagnosis of mixed states in the *Diagnostic and Statistical Manual* are far too narrow, while mixed states, broadly defined, are common (see Chapter 2), and their underdiagnosis leads to underestimation of acute suicide potential. Further, when agitation in patients manifesting a mixed-dysphoric mania is misdiagnosed as unipolar “agitated depression,” inappropriate use of antidepressants

TABLE 25-1. Acute and Chronic Risk Factors for Suicide among Patients with Affective Disorder Who Committed Suicide ($N=25$) versus Patients Who Did Not Commit Suicide ($N=929$)

Symptom	Acute Risk Factor (p Value) ^a	Chronic Risk Factor (p Value) ^a
Hopelessness	.463	.007
Alcohol abuse	.029	.372
Loss of interest or pleasure (anhedonia)	.005	.223
Psychic anxiety/panic attacks	.012	.879
Suicidal ideation (persistent plan)	.613	.041
Suicide attempts	.815	.086
Obsessive-compulsive features	.063	.303
Indecisiveness	.085	.062
Diminished concentration	.028	.078
Global insomnia	.011	.765

Note: “Acute” refers to suicide occurring within 1 year of assessment; “chronic” refers to suicide occurring within 2–10 years of assessment.

^aProbability values for Mann-Whitney U statistics.

Source: Fawcett et al., 1990. Reproduced with permission from the American Psychiatric Association.

may worsen the agitation and heighten the suicide risk (Koukopoulos et al., 1995; Akiskal et al., 2005; Baldessarini and Goodwin, 2005).

It is a matter of clinical judgment to arrive at a qualitative estimate of acute and chronic risk for suicide. Research suggests that some risk factors (e.g., pessimism, aggression/impulsivity) are additive (Oquendo et al., 2004), but they may also be synergistic. Clearly, however, certain risk factors, such as access to a firearm, pose a more immediate danger than others. Later we describe treatment of certain modifiable risk factors.

Protective Factors

Minimum pathology in a suicidal person bereft of strengths may be lethal, while severe pathology in a person with unusual strengths may constitute only a moderate risk. (Motto, 1975, p. 239)

There can be little doubt that certain protective factors mitigate the risk factors for suicide, but it is unclear by how much or under what circumstances. Both sets of factors, which fluctuate over time, can constitute a delicate balance between the decision to live or die.

The focus on protective factors, a relatively recent phenomenon, is a direct outgrowth of the above-noted conceptualization of suicide as a preventable public health problem (IOM, 2002; Knox et al., 2004). For example, psychometric scales have been developed to measure resilience (e.g., Suicide Resilience Inventory; see Osman et al., 2004). One of the few formal studies of protective factors was conducted among psychiatric inpatients, who were administered the Reasons for Living scale, a self-report instrument measuring beliefs and attitudes thought to inhibit suicide, such as coping beliefs, a sense of responsibility to family, child-related concerns, and religious or moral objections to suicide (Malone et al., 2000). The investigators found that higher scores on this scale indicated protection from acting on suicidal thoughts, although it is unclear whether the severity of psychopathology affected the self-reporting of the study subjects.

Some of the same protective factors were observed in an earlier study by Motto (1975). Among the specific factors involved in the ability to survive suicidal inclinations, Motto cited the following: (1) the capacity to control behavior—that is, the ability to stand the pain or resist the impulse; (2) the capacity to relate readily and in a meaningful way to someone else, and the presence of family members and friends who are supportive; (3) a motivation to seek help and willingness to work actively on the problem; and (4) resources that facilitate the therapeutic process and the transition back to a stable life pattern, such as job skills, intelligence, physical health, communication

skills, a capacity to trust, close ties to religion, and freedom from severe personality disturbance or addictive problems. To this list might be added financial resources (particularly important in gaining access to good medical treatment and psychotherapy, remedying financial excesses resulting from manic episodes, and meeting expenses during time lost from work); willingness and ability to follow a prescribed treatment regimen; and the kind of personality during normal times that accumulates a backlog of goodwill with friends, family, and colleagues. Manic-depressive illness strains and depletes relationships, and there is little restocking during periods of mania and depression. The support of family and friends—always crucial for depressed and suicidal individuals, particularly if they are to stay out of the hospital—depends largely on how well relationships were maintained before the depression began.

Some depressed people are better than others at garnering support. Hostile, paranoid, and irritable people are unlikely to do so, whereas those who are passive and sad when depressed will usually be offered help, especially if they normally are more outgoing when well. Unfortunately, the patient with the most dangerous depression—the most perturbed, volatile, irritable, and delusional—is often the most likely to drive away potential sources of support.

CLINICAL MANAGEMENT

The seriously suicidal person with manic-depressive illness, whether bipolar or recurrent unipolar, requires intensive clinical care. Suicide is prevented most effectively by a combination of immediate strategies to keep the patient safe by ameliorating acute risk factors, and long-term strategies to stabilize the patient's underlying illness and thereby prevent recurrences of potentially life-threatening affective episodes. The clinician may need to change or add medications, modify psychotherapeutic practices, and enlist support from the patient's family members and friends. A suicidal crisis while a patient is under psychiatric care often provides the opportunity and impetus to reappraise previous assumptions about diagnosis, psychiatric history, treatment response, and involvement in the treatment process of family members and other individuals of significance to the patient.

The immediate priorities with a suicidal patient are (1) to keep the patient safe by precluding or reducing access to common methods of suicide, such as firearms and medication overdose; (2) to establish a therapeutic alliance; and (3) to treat acute risk symptoms that can be clinically modified (e.g., recurrent severe anxiety/panic, mixed states, agitation, impulsivity, global insomnia, and substance abuse). The second priority is to develop and implement a systematic treatment plan for preventing future episodes of suicidal depression, mania, and mixed states. Chronic-risk patients

usually do not warrant immediate care, but the clinician must be alert to the possibility that they may become acutely suicidal at any time if they experience a worsening of symptoms or situational setbacks or if they fail to respond to treatment. Once an acute risk of suicide is suspected, chronic-risk patients must be reassessed. The overall approach to acute- and chronic-risk patients is depicted in Figure 25–1.

In this section, we first address clinical management of acute and chronic suicide risk. We then examine a number of psychological and other aspects of treatment of patients deemed to be at risk of suicide.

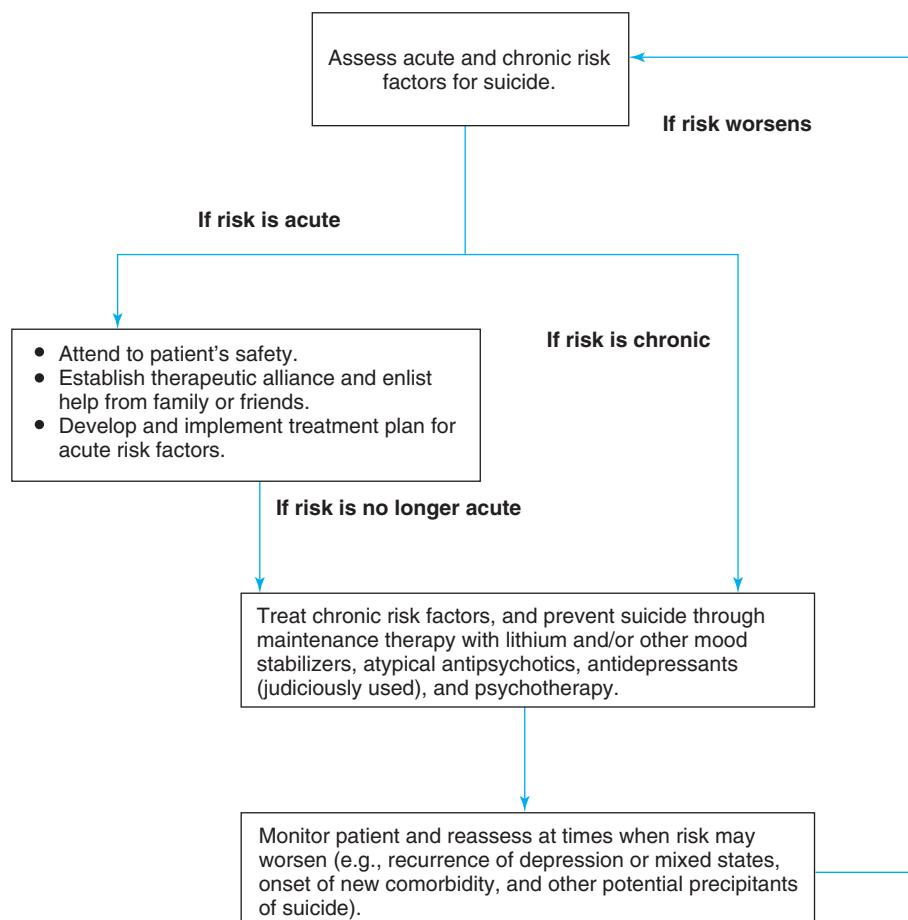

Management of Acute Risk Factors

... I have this almost terrible energy in mind and nothing seems to help. . . . I walk up and down the room—back and forth—and I feel like a caged tiger. (Anne Sexton²)

The “terrible energy” described by the poet Anne Sexton, who ended her life by suicide, is typical of the physical and

psychic agitation experienced by many patients in the midst of episodes of bipolar depression. Agitation—which, like several other acute risk factors, is usually modifiable with treatment—is marked by increased voluntary motor activity, such as pacing, handwriting, and pressured speech patterns, and a subjective sense of perturbation or feeling “wired” (see Chapter 2). The activity is typically repetitive, stereotyped, and purposeless. In suicidal states, agitation is often accompanied by, and difficult to distinguish from, severe anxiety. More severe, persistent, or recurrent anxiety, panic attacks, and agitation in the presence of unipolar or bipolar depression are all acute risk factors for suicide (Coryell, 1988; Fawcett et al., 1990; Busch et al., 2003). Prevalence data for the symptoms of agitation in bipolar disorder are sparse (Allen and Currier, 2004; Sachs, 2006), but their existence is common and potentially dangerous. These potentially dangerous symptoms can usually be reduced in a relatively brief period of time—a matter of hours to days—with appropriate pharmacological therapies. To the extent possible, patients who are agitated should

Figure 25–1. Overall approach to manic-depressive patients with acute and chronic risk factors for suicide.

be isolated from external, exacerbating stimulation through the use of quiet or isolation rooms.

We recommend, at a minimum, regularly administered doses of benzodiazepines, such as clonazepam or lorazepam, for severe anxiety/panic, agitation, and global insomnia in a suicidal patient. For more severe anxiety/panic or insomnia, a typical or atypical antipsychotic or an anxiolytic anticonvulsant, such as valproate or gabapentin, is often appropriate (Battaglia, 2005; Marco and Vaughan, 2005; Marder, 2006). Benzodiazepines must be used cautiously because they may induce outbursts of anger and disinhibition. Atypical antipsychotics or some anticonvulsants may be helpful alternatives in these patients, especially when the risk of disinhibition is high.

The selective serotonin reuptake inhibitors (SSRIs) or serotonin/norepinephrine reuptake inhibitors (SNRIs) may be used for their anxiolytic effects, but with caution. First, SSRIs and other antidepressants have a gradual onset of efficacy (1 to several weeks), with most studies not showing significant decrements in severity of anxiety symptoms before 4 weeks. Second, bipolar patients prescribed antidepressants need to be carefully monitored, and they and their family members advised to be alert to the agitation and precipitous switches in mood that may be associated with use of these medications. Children and adolescents bear even closer monitoring, especially in the early stages of illness. Indeed, the U.S. Food and Drug Administration (FDA, 2004) has issued a black box warning on antidepressants for this age group because of the occasional occurrence of increased suicidal ideation or behavior as an antidepressant-related adverse event (see our later review of the literature on long-term suicide prevention). Some of these reports of suicidality no doubt represent treatment-induced activation of mixed states in young people with an unsuspected bipolar diathesis.³

Although there is danger of inducing mood cycling by administering antidepressants to a bipolar patient, the evidence appears to suggest that the risk is lower for the newer-generation SSRIs, SNRIs, and bupropion than for tricyclic antidepressants (see Chapter 19). In any case, to minimize the risk of inducing mood cycling or mixed states, mood stabilization should be established before antidepressant medications are introduced.

Acute suicidal depression in a manic-depressive patient, whether bipolar or recurrent unipolar, is one of the most compelling indications for the use of electroconvulsive therapy (ECT). This is particularly so given that antidepressants may worsen the course of illness in some bipolar patients, as well as induce mixed states (see Chapter 19), and that even the most up-to-date and effectively used pharmacological interventions will fail in 20 to 30 percent of suicidal patients (Prudic and Sackeim, 1999). Yet ECT continues to be under-

used, particularly in the United States, because of the presence of obstructive legal and bureaucratic pressures that make the treatment difficult and cumbersome to employ; the risk of litigation by a small minority of patients; the availability of alternative antidepressant treatments; the influence of negative publicity from outside the medical field; and, within the psychiatric field, a relative lack of awareness of ECT's advantages in treating the acutely suicidal patient.

ECT has several advantages over pharmacotherapy: the antidepressant response is more rapid, thereby decreasing the immediate risk of suicide; there is less potential for worsening the course of the illness; and the interruption of the depressive episode allows time for the prophylactic effect of a mood stabilizer to take hold (Prudic and Sackeim, 1999). At the same time, however, some caveats are in order. First, ECT does not always relieve these symptoms quickly. Moreover, there may be delays in scheduling or accomplishing required medical tests and examinations, and during this period, the symptomatic patient remains at risk. Finally, ECT may be no more effective than other short-term treatments (see the later discussion).

Management of Chronic Risk Factors

The sophisticated use of medications and ECT in treating manic-depressive illness and preventing relapses is the single best prophylaxis against suicide, although it may not be sufficient; psychotherapy (discussed later) is often essential as well. In choosing pharmacological treatments, the most important considerations are efficacy, adverse events, and adherence. Accordingly, some of the recommendations made here summarize what has been covered in detail elsewhere (see Chapters 17 through 24).

Prevention of recurrent depressive or mixed episodes is the foremost deterrent to suicide; suicide rarely occurs during manic or euthymic states (see Chapter 8). When bipolar or recurrent unipolar patients at significant risk for suicide are maintained on lithium, alone or in combination with other mood stabilizers and/or atypical antipsychotics, the incidence of suicide can be significantly reduced. Carefully timed treatment with antidepressants may also reduce the risk of suicide; as noted previously, however, for bipolar patients antidepressants should generally be preceded by a mood stabilizer, preferably lithium because of its demonstrated antisuicidal effect.

Despite strong evidence of lithium's antisuicidal effect (discussed in detail in a later section), its prescription rate in the United States dropped beginning in the mid- to late 1990s in favor of anticonvulsants, for which there is no systematic evidence of antisuicidal efficacy. We recommend much greater awareness of lithium's value in suicide prevention, alone or in combination with other medication and, when appropriate, psychotherapy.

Psychological Aspects of Treatment

The psychological aspects of treating suicidal bipolar patients, although often emotionally draining and time-consuming for the clinician, are an essential component of preventing suicidal behavior. The suicidal bipolar patient, for example, has many problems that necessitate psychological support or therapy, reassurance, or general informational counseling. Moreover, ongoing professional assessment of suicide risk, as discussed earlier, is vital for those undergoing treatment, whether outpatient or inpatient. Because a suicidal depression often follows a manic episode, the depression is exacerbated by adverse circumstances generated while the patient was manic, such as financial or employment crises, marital problems, and legal difficulties. Other psychological problems arise from reactions to the illness itself (see Chapters 21 and 22) and the pervasive problem of treatment nonadherence (see Chapter 21). General psychotherapeutic issues are discussed more fully in Chapter 22. Here we discuss specific issues that arise during suicidal depressions, including therapeutic style, suicide-oriented therapies, the patient's need for reassurance and information, medication monitoring, clinician availability, and clinician attitudes engendered by the suicidal patient.

Therapeutic Style

Most clinicians agree that psychodynamic psychotherapy is contraindicated for suicidal patients, especially those who have bipolar disorder (Winokur et al., 1969; Hankoff, 1982). Clinical experience suggests that a direct and involved approach is the most effective and compassionate. The therapist should be willing to take more initiative with severely depressed patients than might be appropriate with others. Directness with a suicidal patient is imperative, because the gravity of the situation demands immediate action, and the patient's paralysis of will necessitates active intervention. Also, most suicidal bipolar patients are hyperalert and hypersensitive, as well as guarded and suspicious, and they often possess an uncanny ability to sense fear, irritation, and evasiveness in their therapists. Directness on the part of the clinician can help allay unnecessary anxiety and unwarranted speculation, decrease a pervasive sense of hopelessness, and establish a basis for trust that can extend into other aspects of clinical care. Along with directness, the therapist must demonstrate an ability to understand complex and painful feelings.

Because manic-depressive illness has biological roots, psychotherapeutically oriented clinicians often refer suicidal manic-depressive patients to psychopharmacologists, some of whom may not have the time, interest, or skill to provide psychotherapy and thus may tend to rely too

heavily on medication. Conversely, clinicians who are primarily psychotherapists may tend to place too little emphasis on the importance of medication in alleviating short-term risk factors as well as treating the long-term course of the illness. This clinical problem is especially significant for suicidal patients, who have a particular need for integrated medical and psychotherapeutic care.

Suicide-Oriented Therapies

Contemporary randomized controlled trials of the long-term efficacy of psychotherapy in manic-depressive illness have focused on the bipolar subgroup (see Chapter 22). Disappointingly few of these studies have tested the efficacy of specific suicide-oriented therapies, and none have focused on decreasing suicide, or even "suicidality," per se. Indeed, most clinical trials that address suicidal behaviors have been directed at personality disorders or have grouped together patients with very different diagnoses (Brown et al., 2005). Further, the outcome measure has usually been deliberate self-harm, which encompasses both nonlethal and lethal intent and varying degrees of planning; it is an imperfect proxy for suicide. The primary problem is that most trials are underpowered to detect a decrease in suicide because of its relative rarity.

Systematic reviews of the efficacy and methodology of suicide-oriented clinical trials are available.⁴ The types of therapies examined in such trials include particular cognitive-behavioral therapies (e.g., dialectical behavioral therapy for borderline personality disorder), psychodynamic interpersonal therapy, emergency cards (which allow emergency admission or contact with a physician), and problem-solving therapy. Recently, Miklowitz and Taylor (2006) proposed an adaptation of family-focused therapy for suicidal bipolar patients that holds promise for helping this at-risk group of patients. Given the limitations of the literature, clinical experience suggests that with suicidal bipolar patients, the quality of the relationship between therapist and patient is more important than any particular type of psychotherapy.

Providing Reassurance

The liberal and intelligent use of reassurance, an integral part of the treatment of manic-depressive illness, is particularly important when the patient is suicidal. Indeed, it is reasonable to offer hope when dealing with a generally treatable and spontaneously remitting illness. Winokur and colleagues (1969) suggested frequently reassuring patients and families first, that depression is an illness; second, that it is time-limited; and third, that the clinician is familiar with this kind of problem. While depressed, suicidal patients are unlikely to acknowledge that such reassurance is helpful, although after they have recovered, they often remark on

how important the clinician's reassurance was to them (Coate, 1964; West, 1975; Jamison, 1995). Thus the clinician needs to have considerable skill and perseverance to maintain credibility while reassuring the patient. For example, it is helpful to acknowledge negativistic skepticism, with an understanding of the patient's current depression. By taking a stance of not overreacting and maintaining a positive outlook—knowing that if one treatment approach is not successful, the next may be—the therapist can sustain hope even in the face of failure of a therapeutic trial. The clinician's charge is to convince the patient that the treatment being administered may be able to help and to engage the patient's participation, if not belief, long enough to produce some symptom relief that will encourage continuation with the treatment. The patient needs to hear that the therapist is not going to give up even if initial efforts are unsuccessful. The protective factors discussed earlier, such as family and friends or strong religious beliefs, can be emphasized by the clinician. Certainly, whenever possible and clinically indicated, family members should be actively involved and educated in the patient's treatment.

Communicating Information

Explicit information about both the bipolar and recurrent unipolar forms of manic-depressive illness, their treatment, and their association with suicide is particularly important when dealing with suicidal patients, who may feel profound hopelessness and be severely cognitively impaired. Whenever feasible, information should be provided to such patients in both oral and written form. One of the first messages that must be clearly communicated concerns the limits on confidentiality between suicidal patients and their therapists. This message becomes highly significant for patients who are paranoid, irritable, and hostile or are experiencing mixed states and rapidly fluctuating moods. Other information for the patient and, where appropriate, for the family are listed in Box 25–6.

It is important to communicate consistently that although manic-depressive illness is serious, it can be treated successfully in the great majority of cases. Left untreated, however, particularly early in its course, it not infrequently results in suicide. The clinician must explain to both patient and family that denial of the possibility of recurrence is common, but it can also be dangerous. Such an explanation predicts thoughts and feelings and thereby lends credence to the clinician's recommendations.

The patient must be strongly and persuasively encouraged to take lithium or other medications as prescribed. In the case of lithium, the patient should be informed that the drug has been demonstrated to have a strong antisuicidal effect and that it can sometimes work as effectively against depression as it does against mania, but that it usually takes

BOX 25–6. Communicating Information to Suicidal Patients and Families

General Issues

- Written information whenever possible
- Ways of contacting clinician
- Limits on confidentiality
- Importance of postponing major life decisions
- Treatable nature of affective illness

Medication Issues

- Availability of many effective medications
- Imperative to take medications as prescribed
- Importance of providing instructions in writing
- Side effects usually transient and/or treatable

When to Contact Clinician

- Worsening of suicidal ideation
- Worsening of symptoms, especially:
 - Sleep loss
 - Severe anxiety/panic
 - Agitation, severe restlessness
 - Delusions
 - Feeling of violence, impulsivity
- Problems with medication adherence
- Increased impulsivity and aggressivity

Alcohol and Drugs

- Worsen sleep
- Decrease impulse control and judgment
- Potentiate or interfere with prescribed medications
- Worsen course of illness
- Increase the likelihood of mixed states

Recovery Issues

- High-risk nature of recovery period
- Recovery likely to be frustrating and tumultuous
- Uneven "sawtooth" pattern of recovery
- Time course and recovery pattern with antidepressants (energy and the ability to execute a plan are likely to return more quickly than improved mood or cognition)

more time to have an effect on the former. The patient (and clinician) should not be discouraged by this delay. Patients should be advised as well that strict adherence to lithium therapy is very important because of the increased risk of suicide after stopping the medication (as discussed further below).

It is important to communicate explicitly that many side effects occurring with medications can be ameliorated, while others cannot. The clinician should be specific about

possible side effects and how transitory or permanent they are likely to be. Patients who are started on a medication should be warned that the time course for a drug response may lead to a discrepancy between what their physician sees and what they themselves are experiencing. For example, the physician and family may see improvement because the patient has more energy and is sleeping better, and his face and body are more animated. These changes generally precede improvements in mood and thinking, changes that are likely to be more important to the patient. (Too, increased energy and capacity to act when combined with depressed mood can itself be dangerous.) Warning patients about this discrepancy in perception can lessen some of their discouragement, which is particularly important given that, as noted earlier, they may be at higher risk for suicide at this stage of the illness.

As the patient's condition begins to improve, the clinician should explain that recovery from a suicidal depression is exceptionally difficult, that a particularly frustrating and difficult period may lie ahead, and that temporary setbacks are common. The patient should be aware that alcohol generally worsens depression, interferes with sleep, impairs judgment and impulse control, and undermines the effects of medications (see Chapter 24). The patient should be advised as well to avoid significant occupational, social, or personal changes when depressed and to obtain a leave of absence from school or work rather than quit.

Medication Monitoring

The importance of prescribing only limited amounts of potentially lethal medications to suicidal patients cannot be overstated. Growing reliance on SSRI antidepressants has reduced the likelihood of lethal overdose because they are less toxic than monoamine oxidase inhibitors (MAOIs) and tricyclic antidepressants. In the pre-SSRI era, Murphy (1975) concluded that half of patients who killed themselves through an overdose had obtained their lethal antidepressant dose in a single prescription. Lithium is also potentially lethal and should be monitored accordingly (see Chapter 20).

Instructions regarding medications—dosages, timing, side effects, potentially dangerous adverse reactions, and potentiation/interference by alcohol and other drugs—should be explicit and in writing. If possible, another concerned individual (family member or friend) should become involved in monitoring the medications prescribed for a suicidal patient because confusion, hopelessness, and ambivalence about taking drugs can make depressed patients particularly susceptible to errors in taking medications. Plastic pill boxes with separate sections for each day of the week are helpful to many patients, particularly those who are confused as a result of their depression or are taking more than one medication.

Availability of Clinician

When patients are suicidal, they should be seen and contacted more frequently than usual. If financial or scheduling problems exist, the clinician should attempt to see the patient for shorter periods of time but more often. It may help to establish a time each day, or every few days, for a brief telephone conversation. Because the slowed anergic quality of bipolar depression often makes telephoning a difficult task for the patient, we find it helpful to initiate these contacts, asking the patient frequently and regularly to give his own assessment of suicidal ideation and obtaining as much information as possible from family members about the patient's behavior and suicidal intent.

The clinician's accessibility to the patient and the patient's understanding and acceptance of his alliance with the clinician are dimensions of care that are crucial to keeping the patient alive through the worst times. The patient must be told clearly how to reach the clinician in an emergency or during an acute exacerbation of suicidal thoughts and feelings. Directions for dealing with answering services, on-call systems, and coverage by other clinicians should be explicit and conveyed both orally and in writing. Depressive confusional states, as well as guilt or fear about overburdening and alienating clinicians, often prevent patients from indicating that they do not fully understand such practical details. Putting this information in writing, along with "Do not hesitate to call," can be both concrete and reassuring. The clinician needs to have a clear agreement with all suicidal patients stipulating that they will call if they are in danger of losing control of their feelings or actions, become acutely suicidal, or feel the need for immediate care. It generally is prudent as well to share this information with the closest family member or friend.

Clinician Attitudes

Therapists should always be sensitive to the feelings, thoughts, and actions engendered in them by a patient (see Chapter 22), but this is especially so when the patient is suicidal. The therapist's reactions often reflect the added stress, responsibility, and time commitments involved in treating a suicidal patient, who is frequently irritable and who conveys a sense of contagious hopelessness. The tendency for some therapists to overidentify with patients—professionally successful ones in particular—can increase the therapist's own psychological distress and lead to denial or overprotectiveness. The serious possibility of suicide reminds most therapists of their own limitations. As Cassem (1978, pp. 595–596) noted:

The need to balance consideration for the patient's safety with the goal that he live his life independently . . . reminds

us how limited the therapist's powers are—that is, they are no stronger than the patient's desire to make use of help. The therapist who appreciates his ultimate inability to stop the person who really wants to kill himself is far more likely to be effective in restoring the person's sense of self-esteem and wholeness. . . . Clarifying these limitations with the patient helps convey respect for his autonomy and reminds the therapist that a completed suicide can occur despite complete fulfillment of his responsibility.

Suicidal manic-depressive patients can challenge and frustrate the clinician because of the need for complicated diagnostic judgments and sophisticated psychopharmacological decisions, as well as other problems in managing suicidal behavior, such as obstacles to hospitalization. Consultation with specialists in the pharmacological and psychotherapeutic treatment of affective illness can be helpful clinically, personally, and legally.

Other Aspects of Treatment

Involvement of Family Members and Friends

The involvement of family members and friends can lessen the need for hospitalization and increase the family's and patient's sense of control over a potentially devastating situation. By participating during a patient's acute-risk period, families can be actively involved in much of the decision making that takes place and learn ways to avert future crises. The clinician can alleviate family members' understandable sense of hopelessness and helplessness by providing information and reassurance, by giving them realistic expectations about likely difficulties in the acute and recovery phases, and by establishing clear contingency plans for serious problems that may arise. Families, like patients, should be given direct, preferably written, information about the patient's illness, medications, potentially dangerous adverse reactions, suicide risk, and ways of contacting the clinician.

The clinician can set up a suicide alert system by meeting with the patient, relevant family members, and a few close friends (if advisable) to coordinate an effective and direct method for noting particularly dangerous changes in the patient's mental condition and mood. At that meeting, the clinician should clarify the above-noted limits of confidentiality in situations of potential suicide and should stress that the ultimate responsibility for assessing lethality and making decisions about hospitalization rests with the clinician. Such clarification avoids confusion about responsibility and lessens family members' guilt should suicide or a severe attempt occur. The clinician must frequently assess the stress on all participants, as well as determine whether the patient needs to be hospitalized.

To facilitate communication, relatively new legal instruments, known as psychiatric advance directives, can be used by patients, when well, to document their instructions for care in times of suicidal crisis, including preferences for medication, hospitalization, and ECT and the designation of an individual authorized to make health care decisions on their behalf. More than 20 states have passed specific statutes for psychiatric advance directives. Forms can be downloaded through various gateway Web sites (e.g., Duke University, 2005) and through patient advocacy groups (see the suggested guidelines of the Depressive and Bipolar Support Alliance given in Box 22-1 in Chapter 22).

Hospitalization

The decision to admit a suicidal patient to a psychiatric hospital is often straightforward and reassuring. On the other hand, when a patient equates hospitalization with failure or symbolic defeat or when the stigma of hospitalization may have a severe and negative effect on work or personal relationships, the decision becomes more complicated. The psychological, social, financial, and clinical disadvantages to the patient must be weighed not only against the risk of suicide, but also against the pragmatic and emotional costs to the family and the clinician if the patient remains out of the hospital.

Hospitalization, although decreasing the risk of suicide, does not eliminate it. Robins and colleagues (1959) found that 7 percent of patients in their sample had committed suicide while in a psychiatric hospital. Weeke (1979) reported an even higher rate: 27 percent of manic-depressive patients killed themselves while under hospital care, although half of them were on a pass or had absconded. Weeke emphasized the need for special precautions to supplement hospitalization and the careful observation of such patients even when they appear substantially improved or recovered (see also Winokur et al., 1969; Roose et al., 1983). These measures are not always effective in preventing suicide, however. Busch and colleagues (2003) examined 76 cases of inpatient suicide and found that 42 percent had been on orders for suicide checks every 15 minutes or had been seen by staff within 15 minutes of their suicide. This finding underscores the potential inadequacy of one of the most commonly used precautions for those at acute risk of suicide.

Motto (1975) and Hawton and Catalan (1982) provided specific examples of ways to document evidence and improve communication among hospital staff members to prevent suicide:

- The degree of suicide risk should be carefully assessed and should be stated explicitly (for example, low, moderate, or high).

- The measures to be taken in dealing with the acutely suicidal patient should be stated in clear, specific terms. Most hospitals have devised suicide observation procedures that include detailed instructions to nurses and physicians.
- Nursing staff should be required to document on the patient's chart that the suicide prevention measures have been carried out.

It is especially important to specify whether the risk of suicide for a patient is acute or chronic. Once acute risk has been determined, efforts must be made to reduce that risk, such as by aggressively treating insomnia, agitation, and anxiety symptoms and providing the patient with one-on-one observation until the acute-risk state has ended.

Other factors important to preventing suicide in hospitalized patients are a high staff/patient ratio, a reduced number of exits on the ward or a locked ward, and an awareness that increased risk occurs during a change in nursing shifts and when a crisis on one part of the ward distracts staff attention from the suicidal patient (Hawton and Catalan, 1982). It is essential, when possible, to ask the patient's family members about expressed suicide intent since, as noted earlier, patients more often confide in family members than in their doctors.

Follow-Up Care

The chronic, recurrent, and serious nature of manic-depressive illness makes careful monitoring during the recovery period an essential part of treatment. Even in the early nineteenth century, Benjamin Rush (1812, p. 239) called attention to the danger of this period:

We should be careful to distinguish between a return of reason and a certain cunning, which enables mad people to talk and behave correctly for a short time, and thereby to deceive their attendants, so as to obtain a premature discharge from their place of confinement. To prevent the evils that might arise from a mistake of this kind, they should be narrowly watched during their convalescence, nor should they be discharged until their recovery. . . . Three instances of suicide have occurred in patients soon after they left the Pennsylvania Hospital, and while they were receiving the congratulations of their friends upon their recovery.

Several studies (e.g., Roy, 1982; Fawcett et al., 1987) have found that the first 6 to 12 months after hospital discharge is a period of very high risk for suicide. Appleby and colleagues (1999) retrospectively studied 2,177 cases of suicide among patients who had had contact with mental health services within the year before their death. Of these suicides, 24 percent occurred within the first week of hospital

discharge; 43 percent were in the highest-priority category for community care; and 26 percent had not adhered to treatment. The authors observed that earlier and more intensive follow-up in the community may be required for effective suicide prevention.

Many investigators (Fieve, 1975; Hankoff, 1982; Gitlin and Jamison, 1984) have noted the advantages of specialty affective disorder clinics in providing continuity of care. Because of their medical affiliations, these clinics are sometimes more free of stigma than other psychiatric programs. Such specialty clinics are also able to make rigorous diagnoses, provide highly specialized and up-to-date treatment, and treat a large number of patients with similar types of problems. Nonetheless, most patients with manic-depressive illness are not in fact treated in such facilities, and other settings, such as private practice, can provide some of these advantages as well. On the whole, continuity of care and expertise in diagnosis and treatment (through consultation when necessary) are most important in treating both the recurrent unipolar and bipolar subgroups of manic-depressive illness.

Impact of Suicide on Family Members

While the emphasis of this chapter is on treating and preventing suicidal behavior, suicide will still occur despite the dedicated efforts of clinicians, family members, and friends. The psychological impact of suicide on those left behind has received scant study, although there have been a few investigations. The existing research confirms clinical experience and the intuitive expectation that one of the highest priorities in the wake of a suicide is to attend to surviving relatives, who not only suffer terribly from the loss, but may themselves be at risk for developing psychiatric problems.

Relatives' nearly universal reactions to suicide—grief, guilt, devastation, and distress—are complicated by the stigma associated with the act and lingering questions of why, what if, and what else they could have done. Brent and colleagues (1996) found that most siblings of adolescents who commit suicide are themselves at heightened risk of developing depression within 6 months; within 3 years, however, they do not display excess psychopathology. On the other hand, mothers of children who have died by suicide continue to show long-lasting effects 3 years later, and nearly 30 percent develop depression. Another study, focused on children whose parents committed suicide, found that the anxiety, anger, and shame experienced during the first months after the event give way to behavioral and anxiety symptoms but, at least after 2 years, not to long-term psychopathology (Cerel et al., 1999). Children with preexisting psychopathology are, however, at long-term risk of exacerbation or the onset of new disorder. To

avert long-term effects, children should be told the truth about the suicide, although the surviving parent's natural reaction is often otherwise. Shielding children leads to greater turmoil and potential long-term distress once they inevitably learn the truth from other children or adults. Clinicians, in addition to expressing their condolences and, if possible, attending the funeral or memorial services, should be available to families in the wake of suicide and should make appropriate referrals to other mental health professionals when necessary. Parents and family members can access help through several organizations listed in the appendix at the end of the volume.

Impact of Suicide on the Therapist

Therapists often portray losing a patient to suicide as the most anguishing time in their careers (Gitlin, 1999). Approximately one-half of psychiatrists and one-quarter of psychologists surveyed in the late 1980s reported experiencing a patient's suicide (Chemtob et al., 1988a,b). Therapists' immediate reactions to suicide include shock, grief, guilt, fear of blame, self-doubt, shame, anger, and a sense of betrayal, according to results of research sponsored by the American Foundation for Suicide Prevention (Hendin et al., 2000). About a third of those interviewed reported severe levels of distress, often lasting longer than a year. Severely affected therapists attributed their distress to their failure to hospitalize an acutely suicidal patient who later died, treatment decisions, negative reactions from institutions and peers, and fear of a lawsuit by the patient's family members (Hendin et al., 2004). These findings call for more collegial and institutional support for therapists after a patient's suicide, as well as for postmortem opportunities to learn more about suicide prevention.

REVIEW OF THE LITERATURE

In this section, we review in turn the literature on acute clinical management of suicidal patients and long-term suicide prevention, elaborating on the brief earlier discussion of various medical treatments.

Acute Clinical Management

Evidence concerning successful treatment of patients at acute risk of suicide is quite limited for several reasons. The first concerns ethical issues involved in conducting controlled studies in emergency clinical situations. The second is the limitation in statistical power that results from the relatively small numbers of actual suicides noted previously and the fact that the validity of using attempted suicide or suicidal ideation as a proxy measure is highly questionable (see Chapter 8). Third, the literature on suicide and its prevention generally does not distinguish

acute from chronic risk; instead, it tends to address risk as a single category, perhaps as a result of the retrospective nature of most studies of suicide. Finally, most studies do not compare the incidence of risk factors in those who commit suicide with the incidence in a comparison group of those who do not, nor do they examine the time from the emergence of a putative risk factor to the occurrence of suicide.

Given this dearth of research evidence, it is difficult to assess the effectiveness of various clinical interventions in reducing the acute risk of suicide. The best evidence available is based on clinical trials that show a rapid reduction of high-risk symptoms, not of suicide or attempts per se. The value of this evidence is based on the reasonable, although as yet unproven, inference that reducing or reversing these symptoms will reduce the acute risk of suicide. Below we review this evidence for benzodiazepines, anti-convulsants and antipsychotics, antidepressants with rapid onset, and ECT.

Benzodiazepines

Results of several clinical trials suggest that adequate, regularly administered doses of benzodiazepines, such as clonazepam or lorazepam, can act fairly rapidly to reverse severe anxiety, panic attacks, and agitated states. Smith and colleagues (2002) presented data showing more rapid improvement in depression when clonazepam was added to fluvoxamine. Londborg and colleagues (2000) found over the first 3 weeks of treatment that fluoxetine plus clonazepam at night, versus fluoxetine plus placebo, worked better in reducing total Hamilton Rating Scale for Depression (HAM-D) scores, anxiety, and sleep disturbance. Treatment-emergent anxiety was reported for 25 percent of placebo but only 7 percent of cotherapy patients. An extension study assigned patients to the same dose (20 mg) of fluoxetine or an increased dose (40 mg) at 6 weeks (Smith et al., 2002). One week later, cotherapy (fluoxetine with clonazepam) was found to be superior to fluoxetine with placebo with respect to HAM-D and Clinical Global Impressions (CGI) ratings; response rates were 32 and 4 percent, respectively. Cotherapy with benzodiazepines was also found to be useful for rapid treatment of anxiety and insomnia.

There are caveats, however. The effects of benzodiazepines wear off rapidly, necessitating supervised use until basic antidepressant and/or mood-stabilizing treatment—with medications or ECT—has reduced the severity of depressive symptoms. Although giving one or two doses of anxiolytic medication can result in dramatic improvement in the acute state and thereby potentially lower acute suicidal risk, failure to repeat the dosage on a regular schedule until the underlying affective disorder has improved may

result in a dangerous rebound of anxiety, which can in turn trigger suicide. Careful clinical supervision and follow-up are therefore necessary.

In general, because the treatment is time-limited, there is little risk of inducing dependency on benzodiazepines with proper supervision. At the same time, given that manic-depressive patients (especially the bipolar subgroup) frequently present with comorbid substance abuse (see Chapter 7), the increased risk of misuse of or dependency on benzodiazepines in these patients should be carefully weighed. In the case of recurring anxiety symptoms, especially panic attacks, more moderate doses may need to be continued. In the final analysis, death is a far greater danger than possible benzodiazepine dependency, which can usually be avoided through careful clinical management.

Anticonvulsants and Antipsychotics

The sleep disturbances that often accompany severe anxiety and panic and that represent an independent risk factor for suicide should be treated aggressively with sedative hypnotics, sedating atypical antipsychotics, or sedating and anxiolytic anticonvulsants, such as valproate or gabapentin.

Anticonvulsants and antipsychotics can be used to treat those patients who display disinhibition or outbursts of anger in response to fast-acting benzodiazepines. In these circumstances, anticonvulsants such as divalproex (Schatzberg, 1998), atypical antipsychotics, or sedating typical antipsychotics, such as thioridazine, may be useful, particularly in reducing agitation and anxiety. Indeed, these treatments can be life-saving in some high-risk patients. All of these medications are relatively safe if used skillfully and with the necessary amount of supervision and follow-up. It is important that they be given in sufficient doses, even if temporary sedation results, until the suicidal crisis has been brought under control. The atypical antipsychotics merit special mention because, as discussed later, the atypical clozapine is the only drug other than lithium for which there is replicated evidence of a reduction in suicide risk. (See Chapter 19 for discussion of the use of anticonvulsants and atypical antipsychotics in the treatment of bipolar depression.)

Antidepressants with Rapid Onset

There is suggestive evidence that antidepressants with a mechanism that blocks the type 2 serotonin ($5-HT_2$) receptor, such as mirtazapine (Nutt, 1999) and nefazodone (Fawcett and Barkin, 1998), may have a more rapid effect than other antidepressant medications in reducing agitation and anxiety. Most treatment algorithms for anxiety disorders, however, suggest SSRI antidepressants as a first-line treatment. The FDA has approved paroxetine for the

treatment of panic disorder and social phobia and the SNRI venlafaxine for the treatment of anxiety disorders. The important point is that a rapid anxiolytic and antiagitation effect, within a time frame of hours, is called for in acutely suicidal patients, especially those who are particularly anxious and dysphoric. Identifying and managing a state of acute suicide risk can work to prevent a suicide only if both the immediate and follow-up treatments are successful. To this end, it is necessary to provide comprehensive treatment of the depressive episode or dysphoric-mixed state driving the suicidal state, as well as a maintenance medication regimen. In any patient who is believed to have been at acute risk for suicide, a long-term treatment strategy should be developed as the patient recovers from the episode.

Electroconvulsive Therapy

As noted earlier, the literature on the results of ECT in the prevention of suicide has generally shown that it can be highly effective in the short term; however, it may be no more effective than other short-term treatments (Prudic and Sackeim, 1999; Sharma, 1999, 2001). Despite the known effectiveness of ECT in depressed patients with severe agitation and anxiety, suicides have occurred while the treatment was under way or even soon after a completed course (Bradvik and Berglund, 2000). Prudic and Sackeim (1999) pointed out, however, that more acutely ill, more suicidal patients may tend to be given ECT (because treatment assignment is not randomized), leading to understatement of its broader effectiveness. Bradvik and Berglund (2000) conducted a study of treatment at last contact in 89 cases of suicide in individuals with severe depression matched to 89 individuals who did not commit suicide. No difference in ECT use and medication prescription could be found between the two groups. The authors did find that suicide after ECT was less common in those patients who received continued antidepressant therapy than in those who did not take maintenance antidepressants.

Long-Term Suicide Prevention

Lithium, antidepressants, and atypical antipsychotics are all used for the long-term prevention of suicide. In this section, we review the literature on each of these treatments, including the possible association between SSRIs and increased suicide risk.

Lithium

Several meta-analyses encompassing dozens of studies have shown that lithium is a powerful antisuicide agent. Tondo and Baldessarini (2000) analyzed 22 long-term investigations of lithium therapy published from 1974 to 1998. In the more than 5,600 patients studied (representing nearly

35,000 patient-years of risk), they found a suicide rate among those receiving long-term lithium treatment 9 times lower than that among patients who did not receive or who discontinued the drug. (Most patients in these studies had bipolar disorder, but some had recurrent depression only.) Baldessarini and colleagues (2001) updated this analysis by pooling findings from 33 studies published from 1970 to 2000. They found a 13-fold lower incidence of attempted and completed suicide among those undergoing long-term lithium treatment compared with those who did not receive or who discontinued the drug. Indeed, patients maintained on lithium had rates of attempted and completed suicide comparable to those found in the general population (Fig. 25–2).

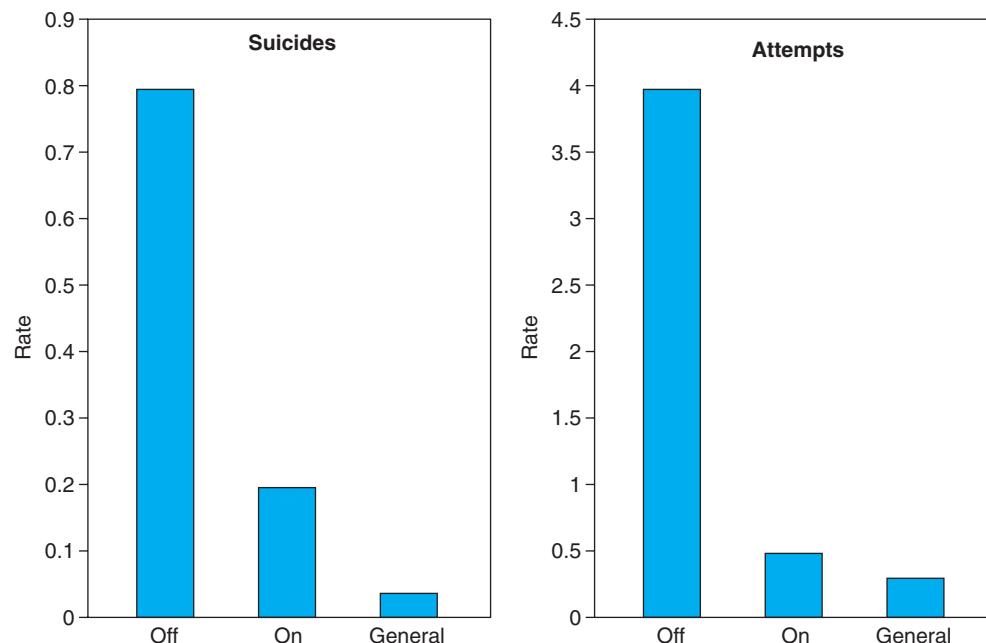

In a subsequent analysis, Baldessarini and colleagues (2003) evaluated findings from 34 studies of patients receiving maintenance lithium (averaging 3.4 years of exposure) and 25 studies of patients not receiving such therapy (followed for 5.9 years). Risks for completed suicide were .17 versus .94 per 100 person-years, respectively—that is, the risk was 82 percent lower for patients receiving maintenance lithium. For suicide attempts, the corresponding rates were .31 and 4.65, a 93 percent difference. Risk reductions for recurrent unipolar depression, bipolar-II, and bipolar-I were 100, 82, and 67 percent, respectively. In

other words, patients with different affective diagnoses showed strong benefits, with those with recurrent unipolar depression appearing to benefit the most.

In the most recent update of the analysis, Baldessarini and colleagues (2006b) pooled 34 studies suitable for meta-analysis. These studies involved 85,636 person-years of exposure (60,094 with and 25,542 without lithium). Figure 25–3 shows risk ratios (RRs) and their 95 percent confidence intervals (CIs) based on random-effects meta-analysis of suicidal risk in these studies (rates of suicides and attempts per 100 person-years). Across all studies, the suicide risk was five-fold lower ($RR=1.00$; 95 percent CI = 3.82–6.31; $z=12.5$, $p<.0001$) in those individuals treated versus those not treated with lithium. Of the 34 studies, 26 were open-label clinical studies, and 8 were randomized clinical trials of lithium versus placebo or another active agent. The pooled RRs are similar for the open trials (5.00; 95 percent CI = 3.83–6.53; $z=11.8$; $p<.0001$) and for the randomized controlled trials (4.29; 95 percent CI = 1.46–12.6 percent; $z=2.64$; $p=.008$). Table 25–2 shows that the degree of risk reduction was similar for suicide and attempted suicide as well as for bipolar and other affective disorders.

In a retrospective cohort study, Goodwin and colleagues (2003) compared the benefits of lithium and divalproex in a population-based sample of 20,638 bipolar-I

Figure 25–2. Rates of suicide and suicide attempts among patients with major affective disorders, without (Off) and with (On) long-term lithium maintenance treatment, and estimated rates in the general population. Rates are in terms of suicidal acts per 100 patient-years (% per year). Note that the suicide attempt rates for patients treated with lithium versus the general population do not differ significantly, but the rate for suicide among treated patients is 10 times higher than that among the general population.

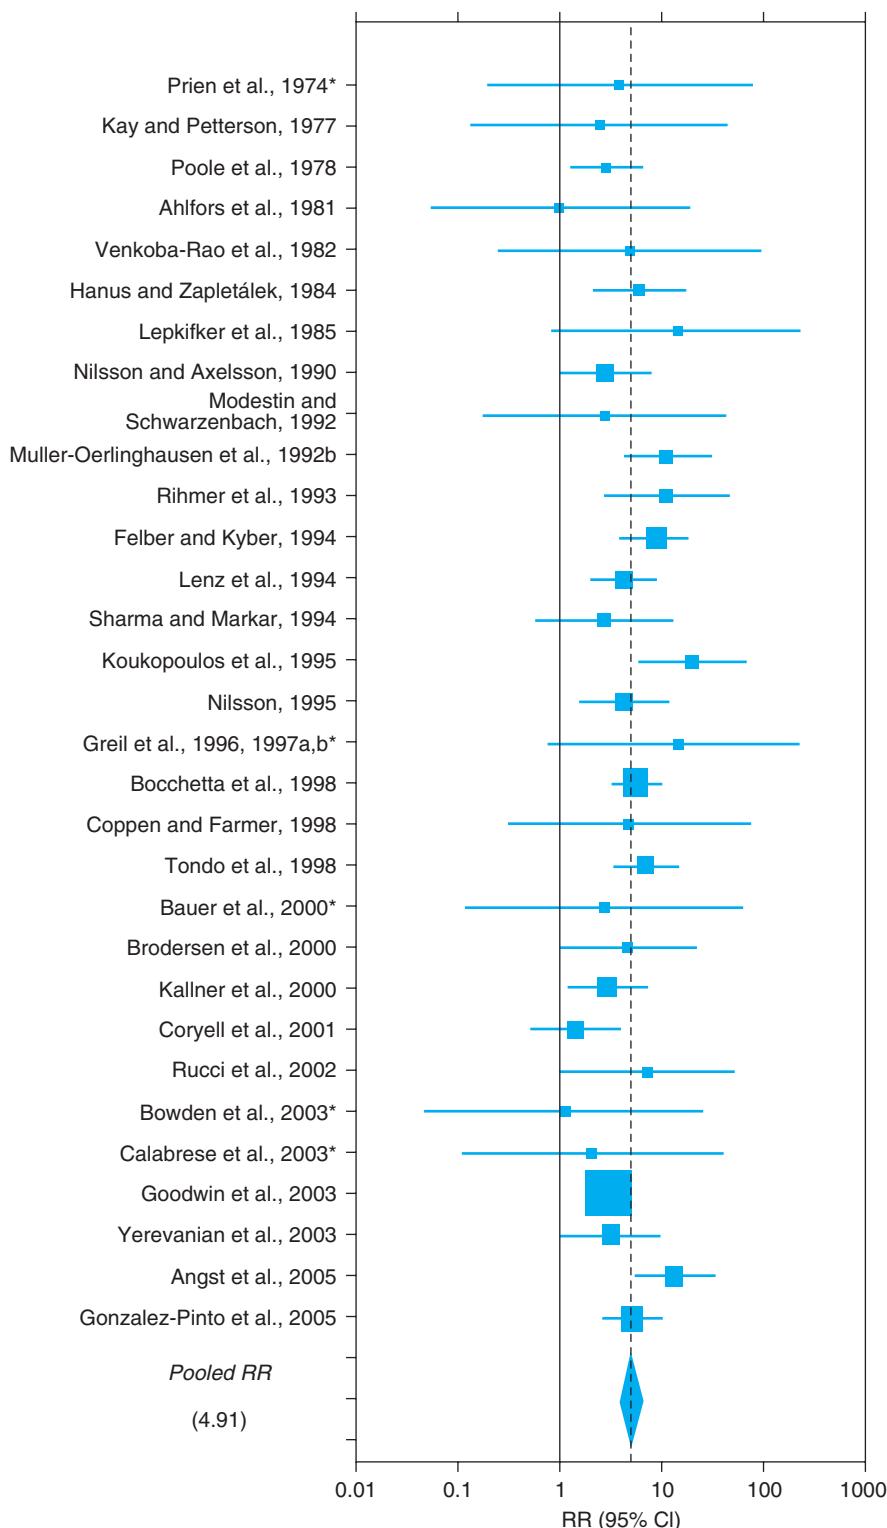

Figure 25–3. Overall random-effects meta-analysis of 31 studies of the risk of suicide and/or suicide attempts with and without lithium treatment. The risk ratio (RR) and 95 percent confidence interval (CI) for each study are shown (squares are proportional to study weight). The computed pooled RR (diamond) is 4.91 (95 percent CI = 3.82–6.31; $z=12.5$, $p<.0001$). The vertical solid line represents the null hypothesis ($RR=100$). Asterisks (*) denote randomized controlled trials. (Source: Baldessarini et al., 2006b. Reproduced with permission from the New York Academy of Sciences.)

TABLE 25–2. Summary of Meta-Analyses: Lithium Treatment vs. Risk for Suicide

Condition ^a	No. of Studies	Risk Ratio	(95% CI)	z	p Value
All two-armed studies ^b	31	4.91	(3.82–6.31)	12.5	<.0001
Omitting Goodwin et al., 2003 ^b	30	5.34	(4.27–6.68)	14.7	<.0001
Suicides only	23	4.86	(3.36–7.02)	8.42	<.0001
Attempts only	17	4.98	(3.56–6.96)	9.42	<.0001
Bipolar disorder ^c	14	5.34	(3.59–7.93)	8.28	<.0001
Major affective disorders ^c	17	4.66	(3.43–6.33)	9.82	<.0001
Quality score ≥ 50% ^d	16	3.92	(2.94–5.23)	9.33	<.0001
Quality score < 50% ^d	15	5.56	(3.98–7.76)	10.1	<.0001

^aAnalyses are based on conservative, random-effects modeling.

^bResults with Goodwin et al., 2003 omitted indicate that inclusion of this very large study did not alter the overall findings.

^cFor studies with bipolar disorder vs. major affective disorder patient samples: $\chi^2 = .91$, $df = 1$, $p = .34$; cases of bipolar-I and -II disorders and some schizoaffective disorders, in various combinations, are included.

^dFor studies with quality ratings at or above vs. below the median.

CI = confidence interval.

patients treated in two large health maintenance organizations. A regression analysis, which controlled for age, gender, health plan, year of diagnosis, concomitant use of other psychotropic medications (e.g., antidepressants, antipsychotics), and comorbid diagnoses indicated that suicide was 2.7 times more likely among patients on divalproex versus lithium. Suicide attempts resulting in hospitalization or emergency department visits were 1.7 times more likely for those taking divalproex than among those on lithium. By far the primary determinant of which stabilizer was being used was the year of initial treatment: at the beginning of the period studied, 1994, more than 80 percent of the patients were prescribed lithium, but by 2001, about half were being given divalproex and half lithium, reflecting the trend in prescribing patterns in the United States during the 1990s (see Chapter 20). Taken together, the role of when patients entered treatment, along with the fact that comorbid diagnoses and coexisting medications were equivalent in the two groups, suggest that, any clinical differences in the patients chosen to receive the two drugs are unlikely to have contributed significantly to the differing suicide rates found.

Another recent meta-analysis that was restricted to randomized controlled trials found similar, albeit somewhat different, outcomes. Cipriani and colleagues (2005) analyzed 32 such trials comparing lithium with placebo ($n=1,389$

patients) or with other pharmacological agents (the mood stabilizers carbamazepine, lamotrigine, and divalproex and the antidepressants imipramine and amitriptyline) ($n=2,069$). The outcomes examined were suicide, deliberate self-harm (including attempted suicide), and death from all causes. The investigators found lithium to be more effective than the three other mood stabilizers as a group. Patients randomized to lithium experienced a 70 percent reduction in the risk of a composite of suicide and deliberate self-harm. The investigators concluded that “lithium remains the treatment with the most substantial evidence base for the prevention of relapse in bipolar disorder and should be a first-line therapy for patients with that disorder, including those at risk of suicidal behavior” (Cipriani et al., 2005, p. 1816).

A recent Danish observational cohort study compared the suicide risk in 13,186 patients who had purchased at least one prescription of lithium with that in 1.2 million subjects from the general population. Although the suicide rate was elevated in those who had purchased the drug, subjects from the general population who had purchased it at least twice had a 44 percent lower rate of suicide (95 percent CI = .28 to .70) than those who had purchased lithium only once (Kessing et al., 2005). The rate of suicide decreased with the number of prescriptions of lithium.

The authors, like Wolf and colleagues (1996) a decade earlier, emphasized the importance of taking into consideration the duration of lithium treatment given not only their own findings, but also those of earlier studies showing higher mortality rates when lithium treatment lasted only 2 to 5 years (Norton and Whalley, 1984; Vestergaard and Aagaard, 1991; Brodersen et al., 2000) versus 5 to 10 years (Coppen et al., 1990, 1991; Muller-Oerlinghausen et al., 1992a). The benefits of prolonged lithium treatment to some extent reflect a selection bias, of course: patients who respond better to lithium may be more likely to continue taking it, while those who respond less well or who otherwise are at increased risk for nonadherence (e.g., patients with substance abuse or personality disorder) may be more likely to stop taking their medication.

Adherence to lithium is key. In a recent 16-year follow-up study of lithium-treated patients with major affective disorders (who met the criterion of two to three affective episodes in a 5-year period), those who adhered to lithium had a standardized mortality ratio (SMR) of 8, while nonadherent patients had an SMR of 31, indicating that adherence reduced the risk of suicide about four-fold (Brodersen et al., 2000). Most of the suicides occurred among the “atypical” patients enrolled in the study (those with schizoaffective disorder, bipolar-II disorder, mixed episodes, and/or rapid cycling). The authors observed that the rate of nonadherence was about 40 percent in the first 2 years of treatment in this sample, but subsequently dropped to 5 to 10 percent. This finding calls for more clinical attention to adherence, especially during the early years of treatment (see Chapter 21). Adherence is particularly important for another reason, alluded to above. There is strong evidence that suicide and suicide attempts sharply increase after discontinuation of lithium, especially abrupt discontinuation (Baldessarini et al., 1999; Tondo and Baldessarini, 2000), as do episodes of affective illness (Faedda et al., 1993; Baldessarini et al., 1999; Baldessarini et al., 2003). Baldessarini and colleagues (1999, p. 81) concluded that “the first months after discontinuation of lithium may carry a particularly high risk of suicidal behavior and included multiple attempts and fatalities, sometimes in persons without previous suicidal acts. Moreover, the fatality rate due to suicide was 1.27 per 100 patient-years after discontinuation of lithium compared with 0.101 during lithium maintenance—an alarming 12.6-fold increase.”

Lithium also has been studied in combination with other medications. Angst and colleagues (2002) provided evidence that a combination of lithium and antidepressant medications taken over a 6-month period can result in a significant reduction in the incidence of suicide in patients with recurrent affective disorders, especially those with bipolar disorder. This study is discussed in detail in the section on antidepressants.

Thus there is strong and consistent evidence of lithium’s ability to prevent suicide in many bipolar patients, and almost certainly in those with recurrent unipolar depression as well. As alluded to earlier, however, psychological and medical autopsy studies suggest that patients at risk for suicide often are not prescribed and/or not taking the drug.⁵ Other than its ability to stabilize mood, lithium’s anti-suicidal mechanism of action is not well understood, although the evidence points to its putative neurogenesis effects and capacity to reduce impulsivity or aggressiveness through its actions on serotonin and other neurotransmitters.⁶

Antidepressants

Antidepressants are efficacious for treating major depression and anxiety, but controversy exists as to whether they prevent suicide or can, under some circumstances, trigger it, and if the latter, in what age group and with what diagnosis or illness severity. We first consider the benefits of antidepressants for suicide prevention and then the possibility that suicide or suicidal behaviors may be precipitated by SSRI antidepressants in a small subgroup of particularly vulnerable individuals.

Most clinical trials of antidepressants have not meaningfully addressed potential efficacy in preventing suicide because they have expressly excluded suicidal patients or those with a history of suicide attempts, selected against severe forms of depression, and because they are of insufficient duration to detect a relatively rare event; they have relied instead on reports of suicidal ideation or attempts. Given the exclusion of high-risk patients, it is not surprising that adequately powered meta-analyses of clinical trials have found no significant difference in rates of suicide between antidepressant and placebo treatment (Khan et al., 2000a, 2003; Storosum et al., 2002). The absence of an observed antisuicide effect may also reflect the failure of antidepressants to reduce acute suicide risk over a relatively short period of treatment (1 to 8 weeks); the drugs may be more effective at reducing long-term risk. Results of epidemiological studies, on the other hand, reveal that suicide rates have been declining since the late 1980s, a time during which the prescribing of SSRIs for both adults and adolescents has risen dramatically.⁷ Much of this increased prescribing has occurred in primary care settings (Pirraglia et al., 2003). A recent analysis of county-level U.S. vital statistics found that SSRIs were associated with lower rates of suicide, whereas tricyclic antidepressants were associated with higher rates (Gibbons et al., 2005). This finding reflects, at least in part, the toxicity of tricyclics when an overdose is taken. It may also reflect the fact that patients who were prescribed tricyclics almost certainly represented a more clinically ill population; the SSRIs have been

prescribed over a broader range of severity. Moreover, there are, of course, limits to inferring causation from epidemiological studies. A recent study of 15,390 patients hospitalized because of a suicide attempt found that current use of antidepressants was associated with a 39 percent increase in suicide attempts but a 32 percent decrease in completed suicides (Tiihonen et al., 2006).

As noted earlier, there have been no clinical trials testing the antisuicide efficacy of antidepressants in patients with bipolar disorder. The only study to have expressly examined the effect of antidepressants in preventing suicide in bipolar patients was a large, nonrandomized, naturalistic one that included more than 30 years of follow-up (Angst et al., 2002). This study provided the best evidence to date that antidepressants, *in combination with lithium or other therapies*, may be effective in suicide prevention. Angst and colleagues in Switzerland studied the value of sustained treatment with antidepressants, particularly among bipolar patients, for prevention of suicide. Their sample included 186 unipolar and 220 bipolar patients, 61 percent of whom had manifested psychotic symptoms and all of whom had been hospitalized at least once. The severity of depression in these patients biased the group toward a higher risk of suicide. The patients were followed for 34 to 38 years; 99.3 percent of the sample could be tracked for the entire follow-up period. Of the original cohort, 76 percent had died by the time the study was completed. Treatment was assessed by obtaining records and calling the physicians responsible for clinical care. To be considered in treatment, a patient had to have been medicated for at least a 6-month period or for the entire period between two episodes. Treatment included lithium, antidepressants, and/or antipsychotics; the dose and duration of each treatment were not recorded. The authors noted that patients

with greater severity of illness tended to be in the treatment group.

The overall SMR for the sample was 1.61 (indicating a 61 percent increase over expected rates for the general population). The SMR for suicide in the patient group as a whole was 18.0 (13.5 for males and 21.9 for females). For bipolar patients specifically, the SMR for suicide was 12.3, and for unipolar patients it was 26.7. Treatment between episodes was much more frequent in bipolar than in unipolar patients—62 versus 38 percent. The suicide rates in treated and untreated unipolar patients were 7.1 and 18.1 percent, respectively; the corresponding rates for bipolar patients were 5.2 and 13.1 percent. Treated unipolar and bipolar patients showed a highly significant reduction in suicides, as well as a lower overall lower mortality rate (see Table 25–3).

With regard to specific treatments, 27.8 percent of the bipolar patients received lithium plus antipsychotics or antidepressants, 9.6 percent lithium alone, and 8.2 percent antipsychotics plus antidepressants (the remainder were untreated). The study design did not permit detail on the type of antipsychotic medication prescribed. Monotherapy with antidepressants was used in 9.1 percent of bipolar patients (compared with 15.6 percent of unipolar patients). Antipsychotic monotherapy was used in 10 percent of both groups. A logistic regression over all 305 unipolar and bipolar patients who had died showed significant effects of antidepressants in reducing suicide; similar effects were found for lithium, but only when it was used in combination with antidepressants or antipsychotics (perhaps because of the relatively small numbers of patients treated with lithium monotherapy—1.6 percent of unipolar and 10 percent of bipolar patients).

Although definitive conclusions cannot be drawn from nonrandomized data, the suggestion that patients receiving long-term antidepressant treatment had a significantly

Source: Angst et al., 2002.

lower overall mortality rate is important, especially given the difficulty of successfully following high-risk patients over 34 to 38 years. The apparent effect of treatment on suicide reduction was greater in the bipolar than in the unipolar group, but there was a significant effect in both conditions. As noted, this study was naturalistic; there was no control group or randomization, meaning that the patients who were kept on adjunctive antidepressants were likely to be those who were doing well on them. The authors pointed out that patients defined as being treated are likely to be more adherent to prescribed therapy, which in itself may mitigate against suicide. They also stressed that the treatment had to be received for longer than 6 months or over a full affective cycle until full remission had been attained.

These data do not prove a direct effect of antidepressant treatment on reducing suicide, but they do suggest that long-term adjunctive treatment with these medications may reduce suicide in some bipolar and to a lesser extent some unipolar patients.⁸ Results of another naturalistic (non-randomized) follow-up study on the same sample, conducted in 2003, further support these conclusions, revealing that treatment significantly reduced suicides and that combined treatments were more effective than monotherapy (Angst et al., 2005).

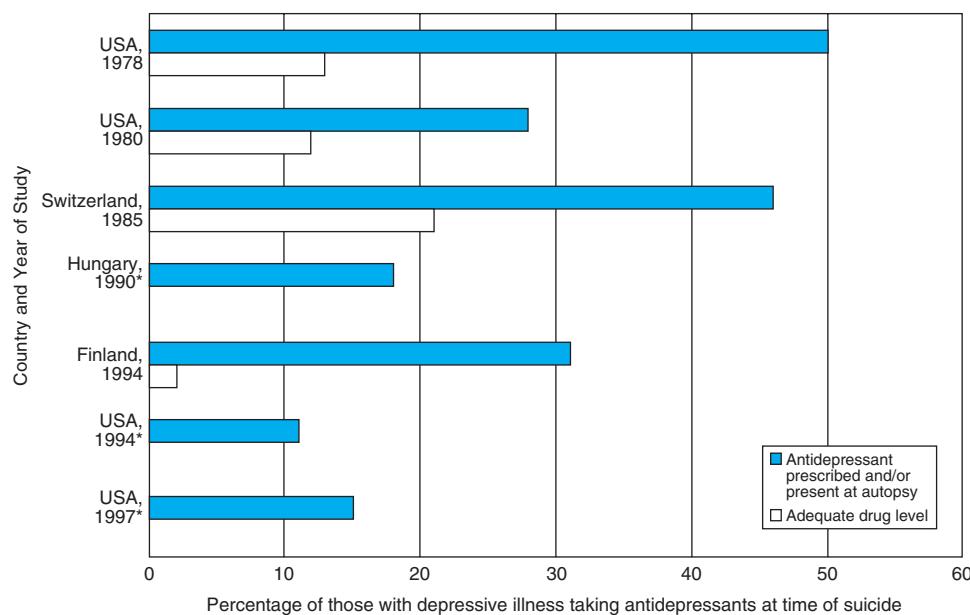

Despite evidence for the effectiveness of antidepressants, they continue to be under prescribed in depressed patients at risk of suicide, according to a summary of seven American and European toxicological and autopsy studies (Jamison, 1999). Even fewer—typically less than half of medicated patients—were taking a therapeutic dose (see

Fig. 25–4). The undertreatment of depression in general is consistent with research indicating that physicians fail to prescribe adequate doses of antidepressants (Isacsson et al., 1994; Isometsa et al., 1994). The reader is referred to Chapter 19 for a comprehensive discussion of the complex and controversial subject of the proper role of antidepressants in treating bipolar depression.

Antidepressants and Possible Increased Suicide Risk

The question of a possible increased risk of suicidal behavior associated with the use of SSRI antidepressants surfaced in the early 1990s in case reports of depressed adults⁹ and children with obsessive-compulsive disorder (King et al., 1991). These case reports prompted regulatory agencies to reanalyze existing clinical trial data; however, no action was taken until more than a decade later after additional clinical trial data had become available, and one drug sponsor had submitted an analysis indicating that suicidal behavior was an adverse event with paroxetine use in young patients. After systematic evaluation of pooled data from clinical trials, drug regulators in both the United States and the United Kingdom issued strong warnings to physicians about the risk of suicidality and called for stronger monitoring of antidepressant use in young patients. The decade-long debate over the utility of these regulatory warnings has pitted those concerned about drug safety against others who are concerned that strong warnings may limit access to necessary and effective treatment. After regulatory warnings were issued in 2003 and 2004, according to reports from firms monitoring pharmaceutical

Figure 25–4. Antidepressant use at the time of suicide. An asterisk (*) indicates that no information is available about adequacy of dosage. (Source: Adapted from Jamison, 1999.)

benefits, prescribing of SSRIs for young people decreased. The full impact on prescribing patterns is not yet known, nor is the impact on suicide rates.

Analysis of data from pediatric clinical trials by independent researchers has been hampered by the fact that the results of the majority of such trials are unpublished, and most of the trials had methodological limitations, particularly for extrapolation to bipolar illness. None specifically studied patients with bipolar or recurrent unipolar disorder. Rather, the trials involved patients with major depressive disorder with recurrence not specified (often with only moderate levels of depression given ethical constraints against exposing sick children to placebo, which makes it more difficult to evaluate treatment effects), obsessive-compulsive disorder, and attention-deficit hyperactivity disorder (ADHD). Exclusionary entry criteria, that is, excluding children and adolescents if they had previously attempted suicide or were actively suicidal, are a particularly problematic issue (Emslie et al., 2002; Wagner et al., 2004; Dubicka et al., 2006). The outcomes studied were suicidal ideation and suicide attempts; these are, as discussed earlier, quite limited predictors of completed suicide. Suicide itself was not studied, largely because the trials were conducted within a short time frame, and their entry criteria excluded suicidal patients.

The above methodological problems aside, one explanation for the emergence of suicidal behavior early in treatment with SSRIs stems from misdiagnosis of the depressive phase of bipolar disorder as unipolar depression. Use of antidepressant medications in patients who are in the depressive phase of bipolar disorder may trigger agitation and other behavior reflecting the induction of mixed states (see Chapter 19), which can be associated with an increased risk of suicide (see Chapter 8) (Shi et al., 2004; Ferguson et al., 2005; McElroy et al., 2006).

In 2004, the FDA evaluated pooled data from both unpublished and published clinical trials involving more than 4,000 children and adolescents. The FDA's conclusion was that although suicidal ideation or attempts were rare in these trials, the likelihood of such events occurring during antidepressant treatment was increased two-fold, from 2 percent with placebo to about 4 percent with the drugs (FDA, 2004). On the other hand, evidence for efficacy was not particularly strong, with only 3 of 15 randomized controlled trials (2 for fluoxetine) showing efficacy in treating depression (Advisory Committee to FDA, 2004). With less demonstrated efficacy (albeit from trials in which more severely depressed children were underrepresented) and a slight elevation in risk, the risk/benefit assessment in younger patients tilted in favor of risk (Leon, 2005).

This analysis led the FDA to require a black box warning for physicians and to extend that warning to *all* antide-

pressants sold in the United States—not just SSRIs. The warning states: "Antidepressants increased the risk of suicidal thinking and behavior (suicidality) in short-term studies in children and adolescents with Major Depressive Disorder (MDD) and other psychiatric disorders. Anyone considering the use of antidepressants in a child or adolescent must balance this risk with the clinical need. Patients who are started on therapy should be observed closely for clinical worsening, suicidality, or unusual changes in behavior." We strongly concur that patients and their families should be advised about potentially dangerous exacerbations of agitation and impulsivity early in the treatment of depression and that physicians must closely monitor patients in the early phases of treatment, but we are also very concerned that this black box warning may have a chilling effect on the legitimate and well-advised prescription of potentially life-saving medications.

Four recent studies bear mentioning. One, a large-scale investigation of computerized health plan records, identified 65,103 patients with 82,285 episodes of antidepressant treatment (Simon et al., 2006). The risk of suicide during the acute phase of treatment was approximately 1 in 3,000 treatment episodes; the risk of serious suicide attempts was 1 in 1,000. There was no indication of an increased risk of suicide or suicide attempts after starting antidepressant medications. Data on antidepressant medication prescription rates and U.S. county-level suicide rates for children ages 5 to 14 were examined for the years 1996–1998 (Gibbons et al., 2006). After adjustment for access to mental health care, as well as for gender, race, income level, and county-to-county variability in suicide rates, higher SSRI prescription rates (expressed as the number of pills prescribed per person) were associated with lower suicide rates in children and adolescents. Olfson and colleagues (2006) examined the risk of suicide and suicide attempts in Medicaid beneficiaries from all 50 states who received inpatient treatment for depression (the study specifically excluded bipolar patients). They concluded that antidepressant treatment in adults was not significantly associated with suicide or suicide attempts; in children and adolescents, however, treatment with antidepressants significantly increased the risk of both suicide and suicide attempts. Finally, Bauer and colleagues (2006a,b) prospectively studied 425 Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) participants who experienced a new-onset major depressive episode without initial suicidal ideation. They found no evidence that increased antidepressant exposure was associated with new-onset suicidality in this high-risk population. (New-onset suicidality was, on the other hand, associated with a history of a prior attempt and higher depressive or manic symptom ratings at index episode.) There was no association between antidepressant treatment and suicidality in the younger (age 21 or less) patients.

In summary, antidepressant medications are effective for treating major mood disorders, but their use should be monitored carefully by clinicians. This is particularly true for young patients, whose brain development is different from that of adults (see Chapter 23). Patients can worsen after the initiation of antidepressant treatment. Patients and their families should be warned of this possibility, and the prescribing physician should be contacted if symptoms, especially agitation and impulsivity, worsen after the initiation of treatment.

Atypical Antipsychotics

Several studies have found that clozapine reduces rates of suicide or attempted suicide in patients with schizophrenia or schizoaffective disorder. The first such study to be published was of 183 neuroleptic-resistant patients who had been consecutively hospitalized. After being prescribed clozapine, they were followed for periods of 6 months to 7 years. The number of suicide attempts with high lethality was reduced from five before the index hospitalization to zero afterward (Meltzer and Okayli, 1995). Walker and colleagues (1997) found a significant decrease in death rates from suicide in an epidemiologic sample of 67,072 users of clozapine. Likewise, Reid and colleagues (1998), comparing rates of suicide in a subset of patients treated with clozapine ($n=1,310$) in a group of 30,000 schizophrenic patients treated in the Texas mental health system, found a marked reduction in the clozapine-treated group. More recently, Modestin and colleagues (2005) found that clozapine diminished the frequency of serious suicidal acts in a sample of 75 patients with schizophrenia, 14 with schizoaffective disorder, and 5 with affective illness. On the other hand, Sernyak and colleagues (2001), retrospectively studying a group of 1,415 schizophrenic patients treated with clozapine, found no reduction in suicide compared with a schizophrenic control group not treated with the drug.

There is some evidence that olanzapine, another atypical antipsychotic, also reduces suicide attempts. Olanzapine, as compared with haloperidol, was associated with a significant decrease in rates of attempted suicide in schizophrenic patients treated over 1 year (this study included schizoaffective patients) (Glazer, 1997). In a post hoc analysis of a randomized clinical trial, olanzapine given over a period of 28 weeks was found to be superior to risperidone in reducing suicide attempts (Tran et al., 1998). These findings suggest that olanzapine may have effects similar to those of clozapine in reducing suicide in schizophrenia. More recently, Houston and colleagues (2006) found that the addition of olanzapine (versus placebo) to lithium or divalproex monotherapy significantly reduced suicidal ideation (as measured by HAM-D-3 scores) in 58 bipolar-I mixed-state patients.

The comparative benefits of clozapine and olanzapine for suicide prevention were examined by Meltzer and colleagues (2003) in the International Suicide Prevention Trial. Over a 2-year period, that trial followed 980 patients with schizophrenia or schizoaffective disorder deemed to be at high risk for suicide. Suicide-related outcomes included suicide attempts, hospitalizations to prevent suicide, and a rating of "much worsening of suicidality." It was found that clozapine-treated patients had significantly fewer suicide attempts, hospitalizations, and rescue interventions. The study did not have sufficient power to compare suicide rates.

Although most studies of clozapine have been carried out in patients with schizophrenia, Ciapparelli and colleagues (2000) found in a naturalistic study that clozapine was also effective in patients with treatment-resistant schizoaffective disorder, as well as in psychotic bipolar patients, over a 24-month observation period. This finding suggests that the antisuicide effect seen with clozapine in schizophrenic patients may also be seen in those with bipolar disorder.

CONCLUSIONS

The seriously suicidal person with manic-depressive illness, whether bipolar or recurrent unipolar, requires intensive clinical care. Suicidal behavior is treated and prevented most effectively by a combination of immediate and long-term strategies. The immediate strategy is to keep the suicidal patient safe by ameliorating acute risk factors, such as global insomnia, agitation, and severe anxiety. The long-term strategy is to stabilize the patient's underlying illness, particularly recurrent depressive or mixed episodes. When bipolar or recurrent unipolar patients at chronic risk for suicide are maintained on lithium, alone or in combination with other mood stabilizers and/or atypical antipsychotics, the incidence of suicide can be significantly reduced. Lithium's antisuicidal effect has been demonstrated by meta-analyses of more than 30 studies that reveal an approximately five-fold reduction in suicide risk among patients treated with versus those not treated with lithium.

Careful treatment with antidepressants may also reduce the risk of suicide, but for bipolar patients antidepressants should generally be preceded by a mood stabilizer, preferably lithium because of its demonstrated antisuicidal effect. When administered alone, antidepressants may induce mood cycling or mixed states, which may in turn heighten the risk of suicide. Bipolar patients prescribed antidepressants, particularly children and adolescents, should be carefully monitored, and they and their family members advised to be alert to possible agitation and precipitous switches in mood.

Finally, the psychological aspects of treating suicidal manic-depressive patients are also an essential component of preventing suicidal behavior. Assessment of suicide risk should be performed during the initial patient evaluation and at certain points when the risk is likely to increase, such as in the presence of a new or exacerbated comorbidity or within 3 to 6 months after hospital discharge. The clinician's vigilance in suicide assessment and treatment with a combination of psychotherapeutic interventions can reduce the risk of suicide and save lives.

NOTES

2. Anne Sexton, probably 1977. Dr. Orne file, restricted collection. Cited in Middlebrook (1991, p. 36).
3. A very large percentage of adolescent-onset depression is bipolar (see Chapter 6), and psychiatrists initially misdiagnose 40 to 60 percent of bipolar patients as unipolar; primary care physicians and pediatricians miss an even larger percentage (see Chapter 3).
4. Hawton et al., 1998, 2000; IOM, 2002; Jacobs et al., 2003; Hepp et al., 2004; Soomro, 2004; Miklowitz and Taylor, 2006.
5. Isometsa and colleagues (1994), for example, identified 31 bipolar-I patients among all 1,397 suicides in Finland within a 12-month period. Of these patients, 74 percent were receiving psychiatric care at the time of their suicide, and 39 percent had explicitly communicated their intent to kill themselves to health personnel during the final 3 months of their lives, yet only 32 percent had received lithium (11 percent had received antidepressants, and none had received ECT). An international symposium evaluated current knowledge of the effects of medical treatment on suicidal behavior; one of its major conclusions was that there was a profound gap between the strong evidence base for lithium's effectiveness against suicidal behavior and what practicing clinicians knew (Baldessarini and Jamison, 1999). Likewise, Muller-Oerlinghausen (2003) found that lithium was infrequently prescribed in Germany.
6. Sheard, 1975; Treiser et al., 1981; Dixon and Hokin, 1998; Baldessarini et al., 2003; Brown et al., 2005.
7. Isacsson, 2000; Grunebaum et al., 2003; Olfson et al., 2003; Zito et al., 2003. Rihmer et al., 1995, 2004; Ludwig and Martotte, 2005.
8. As reviewed in Chapter 19, only a minority of bipolar patients do well on long-term antidepressants; because Angst's patients were not randomized, we can assume that the patients who stayed on long-term antidepressants were those who had not been destabilized by them—which, according to the studies reviewed in Chapter 19, may represent about 20 percent of the bipolar group.
